Unsorted plastics can be melted and reformed into some low-value products. This operation is known as *downcycling*, since each successful cycle further degrades the material. This method is suitable only for a small fraction of the overall recyclable plastic.

Other operations that can reuse the compounds found in plastic products include hydrogenation, pyrolysis, and gasification. *Hydrogenation* is the conversion of mixed plastic scrap to "syncrude" (synthetic crude oil), in a high-temperature (i.e., 750–880°F (400–470°C)), high-pressure (i.e., 2200–4400 psig (15–30 MPa)), hydrogen-rich atmosphere. Since the end product is a crude oil

substitute, hydrogenation operations must be integrated into refinery or petrochemical operations.

Gasification and pyrolysis are stand-alone operations that do not require integration with a refinery. *Pyrolysis* takes place in a fluidized bed between 750°F and 1475°F (400°C and 800°C). Cracked polymer gas or other inert gas fluidizes the sand bed, which promotes good mixing and heat transfer, resulting in liquid and gaseous petroleum products.

*Gasification* operates at higher temperatures, 1650–3600°F (900–2000°C), and lower pressures, around 870 psig (6 MPa). The waste stream is pyrolyzed at lower temperatures before being processed by the gasifier. The gas can be used on-site to generate steam. Gasification has the added advantage of being able to treat the entire municipal solid waste stream, avoiding the need for sorting plastics.

Biodegradable plastics have focused on polymers that are derived from agricultural sources (e.g., corn, potato, tapioca, and soybean starches), rather than from petroleum. *Bioplastics* have various degrees of *biodegradation* (i.e., breaking down into carbon dioxide, water, and biomass), *disintegration* (losing their shapes and identities and becoming invisible in the compost without needing to be screened out), and *eco-toxicity* (containing no toxic material that prevents plant growth in the compost). A bioplastic that satisfies all three characteristics is a *compostable plastic*. A *biodegradable plastic* will eventually be acted on by naturally occurring bacteria or fungi, but the time required is indeterminate. Also, biodegradable plastics may leave some toxic components. A *degradable plastic* will experience a significant change in its chemical structure and properties under specific environmental conditions, although it may not be affected by bacteria (i.e., be biodegradable) or satisfy any of the requirements for a compostable plastic.

Some engineers point out that biodegrading is not even a desirable characteristic for plastics and that being nonbiodegradable is not harmful. Biodegrading converts materials (such as the paper bags often preferred over plastic bags) to water and carbon dioxide, contributing to the greenhouse effect without even receiving the energy benefit of incineration. Biodegrading of most substances also results in gases and leachates that can be more harmful to the environment than the original substance. In a landfill, biodegrading serves no useful purpose, since the space occupied by the degraded plastic does not create additional useful space (volume).

### 33. RADON

Radon gas is a radioactive gas produced from the natural decay of radium within the rocks beneath a building. Radon accumulates in unventilated areas (e.g., basements), in stagnant water, and in air pockets formed when the ground settles beneath building slabs.

Radon also can be brought into the home by radon-saturated well water used in baths and showers. The EPA's action level of 4 pCi/L for radon in air is contested by many as being too high.

Radon mitigation methods include (a) pressurizing to prevent the infiltration of radon, (b) installing depressurization systems to intercept radon below grade and vent it safely, (c) removing radon-producing soil, and (d) abandoning radon-producing sites.

### 34. RAINWATER RUNOFF

Rainwater percolating through piles of coal, fly ash, mine tailings, and other stored substances can absorb toxic compounds and eventually make its way into the earth, possibly contaminating soil and underground aquifers.

### 35. RAINWATER RUNOFF FROM HIGHWAYS

The *first flush* of a storm is generally considered to be the first half-inch of storm runoff or the runoff from the first 15 min of the storm. Along highways and other paved transportation corridors, the first flush contains potent pollutants such as petroleum products, asbestos fibers from brake pads, tire rubber, and fine metal dust from wearing parts. Under the National Pollutant Discharge Elimination System (NPDES), stormwater runoff in newly developed watersheds must be cleaned before it reaches existing drainage facilities, and runoff must be maintained at or below the present undeveloped runoff rate.

A good stormwater system design generally contains two separate basins or a single basin with two discrete compartments. The function of one compartment is water quality control, and the function of the other is peak runoff control.

The *water quality compartment* (WQC) should normally have sufficient volume and discharge rates to provide a minimum of one hour of detention time for 90–100% of the first flush volume. “Treatment” in the WQC consists of sedimentation of suspended solids and evaporation of volatiles. A removal goal of 75% of the suspended solids is reasonable in all but the most environmentally sensitive areas.

In environmentally sensitive areas, a filter berm of sand, a sand chamber, or a sand filter bed can further clarify the discharge from the WQC.

After the WQC becomes full from the first flush, subsequent runoff will be diverted to the *peak-discharge compartment* (PDC). This is done by designing a junction structure with an inlet for the incoming runoff and separate outlets from each compartment. If the elevation of the WQC outlet is lower than the inlet to the PDC, the first flush will be retained in the WQC.

Sediment from the WQC chamber and any filters should be removed every one to three years, or as required. The sediment must be properly handled, as it may be considered to be hazardous waste under the EPA’s “mixture” and “derived-from” rules and its “contained-in” policy.

When designing chambers and filters, sizing should accommodate the first flush of a 100-year storm. The top of the berm between the WQC and PDC should include a minimum of 1 ft (0.3 m) of freeboard. In all cases, an emergency overflow weir should allow a storm greater than the design storm to discharge into the PDC or receiving water course.

Minimum chamber and berm width is approximately 8 ft (2.4 m). Optimum water depth in each chamber is approximately 2–5 ft (0.6–1.5 m). Each compartment can be sized by calculating the divided flows and staging each compartment. The outlet from the WQC should be sufficient to empty the compartment in approximately 24–28 hours after a 25-year storm.

A *filter berm* is essentially a sand layer between the WQC and the receiving chamber that filters water as it flows between the two compartments. The filter should be constructed as a layer of sand placed on geosynthetic fabric, protected with another sheet of geosynthetic fabric, and covered with coarse gravel, another geosynthetic cover, and finally a layer of medium stone. The sand, gravel, and stone layers should all have a minimum thickness of 1 ft (0.3 m). The rate of permeability is controlled by the sand size and front-of-fill material. Permeability calculations should assume that 50% of the filter fabric is clogged.

A *filter chamber* consists of a concrete structure with a removable filter pack. The filter pack consists of geosynthetic fabric wrapped around a plastic frame (core) that can be removed for backwashing and maintenance. The filter is supported on a metal screen mounted in the concrete chamber. The outlet of the chamber should be located at least 1 ft (0.3 m) behind the filter pack. The opening's size will determine the discharge rate through the filter, which should be designed as less than 2 ft/sec (60 cm/s) assuming that 50% of the filter area is clogged.

A *sand filter bed* is similar to the filter beds used for tertiary sewage treatment. The sand filter consists of a series of 4 in (100 mm) perforated PVC pipes in a gravel bed. The gravel bed is covered by geotextile fabric and 8 in (200 mm) of fine-to-medium sand. The perforated underdrains lead to the outlet channel or chamber.

### 36. SMOG

*Photochemical smog* (usually, just *smog*) consists of ground-level ozone and peroxyacetyl nitrates (PAN). Smog is produced by the sunlight-induced reaction of ozone precursors, primarily nitrogen dioxide (NO<sub>x</sub>),

hydrocarbons, and volatile organic compounds (VOCs). NO<sub>x</sub> and hydrocarbons are emitted by combustion sources such as automobiles, refineries, and industrial boilers. VOCs are emitted by manufacturing processes, dry cleaners, gasoline stations, print shops, painting operations, and municipal wastewater treatment plants. (See also Sec. 32.28.)

### 37. SMOKE

Smoke results from incomplete combustion and indicates unacceptable combustion conditions. In addition to being a nuisance problem, smoke contributes to air pollution and reduced visibility. Smoke generation can be minimized by proper furnace monitoring and control.

Opacity can be measured by a variety of informal and formal methods, including transmissometers mounted on the stack. The sum of the *opacity* (the fraction of light blocked) and the *transmittance* (the fraction of light transmitted) is 1.0.

*Optical density* is calculated from Eq. 32.7. The *smoke spot number* (SSN) can also be used to quantify smoke levels.

$$\text{optical density} = \log_{10} \frac{1}{1 - \text{opacity}} \quad 32.7$$

Visible moisture plumes with opacities of 40% are common at large steam generators even when there are no unburned hydrocarbons emitted. High-sulfur fuels and the presence of ammonium chloride (a by-product of some ammonia-injection processes) seem to increase formation of visible plumes. Moisture plumes from saturated gas streams can be avoided by reheating prior to discharge to the atmosphere.

### 38. SPILLS, HAZARDOUS

Contamination by a hazardous material can occur accidentally (e.g., a spill) or intentionally (e.g., a previously used chemical-holding lagoon). Soil that has been contaminated with hazardous materials from spills or leaks from *underground storage tanks* (commonly known as *UST wastes*) is itself a hazardous waste.

The type of waste determines what laws are applicable, what permits are required, and what remediation methods are used. With contaminated soil, spilled substances can be (a) solid and nonhazardous or (b) nonhazardous liquid petroleum products (e.g., “UST nonhazardous”), and Resource Conservation and Recovery Act- (RCRA-) listed (c) hazardous substances, and (d) toxic substances.

Cleaning up a hazardous waste requires removing the waste from whatever air, soil, and water (lakes, rivers, and oceans) have been contaminated. The term *remediation* is used to mean the corrective steps taken to return the environment to its original condition.

*Stabilization* refers to the act of reducing the waste concentrations to lower levels so that the waste can be transported, stored, or landfilled.

Remediation methods are classified as available or innovative. *Available methods* can be implemented immediately without being further tested. *Innovative methods* are new, unproven methods in various stages of study.

The remediation method used depends on the waste type. The two most common available methods are incineration and landfilling after stabilization.<sup>29</sup> Incineration can occur in rotary kilns, injection incinerators, infrared incineration, and fluidized-bed combustors. Landfilling requires the contaminated soil to be stabilized chemically or by other means prior to disposal. Technologies for general VOC-contaminated soil include vacuum extraction, bioremediation, thermal desorption, and soil washing.

### 39. SULFUR OXIDES

*Sulfur oxides* (SO<sub>x</sub>), consisting of *sulfur dioxide* (SO<sub>2</sub>) and *sulfur trioxide* (SO<sub>3</sub>), are the primary cause of acid rain. *Sulfurous acid* (H<sub>2</sub>SO<sub>3</sub>) and sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) are produced when oxides of sulfur react with moisture in the flue gas. Both of these acids are corrosive.

*Fuel switching* (*coal substitution/blending* (CS/B)) is the burning of low-sulfur fuel. (Low-sulfur fuels are approximately 0.25–0.65% sulfur by weight, compared to high-sulfur coals with 2.4–3.5% sulfur.) However, unlike nitrogen oxides, which can be prevented during combustion, formation of sulfur oxides cannot be avoided when low-cost, high-sulfur fuels are burned.

Some air quality regulations regarding SO<sub>x</sub> production may be met by a combination of options. These options include fuel switching, flue gas scrubbing, derating, and allowance trading. The most economical blend of these options will vary from location to location.

In addition to fuel switching, available technology options for retrofitting existing coal-fired plants include wet scrubbing, dry scrubbing, sorbent injection, repowering with clean coal technology (CCT), and co-firing with natural gas.

### 40. TIRES

Discarded tires are more than a disposal problem. At 15,000 Btu/lbm (35 MJ/kg), their energy content is nearly 80% that of crude oil. Discarded tires are wasted energy resources. While tires can be incinerated, other

<sup>29</sup>Other technologies include in situ and ex situ bioremediation, chemical treatment, in situ flushing, in situ vitrification, soil vapor extraction, soil washing, solvent extraction, and thermal desorption.

processes can be used to gasify them to produce clean synthetic gas (i.e., *syngas*). The low-sulfur, hydrogen-rich syngas can subsequently be burned in combined-cycle plants or used as a feedstock for ammonia and methanol production, or the hydrogen can be recovered for separate use. Tires can also be converted in a non-chemical process into a strong asphalt-rubber pavement.

#### **41. VOLATILE INORGANIC COMPOUNDS**

*Volatile inorganic compounds* (VICs) include H<sub>2</sub>S, NO<sub>x</sub> (except N<sub>2</sub>O), SO<sub>2</sub>, HCl, NH<sub>3</sub>, and many other less common compounds.

#### **42. VOLATILE ORGANIC COMPOUNDS**

*Volatile organic compounds* (VOCs) (e.g., benzene, chloroform, formaldehyde, methylene chloride, napthalene, phenol, toluene, and trichloroethylene) are highly soluble in water. VOCs that have leaked from storage tanks or have been discharged often end up in groundwater and drinking supplies.

There are a large number of methods for removing VOCs, including incineration, chemical scrubbing with oxidants, water washing, air or steam stripping, activated charcoal adsorption processes, SCR (selective catalytic reduction), and bioremediation. Incineration of VOCs is fast and 99%+ effective, but incineration requires large amounts of fuel and produces NO<sub>x</sub>. Using SCR with heat recovery after incineration reduces the energy input but adds to the expense.

#### **43. WATER VAPOR**

Emitted water vapor is not generally considered to be a pollutant.

# Storage and Disposition of Hazardous Materials

1. General Storage .....	33-1
2. Storage Tanks .....	33-1
3. Disposition of Hazardous Wastes .....	33-2

## 1. GENERAL STORAGE

Storage of *hazardous materials (hazmats)* is often governed by local building codes in addition to state and federal regulations. Types of construction, maximum floor areas, and building layout may all be restricted.<sup>1</sup>

Good engineering judgment is called for in areas not specifically governed by the building code. Engineering consideration will need to be given to the following aspects of storage facility design: (1) spill containment provisions, (2) chemical resistance of construction and storage materials, (3) likelihood of and resistance to explosions, (4) exiting, (5) ventilation, (6) electrical design, (7) storage method, (8) personnel emergency equipment, (9) security, and (10) spill cleanup provisions.

## 2. STORAGE TANKS

Underground storage tanks (USTs) have traditionally been used to store bulk chemicals and petroleum products. Fire and explosion risks are low with USTs, but subsurface pollution is common since inspection is limited. Since 1988, the U.S. Environmental Protection Agency (EPA) has required USTs to have secondary containment, corrosion protection, and leak detection. UST operators also must carry insurance in an amount sufficient to clean up a tank failure.

Because of the cost of complying with UST legislation, above-ground storage tanks (ASTs) are becoming more popular. AST strengths and weaknesses are the reverse of USTs: ASTs reduce pollution caused by leaks, but the expected damage due to fire and explosion is greatly increased. Because of this, some local ordinances prohibit all ASTs for petroleum products.<sup>2</sup>

The following factors should be considered when deciding between USTs and ASTs: (1) space available,

(2) zoning ordinances, (3) secondary containment, (4) leak-detection equipment, (5) operating limitations, and (6) economics.

Most ASTs are constructed of carbon or stainless steel. These provide better structural integrity and fire resistance than fiberglass-reinforced plastic and other composite tanks. Tanks can be either field-erected or factory-fabricated (capacities greater than approximately 50,000 gal (190 kL)). Factory-fabricated ASTs are usually designed according to UL-142 (Underwriters Laboratories *Standard for Safety*), which dictates steel type, wall thickness, and characteristics of compartments, bulkheads, and fittings. Most ASTs are not pressurized, but those that are must be designed in accordance with the ASME *Boiler and Pressure Vessel Code*, Section VIII.

NFPA 30 (*Flammable and Combustible Liquids Code*, National Fire Protection Association, Quincy, MA) specifies the minimum separation distances between ASTs, other tanks, structures, and public right-of-ways. The separation is a function of tank type, size, and contents. NFPA 30 also specifies installation, spill control, venting, and testing.

ASTs must be double-walled, concrete-encased, or contained in a dike or vault to prevent leaks and spills, and they must meet fire codes. Dikes should have a capacity in excess (e.g., 110% to 125%) of the tank volume. ASTs (as do USTs) must be equipped with overfill prevention systems. Piping should be above-ground wherever possible. Reasonable protection against vandalism and hunters' bullets is also necessary.<sup>3</sup>

Though they are a good idea, leak-detection systems are not typically required for ASTs. Methodology for leak detection is evolving, but currently includes vacuum or pressure monitoring, electronic gauging, and optical and sniffing sensors. Double-walled tanks may also be fitted with sensors within the interstitial space.

Operationally, ASTs present special problems. In hot weather, volatile substances vaporize and represent an additional leak hazard. In cold weather, viscous content may need to be heated (often by steam tracing).

ASTs are not necessarily less expensive than USTs, but they are generally thought to be so. Additional hidden costs of regulatory compliance, secondary containment, fire protection, and land acquisition must also be considered.

<sup>1</sup>For example, flammable materials stored in rack systems are typically limited to heights of 25 ft (8.3 m).

<sup>2</sup>The American Society of Petroleum Operations Engineers (ASPOE) policy statement states, "Above-ground storage of liquid hydrocarbon motor fuels is inherently less safe than underground storage. Above-ground storage of Class 1 liquids (gasoline) should be prohibited at facilities open to the public."

<sup>3</sup>Approximately 20% of all spills from ASTs are caused by vandalism.

### 3. DISPOSITION OF HAZARDOUS WASTES

When a hazardous waste is disposed of, it must be taken to a registered *treatment, storage, or disposal facility* (TSDF). The EPA's *land ban* specifically prohibits the disposal of hazardous wastes on land prior to treatment. Incineration at sea is also prohibited. Waste must be treated to specific maximum concentration limits by specific technology prior to disposal in landfills.

Once treated to specific regulated concentrations, hazardous waste residues can be disposed of by incineration, by landfilling, or, less frequently, by deep-well injection. All disposal facilities must meet detailed design and operational standards.

**1. INTRODUCTION**

This chapter discusses (in alphabetical order) the methods and equipment that can be used to reduce or eliminate pollution. Legislation often requires use of the *best available control technology* (BACT)—also known as the *best available technology*—BAT) and the *maximum achievable control technology* (MACT), *lowest achievable emission rate* (LAER), and *reasonably available control technology* (RACT) in the design of pollution-prevention systems.

**2. ABSORPTION, GAS (GENERAL)**

Gas absorption processes remove a gas (the *target substance*) from a gas stream by dissolving it in a liquid solvent.<sup>1</sup> Absorption can be used for flue gas cleanup (FGC) to remove sulfur dioxide, hydrogen sulfide, hydrogen chloride, chlorine, ammonia, nitrogen oxides, and light hydrocarbons. Gas absorption equipment includes packed towers, spray towers and chambers, and venturi absorbers.<sup>2</sup>

**3. ABSORPTION, GAS (SPRAY TOWERS)**

In a general spray tower or spray chamber (i.e., a *wet scrubber*), liquid and gas flow countercurrently or cross-currently. The gas moves through a liquid spray that is carried downward by gravity. A mist eliminator removes entrained liquid from the gas flow. (See Fig. 34.1.) The liquid can be recirculated. The removal efficiency is moderate.

Spray towers are characterized by low pressure drops—typically 1 in wg to 2 in wg<sup>3</sup> (0.25 kPa to 0.5 kPa)—and their liquid-to-gas ratios—typically 20 gal/1000 ft<sup>3</sup> to 100 gal/1000 ft<sup>3</sup> (3 L/m<sup>3</sup> to 14 L/m<sup>3</sup>). For self-contained units, fan power is also low—approximately  $3 \times 10^{-4}$  kW/ft<sup>3</sup> (0.01 kW/m<sup>3</sup>) of gas moved.

*Flooding* of spray towers is an operational difficulty where the liquid spray is carried up the column by the gas stream. Flooding occurs when the gas stream velocity approaches the *flooding velocity*. To prevent this, the tower diameter is chosen as approximately 50% to 75% of the flooding velocity.

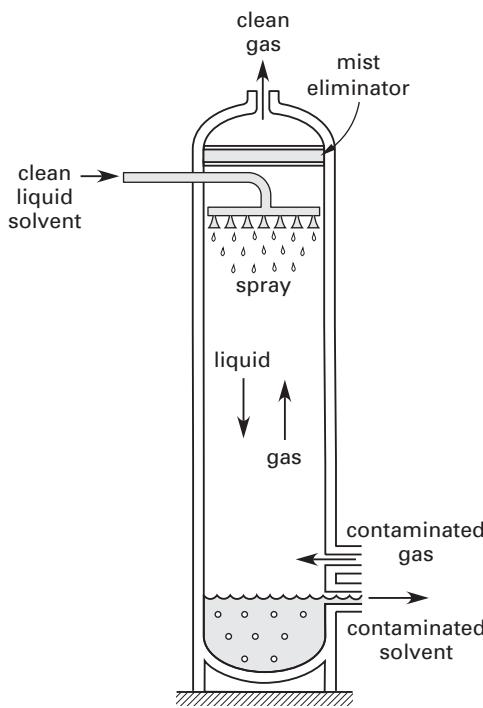

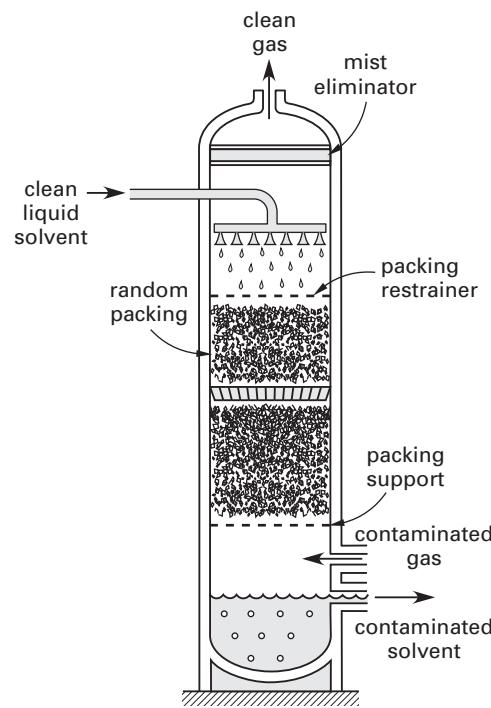

*Flue gas desulfurization* (FGD) wet scrubbers can remove approximately 90% to 95% of the sulfur with efficiencies of 98% claimed by some installations. Stack effluent leaves at approximately 150°F (65°C) and is saturated (or nearly saturated) with moisture. Dense steam plumes may be present unless the scrubbed stream is reheated.

<sup>1</sup>Scrubbing, gas absorption, and stripping are distinguished by their target substances, the carrier flow phase, and the directions of flow. *Scrubbing* is the removal of particulate matter from a gas flow by exposing the flow to a liquid or slurry spray. *Gas absorption* is a countercurrent operation for the removal of a target gas from a gas mixture by exposing the mixture to a liquid bath or spray. *Stripping*, also known as *gas desorption* (also a countercurrent operation), is the removal of a dissolved gas or other volatile component from liquid by exposing the liquid to air or steam. Stripping is the reverse operation of gas absorption.

Packed towers can be used for both gas absorption and stripping processes, and the processes look similar. The fundamental difference is that in gas absorption processes, the target substance (i.e., the substance to be removed) is in the gas flow moving up the tower, and in stripping processes, the target substance is in the liquid flow moving down the tower.

<sup>2</sup>Spray and packed towers, though they are capable, are not generally used for desulfurization of furnace or incineration combustion gases, as scrubbers are better suited for this task.

<sup>3</sup>"inwg" and "iwg" are abbreviations for "inches water gage," also referred to as "iwc" for "inches water column" and "inches of water."

**Figure 34.1** Spray Tower Absorber**Figure 34.2** Packed Bed Spray Tower

Collected sludge waste and fly ash are removed within the scrubber by purely inertial means. After being dewatered, the sludge is landfilled.<sup>4</sup>

Spray towers, though simple in concept and requiring little energy to operate, are not simple to operate and maintain. Other disadvantages of spray scrubbers include high water usage, generation of wastewater or sludge, and low efficiency at removing particles smaller than  $5\text{ }\mu\text{m}$ . Relative to dry scrubbing, the production of wet sludge and the requirement for a sludge-handling system is the major disadvantage of wet scrubbing.

#### 4. ABSORPTION, GAS (IN PACKED TOWERS)

In a packed tower, clean liquid flows from top to bottom over the tower packing media, usually consisting of synthetic engineered shapes designed to maximize liquid-surface contact area. (See Fig. 34.2.) The contaminated gas flows countercurrently, from bottom to top, although crosscurrent designs also exist. As in spray towers, the liquid can be recirculated, and a mist eliminator is used.

Pressure drops are in the 1 in wg to 8 in wg (0.25 kPa to 2.0 kPa) range. Typical liquid-to-gas ratios are 10 gal/1000 ft<sup>3</sup> to 20 gal/1000 ft<sup>3</sup> (1 L/m<sup>3</sup> to 3 L/m<sup>3</sup>). Although the pressure drop is greater than in spray towers, the removal efficiency is much higher.

<sup>4</sup>A typical 500 MW plant burning high-sulfur fuel can produce as much as  $10^7\text{ ft}^3$  ( $300,000\text{ m}^3$ ) of dewatered sludge per year.

#### 5. ADSORPTION (ACTIVATED CARBON)

Granular activated carbon (GAC), also known as *activated carbon* and *activated charcoal* (AC), processes are effective in removing a number of compounds, including volatile organic compounds (VOCs), heavy metals (e.g., lead and mercury), and dioxins.<sup>5</sup> AC is an effective adsorbent<sup>6</sup> for both air and water streams, and a VOC removal efficiency of 99% can be achieved. AC can be manufactured from almost any carbonaceous raw material, but wood, coal, and coconut shell are widely used.

Pollution control processes use AC in both solvent capture-recovery (i.e., recycling) and capture-destruction processes. AC is available in powder and granular form. Granules are preferred for use in recovery systems since the AC can be regenerated when *breakthrough*, also known as *breakpoint*, occurs. This is when the AC has become saturated with the solvent and traces of the solvent begin to appear in the exit air. Until breakthrough, removal efficiency is essentially constant. The *retentivity* of the AC is the ratio of adsorbed solvent mass to carbon mass.

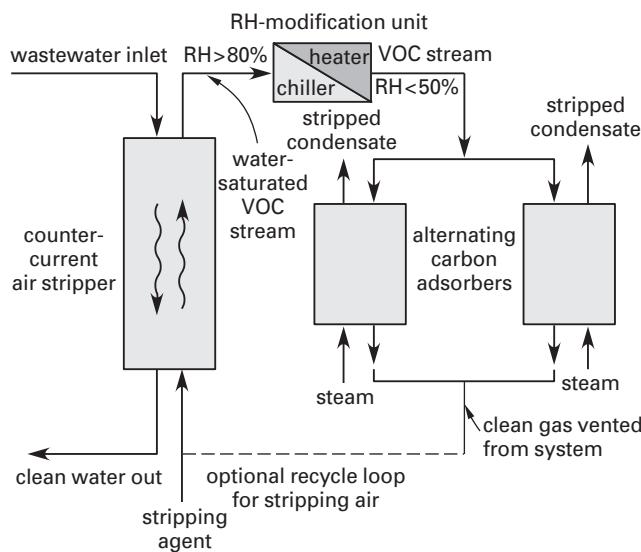

<sup>5</sup>The term *activated* refers to the high-temperature removal of tarry substances from the interior of the carbon granule, leaving a highly porous structure.

<sup>6</sup>An *adsorbent* is a substance with high surface area per unit weight, an intricate pore structure, and a hydrophobic surface. An *adsorbent material* traps substances in fluid (liquid and gaseous) form on its exposed surfaces. In addition to activated carbon, other common industrial adsorbents include alumina, bauxite, bone char, Fuller's earth, magnesia, and silica gel.

## 6. ADSORPTION (SOLVENT RECOVERY)

AC for solvent recovery is used in a cyclic process where it is alternately exposed to the target substance and then regenerated by the removal of the target substance. For solvent recovery to be effective, the VOC inlet concentration should be at least 700 ppm. Regeneration of the AC is accomplished by heating, usually by passing low-pressure (e.g., 5 psig) steam over the AC to raise the temperature above the solvent-capture temperature. Figure 34.3 shows a stripping-AC process with recovery.

**Figure 34.3** Stripping-AC Process with Recovery

There are three main processes for solvent recovery. In a traditional *open-loop recovery system*, a countercurrent air stripper separates VOC from the incoming stream. The resulting VOC air/vapor stream passes through an AC bed. Periodically, the air/vapor stream is switched to an alternate bed, and the first bed is regenerated by passing steam through it. The VOC is recovered from the steam. The VOC-free air stream is freely discharged. Operation of a *closed-loop recovery system* is the same as an open loop system, except that the VOC-free air stream is returned to the air stripper.

For VOC-laden gas flows from 5000 SCFM to 100,000 SCFM (2.3 kL/s to 47 kL/s), a third type of solvent recovery system involves a *rotor concentrator*. VOCs are continuously adsorbed onto a multilayer, corrugated wheel whose honeycomb structure has been coated with powdered AC. The wheel area is divided into three zones: one for adsorption, one for desorption (i.e., regeneration), and one for cooling. Each of the zones is isolated from the other by tight sealing. The wheel rotates at low speed, continuously exposing new portions of the streams to each of the three zones. Though the equipment is expensive, operational efficiencies are high—95% to 98%.

## 7. ADSORPTION, HAZARDOUS WASTE

AC is particularly attractive for flue gas cleanup (FGC) at installations that burn spent oil, electrical cable, biosolids (i.e., sewage sludge), waste solvents, or tires as supplemental fuels. As with liquids, flue gases can be cleaned by passing them through fixed AC. Heavy metal dioxins are quickly adsorbed by the AC—in the first 8 in (20 cm) or so. AC injection (direct or spray) can remove 60% to 90% of the target substance present.

The spent AC creates its own waste disposal problem. For some substances (e.g., dioxins), AC can be incinerated. Heavy metals in AC must be removed by a wash process. Another process in use is vitrifying the AC and fly ash into a glassy, unleachable substance. *Vitrification* is a high-temperature process that turns incinerator ash into a safe, glass-like material. In some processes, heavy-metal salts are recovered separately. No gases and no hazardous wastes are formed.

## 8. ADVANCED FLUE GAS CLEANUP

Most air pollution control systems reduce NOx in the burner and remove SOx in the stack. *Advanced flue gas cleanup* (AFGC) methods combine processes to remove both NOx and SOx in the stack. Particulate matter is removed by an electrostatic precipitator or baghouse as is typical. Promising AFGC methods include wet scrubbing with metal chelates such as ferrous ethylenediaminetetraacetate (Fe(II)-EDTA) (NOx/SOx removal efficiencies of 60%/90%), adding sodium hydroxide injection to dry scrubbing operations (35% NOx removal), in-duct sorbent injection of urea (80% NOx removal), in-duct sorbent injection of sodium bicarbonate (35% NOx removal), and the NOXSO process using a fluidized bed of sodium-impregnated alumina sorbent at approximately 250°F (120°C) (70% to 90%/90% NOx/SOx removal).

## 9. ADVANCED OXIDATION

The term *advanced oxidation* refers to the use of ozone, hydrogen peroxide, ultraviolet radiation, and other exotic methods that produce free hydroxyl radicals ( $\text{OH}^-$ ). (See also Sec. 34.38.) Table 34.1 shows the relative oxidation powers of common oxidants.

## 10. BAGHOUSES

*Baghouses* have a reputation for excellent particulate removal, down to 0.005 grains/ $\text{ft}^3$  (0.18 grains/ $\text{m}^3$ ) (dry), with particulate emissions of 0.01 grains/ $\text{ft}^3$  (0.35 grains/ $\text{m}^3$ ) being routine. Removal efficiencies are in excess of 99% and are often as high as 99.99% (weight basis). Fabric filters have a high efficiency for removing particulate matter less than 10  $\mu\text{m}$  in size. Because of this, baghouses are effective at collecting air toxics, which preferentially condense on these particles at the baghouse operating temperature—less than

**Table 34.1** Relative Oxidation Powers of Common Oxidants

oxidant	oxidation power (relative to chlorine)
fluorine	2.25
hydroxyl radical ( $\text{OH}$ )	2.05
ozone ( $\text{O}_3$ )	1.52
permanganate radical ( $\text{MnO}_4$ )	1.23
chlorine dioxide ( $\text{ClO}_2$ )	1.10
hypochlorous acid ( $\text{HClO}$ )	1.10
chlorine	1.00
bromine	0.80
iodine	0.40
oxygen	0.29

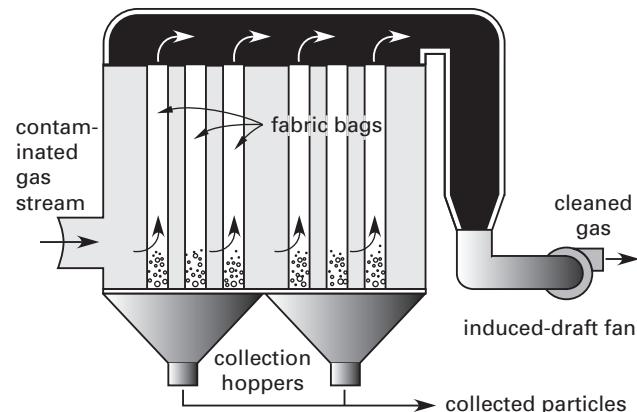

300°F (150°C). Gas temperatures can be up to 500°F (260°C) with short periods up to about 550°F (288°C), depending on the filter fabric. Most of the required operational power is to compensate for the system pressure drops due to bags, cake, and ducting.

Baghouse filter fabric has micro-sized holes but may be felted or woven, with the material depending on the nature of the flue gas and particulates. Woven fabrics are better suited for lower filtering velocities in the 1 ft/min to 2 ft/min (0.3 m/min to 0.7 m/min) range, while felted fabrics are better at 5 ft/min (1.7 m/min). The fabric is often used in tube configuration, but envelopes (i.e., flat bags) and pleated cartridges are also available.

The particulate matter collects on the outside of the bag, forming a cake-like coating. If lime has been introduced into the stream in a previous step, some of the cake will consist of unreacted lime. As the gases pass through this cake, additional neutralizing takes place.

When the pressure drop across the filter reaches a preset limit (usually 6 in wg to 8 in wg (1.5 kPa to 2 kPa)), the cake is dislodged by mechanical shaking, reverse-air cleaning, or pulse-jetting. The dislodged fly ash cake falls into collection hoppers below the bags. Fly ash is transported by pressure or vacuum conveying systems to the conditioning system (consisting of surge bins, rotary feeders, and pug mills). Figure 34.4 shows a typical baghouse.

Baghouses are characterized by their air-to-cloth ratios and pressure drop. The *air-to-cloth ratio*, also known as *filter ratio*, *superficial face velocity*, and *filtering velocity*, is the ratio of the air volumetric flow rate in  $\text{ft}^3/\text{min}$  ( $\text{m}^3/\text{s}$ ) to the exposed surface area in  $\text{ft}^2$  ( $\text{m}^2$ ). After canceling, the units are  $\text{ft}/\text{min}$  ( $\text{m}/\text{s}$ ), hence the name *filtering velocity*. The higher the ratio, the smaller the baghouse and the higher the pressure drop. Shaker and reverse-air baghouses with woven fabrics have typical air-to-cloth ratios ranging from 1.0 ft/min to 6.0 ft/min (0.056 m/s to 0.34 m/s). Pulse-jet collectors with felted fabrics have higher ratios, ranging from 3.5 ft/min to 5.0 ft/min (0.0175 m/s to 0.025 m/s).

**Figure 34.4** Typical Baghouse

Advantages of baghouses include high efficiency and performance that is essentially independent of flow rate, particle size, and particle (electrical) resistivity. Also, baghouses produce the lowest opacity (generally less than 10, which is virtually invisible). Disadvantages include clogging, difficult cleaning, and bag breakage.

In a baghouse with  $N$  compartments, each with multiple bags, the *gross filtering velocity*, *gross air-to-cloth ratio*, and *gross filtering area*,  $v_{f,N}$ , refer to having all  $N$  compartments operating simultaneously. (See Eq. 34.1.) The *design filtering velocity*, *net filtering velocity*, *net air-to-cloth ratio*, and *net filtering area*,  $v_{f,N-1}$ , refer to one compartment taken offline for cleaning, meaning  $N-1$  compartments are operating simultaneously. (See Eq. 34.2.) *Net net* refers to having  $N-2$  compartments operating simultaneously.

$$v_{f,N} = \frac{Q_t}{A_N \text{ compartments}} = \frac{Q_t}{N A_{\text{one compartment}}} \quad 34.1$$

$$v_{f,N-1} = \frac{Q_t}{(N-1) A_{\text{one compartment}}} \quad 34.2$$

The number of bags is

$$n_{\text{bags}} = \frac{A_N}{A_{\text{bag}}} = \frac{A_N}{\pi d h} \quad 34.3$$

The *areal dust density*,  $W$ , is the mass of dust cake on the filter per unit area. The areal dust density can be calculated from the incoming particle concentration (*dust loading*, *fabric loading*),  $C$ , filtering velocity, and collection efficiency. Typical units are  $\text{lbm}/\text{ft}^2$  ( $\text{kg}/\text{m}^2$ ).

$$W = \eta C v_f t \approx C v_f t \quad 34.4$$

In the *filter drag model*, the pressure drop through the baghouse is calculated from the *filter drag* (*filter resistance*),  $S$ , in units of  $\text{in wg}\cdot\text{min}/\text{ft}$  ( $\text{Pa}\cdot\text{min}/\text{m}$ ), which depends on the permeabilities of the cloth,  $K_1$ ,  $K_0$ , or  $K_e$ , and the particle cake,  $K_2$  or  $K_s$ . ( $K_1$  is also known as the *flow resistance* of the clean fabric;  $K_2$  is the *specific*

*resistance of the cake.)* Since Eq. 34.6 represents a straight line,  $K_e$  and  $K_s$  can be determined by plotting  $S$  versus  $W$  for a few test points. Maximum pressure drop is typically in the 5–20 in wg (1.2–5.0 kPa) range.

$$\Delta p = v_{\text{filtering}} S \quad 34.5(a)$$

$$\Delta p_{\text{in wg}} = v_{f,\text{ft/min}} S_{\text{in wg-min/ft}} \quad 34.5(b)$$

$$S = K_e + K_s W \quad 34.6$$

Baghouses commonly have multiple compartments, and sufficient capacity must remain when one compartment is taken offline for cleaning. If there are  $N$  compartments, the time for  $N$  cycles of filtration (known as the *filtration time*) will be<sup>7</sup>

$$t_{\text{filtration}} = N(t_{\text{run}} + t_{\text{cleaning}}) - t_{\text{cleaning}} \quad 34.7$$

Filtering velocity and pressure drop depend on the number of compartments that are online (i.e., they increase when one of the compartments is taken offline). The maximum pressure drop,  $\Delta p_m$ , occurs several times during the filtration time. The maximum pressure drop can be calculated from the maximum filter drag, which in turn, depends on the maximum areal density. The *actual filtering velocity*,  $v_{f,\max \Delta p}$ , is the velocity at the time the maximum pressure drop occurs.<sup>8</sup>  $c$  in Eq. 34.11 is a scaling constant that depends on the number of compartments. (See Table 34.2.)

$$\Delta p_{\max} = S_{\max \Delta p} v_{f,\max \Delta p} \quad 34.8$$

$$S_{\max \Delta p} = K_e + K_s W_{\max \Delta p} \quad 34.9$$

$$W_{\max \Delta p} = (N - 1)C(v_{f,N} t_{\text{run}} + v_{f,N-1} t_{\text{cleaning}}) \quad 34.10$$

$$v_{f,\max \Delta p} = cv_{f,N-1} \quad 34.11$$

**Table 34.2** Values for Scaling Constant,  $c$ , Based on Number of Compartments,  $N$

number of compartments, $N$	$c$
3	0.87
4	0.80
5	0.76
7	0.71
10	0.67
12	0.65
15	0.64
20	0.62

<sup>7</sup>By convention, the filtration time includes only  $N - 1$  cleanings.

<sup>8</sup>The name “actual filtering velocity” is definitely confusing.

The motor for the fan (blower) is sized based on the maximum pressure loss.

$$P = Q_t \Delta p_{\max} \quad 34.12(a)$$

$$P_{\text{hp}} = \frac{Q_{t,\text{ft}^3/\text{min}} \Delta p_{\max,\text{in wg}}}{6356 \eta_{\text{motor}}} \quad [\text{U.S. only}] \quad 34.12(b)$$

There is no single formula derived from basic principles that predicts baghouse collection efficiency,  $\eta$ . Baghouse designs are normally based on experience, not on fractional efficiency curves. The instantaneous collection efficiency (as well as the pressure drop) of a baghouse increases with time as pores fill with particles. The empirical rate constant,  $k$ , is derived from a curve fit of actual performance.

$$\eta = 1 - e^{-kt} \quad 34.13$$

## 11. BIOREMEDIATION

*Bioremediation* encompasses the methods of biofiltration, bioreaction, bioreclamation, activated sludge, trickle filtration, fixed-film biological treatment, landfilling, and injection wells (for in situ treatment of soils and groundwater). Bioremediation relies on microorganisms in a moist, oxygen-rich environment to oxidize solid, liquid, or gaseous organic compounds, producing carbon dioxide and water. Bioremediation is effective for removing volatile organic compounds (VOCs) and easy-to-degrade organic compounds such as BTEXs (benzene, toluene, ethylbenzene, and xylene).<sup>9</sup> Wood-preserving wastes, such as creosote and other polynuclear aromatic hydrocarbons (PAHs), can also be treated.

Bioremediation can be carried out in open tanks, packed columns, beds of porous synthetic materials, composting piles, or soil. The effectiveness of bioremediation depends on the nature of the process, the time and physical space available, and the degradability of the substance. Table 34.3 categorizes gases according to their general degradabilities.

Though slow, limited by microorganisms with the specific affinity for the chemicals present, and susceptible to compounds that are toxic to the microorganisms, bioremediation has the advantage of destroying substances rather than merely concentrating them. Bioremediation is less effective when a variety of different compounds are present simultaneously.

## 12. BIOFILTRATION

The term *biofiltration* refers to the use of composting and soil beds. A *biofilter* is a bed of soil or compost through which runs a distribution system of perforated pipe. Contaminated air or liquid flows through the pipes and into the bed. Volatile organic compounds (VOCs) are oxidized to CO<sub>2</sub> by microorganisms. Volatile inorganic compounds (VICs) are oxidized to acids (e.g., HNO<sub>3</sub> and H<sub>2</sub>SO<sub>4</sub>) and salts.

<sup>9</sup>BTEXs are common ingredients in gasoline.

**Table 34.3** Degradability of Volatile Organic and Inorganic Gases

rapidly degradable VOCs	rapidly reactive VICs	slowly degradable VOCs	very slowly degradable VOCs
alcohols	H <sub>2</sub> S	hydrocarbons <sup>a</sup>	halogenated hydrocarbons <sup>b</sup>
aldehydes	NO <sub>x</sub> (but not N <sub>2</sub> O)	phenols	hydrocarbons <sup>b</sup>
ketones		methylene	polyaromatic hydrocarbons
ethers	SO <sub>2</sub>	chloride	hydrocarbons
esters	HCl		CS <sub>2</sub>
organic acids	NH <sub>3</sub>		
amines	PH <sub>3</sub>		
thiols	SiH <sub>4</sub>		
other molecules containing O, N, or S functional groups	HF		

<sup>a</sup>Aliphatics degrade faster than aromatics, such as xylene, toluene, benzene, and styrene.

<sup>b</sup>These include trichloroethylene, trichloroethane, carbon tetrachloride, and pentachlorophenol.

Biofilters require no fuel or chemicals when processing VOCs, and the operational lifetime is essentially infinite. For VICs, the lifetime depends on the soil's capacity to neutralize acids. Though reaction times are long and absorption capacities are low (hence the large areas required), the oxidation continually regenerates (rather than depletes) the treatment capacity. Once operational, biofiltration is probably the least expensive method of eliminating VOCs and VICs.

The *removal efficiency* of a biofilter is given by Eq. 34.14. *k* is an empirical *reaction rate constant*, and *t* is the *bed residence time* of the carrier fluid (water or air) in the bed. The reaction rate constant depends on the temperature but is primarily a function of the biodegradability of the target substance. Biofiltration typically removes 80% to 99% of volatile organic and inorganic compounds (VOCs and VICs).

$$\eta = 1 - \frac{C_{\text{out}}}{C_{\text{in}}} = 1 - e^{-kt} \quad 34.14$$

### 13. BIOREACTION

*Bioreactors (reactor tanks)* are open or closed tanks containing dozens or hundreds of slowly rotating disks covered with a biological film of microorganisms (i.e., colonies). Closed tanks can be used to maintain anaerobic or other design atmosphere conditions. For example, methanotrophic bacteria are useful in breaking down chlorinated hydrocarbons (e.g., trichlorethylene (TCE), dichloroethylene (DCE), and vinyl chloride (VC)) that would otherwise be considered nonbiodegradable. Methanotrophic bacteria derive their food from methane gas that is added to the bioreactor. An enzyme, known as MMO, secreted by the bacteria breaks down the chlorinated hydrocarbons.

### 14. BIOVENTING

*Bioventing* is the treatment of contaminated soil in a large plastic-covered tank. Clean air, water, and nutrients are continuously supplied to the tank while off-gases are suctioned off. The off-gas is cleaned with activated carbon (AC) adsorption or with thermal or catalytic oxidation prior to discharge. Bioventing has been used successfully to remove volatile hydrocarbon compounds (e.g., gasoline and BTEX compounds) from soil.

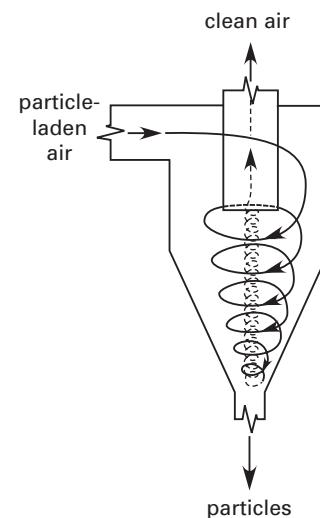

### 15. COAL CONDITIONING

Coal intended for electrical generating plants can be modified into "self-scrubbing" coal by conditioning prior to combustion. Conditioning consists of physical separation by size, by cleaning (e.g., cycloning to remove noncombustible material, including up to 90% of the pyritic sulfur), and by the optional addition of limestone and other additives to capture SO<sub>2</sub> during combustion. Small-sized material is pelletized to reduce loss of fines and particulate emissions (dust).

### 16. CYCLONE SEPARATORS

*Inertial separators* of the double-vortex, single cyclone variety are suitable for collecting medium- and large-sized (i.e., greater than 5 μm) particles from spot sources. During operation, particulate matter in the incoming gas stream spirals downward at the outside and upward at the inside.<sup>10</sup> The particles, because of their greater mass, move toward the outside wall, where they drop into a collection bin. Figure 34.5 shows a double-vortex, single cyclone separator.

**Figure 34.5** Double-Vortex, Single Cyclone

<sup>10</sup>The number of gas revolutions varies approximately between 0.5 and 10.0, with averages of 1.5 revolutions for simple cyclones and 5 revolutions for high-efficiency cyclones.

The *cut size* is the diameter of particles collected with a 50% efficiency. Separation efficiency varies directly with (1) particle diameter, (2) particle density, (3) inlet velocity, (4) cyclone body length (ratio of cyclone body diameter to outlet diameter), (5) smoothness of inner wall, (6) number of gas revolutions, and (7) amount of particles in the flow. Collection efficiency decreases with increases in (1) gas viscosity, (2) gas density, (3) cyclone diameter, (4) gas outlet diameter, (5) gas inlet duct width, and (6) inlet area.

Collection efficiencies are not particularly high, and dusts ( $5 \mu\text{m}$  to  $10 \mu\text{m}$ ) are too fine for most cyclones. For geometrically similar cyclones, the collection efficiency varies directly with the dimensionless *separation factor*,  $S$ .

$$S = \frac{v_{\text{inlet}}^2}{rg} \quad 34.15$$

Pressure drop,  $h$ , in feet (meters) of air across a cyclone can be roughly (i.e., with an accuracy of only approximately  $\pm 30\%$ ) estimated by Eq. 34.16.  $H$  and  $B$  are the height and width of the rectangular cyclone inlet duct, respectively;  $D_e$  is the gas exit duct diameter; and  $K$  is an empirical constant that varies from approximately 7.5 to 18.4.

$$h = \frac{KBHv_{\text{inlet}}^2}{2gD_e^2} \quad 34.16$$

## 17. DECHLORINATION

Industrial and municipal wastewaters containing excessive amounts of *total residual chlorine* (TRC) must be dechlorinated prior to discharge. Sulfur dioxide, sodium metabisulfite, and sulfite salts are effective dechlorinating agents. For sulfur dioxide, the dose is approximately 0.9 lbm/lbm (0.9 kg/kg) of chlorine to be removed. Reaction is essentially instantaneous, being completed within 10 pipe diameters at turbulent flow. For open channels, a submerged weir may be necessary to obtain the necessary turbulence. TRC is reduced to less than detectable levels.

## 18. ELECTROSTATIC PRECIPITATORS

*Electrostatic precipitators* (ESPs) are used to remove particulate matter from gas streams. Collection efficiency for particulate matter is usually in the 95% to 99% range. ESPs are preferred over scrubbers because they are more economical to operate, dependable, and predictable and because they don't produce a moisture plume.

ESPs used on steam generator/electrical utility units treat gas that is approximately  $280^\circ\text{F}$  to  $300^\circ\text{F}$  ( $140^\circ\text{C}$

to  $150^\circ\text{C}$ ) with moisture being superheated.<sup>11</sup> This high temperature enhances buoyancy and plume dissipation. However, ESPs generally cannot be used with moist flows, mists, or sticky or hygroscopic particles. Scrubbers should be used in those cases. Relatively humid flows can be treated, although entrained water droplets can insulate particles, lowering their resistivities. Table 34.4 gives typical design parameters for ESPs.

**Table 34.4** Typical Electrostatic Precipitator Design Parameters

parameter	typical range	
	U.S.	SI
efficiency	90% to 98%	
gas velocity	2 ft/sec to 4 ft/sec	0.6 m/s to 1.2 m/s
gas temperature		
standard	$\leq 700^\circ\text{F}$	$\leq 370^\circ\text{C}$
high-temperature	$\leq 1000^\circ\text{F}$	$\leq 540^\circ\text{C}$
special	$\leq 1300^\circ\text{F}$	$\leq 700^\circ\text{C}$
drift velocity	0.1 ft/sec to 0.7 ft/sec	0.03 m/s to 0.21 m/s
treatment/residence time		2 sec to 10 sec
draft pressure loss	0.1 iwg to 0.5 iwg	0.025 kPa to 0.125 kPa
plate spacing	12 in to 16 in	30 cm to 41 cm
plate height	30 ft to 50 ft	9 m to 15 m
plate length/height ratio		1.0 to 2.0
applied voltage		30 kV to 75 kV

In operation, the gas passes over negatively charged tungsten *corona wires* or grids. Particles are attracted to positively charged collection plates.<sup>12</sup> The speed at which the particles move toward the plate is known as the *drift velocity*,  $w$ . Drift velocity is approximately 0.20 ft/sec to 0.30 ft/sec (0.06 m/s to 0.09 m/s), with 0.25 ft/sec (0.075 m/s) being a reasonable design value. Periodically, *rappers* vibrate the collection plates and dislodge the particles, which drop into collection hoppers.

Advantages of ESPs include high reliability, low maintenance, low power requirements, and low pressure drop. Disadvantages are sensitivity to particle size and resistivity, and the need to heat ESPs during start-up and shutdown to avoid corrosion from acid gas condensation.

For a rectangular electrostatic precipitator (ESP) with interior dimensions  $W \times H \times L$ , the flow rate is

$$Q = v_g WH \quad 34.17$$

<sup>11</sup>The flue gas, at approximately  $1400^\circ\text{F}$  ( $760^\circ\text{C}$ ), is cooled to this temperature range in a conditioning tower. Injected water increases the moisture content of the flue gas to approximately 25% by volume.

<sup>12</sup>The *tubular ESP*, used for collecting moist or sticky particles, is a variation on this design.

The *residence time* (*exposure time*),  $t_r$ , is

$$t_r = \frac{L}{v_g} \quad 34.18$$

Collection efficiency is affected by particle *resistivity*, which is divided into three categories: low (less than  $1 \times 10^8 \Omega\text{-cm}$ ); medium, moderate, or normal ( $1 \times 10^8 \Omega\text{-cm}$  to  $2 \times 10^{11} \Omega\text{-cm}$ ); and high (more than  $2 \times 10^{11} \Omega\text{-cm}$ ). Particles in the medium resistivity range are collected most easily. Particles with low resistivity are easily charged, but upon contact with the charged plate, they rapidly lose their charges and are re-entrained into the gas flow. Particles with high resistivity coat the collection plate with a layer of insulation, causing *flashovers* and *back corona*, a localized electrical discharge. High resistivity particles can be brought into the moderate range by *particle conditioning*. When the gas temperature is below  $350^\circ\text{F}$  ( $177^\circ\text{C}$ ), adding moisture to the gas stream, reducing the temperature, or adding  $\text{SO}_3$  and ammonia will reduce resistivity into the moderate range. When the gas temperature is above  $350^\circ\text{F}$  ( $177^\circ\text{C}$ ), increasing the temperature lowers particle resistivity.

Collection efficiency is also affected by the particle size. The theoretical *drift velocity* (*migration velocity* or *precipitation rate*) is proportional to the particle diameter. The theoretical drift velocity,  $w$ , of a particle in an electric field can be calculated from basic principles. In Eq. 34.19,  $q$  is the charge on the particle, which can be many times the charge on an electron,  $q_e$  ( $1.602 \times 10^{-19} \text{ C}$ );  $E$  is the electric field strength in  $\text{V/m}$ ;  $\epsilon$  is the particle's *dielectric constant* (*relative permittivity*), approximately 1.5–2.6 for fly ash;<sup>13</sup> and  $\epsilon_0$  is the *permittivity of free space*, equal to  $8.854 \times 10^{-12} \text{ F/m}$  (same as  $\text{C/V}$ ,  $\text{C}^2/\text{N}\cdot\text{m}^2$ , and  $\text{A}^2\cdot\text{s}^4/\text{kg}\cdot\text{m}^3$ ).  $C_c$  is the *Cunningham slip factor* (*Cunningham correction factor*), which accounts for the reduction in drag on particles less than  $1 \mu\text{m}$  in size when gas molecules slip past them.  $C_c$  approaches 1.0 for particles with  $d_p > 5 \mu\text{m}$ .  $\lambda$  is the *mean free path length* of the gas. For air at  $68^\circ\text{F}$  ( $20^\circ\text{C}$ ) and 1 atm,  $\lambda$  is approximately  $0.0665 \mu\text{m}$ . (See Eq. 34.20.)

$$w \approx \frac{qEC_c}{3\pi\mu_g d_p} = \frac{Nq_e EC_c}{3\pi\mu_g d_p} \approx \frac{\epsilon\epsilon_0 E^2 d_p C_c}{(\epsilon + 2)\mu_g} \Big|_{\text{sat}} \quad 34.19$$

$$C_c \approx 1 + \frac{\lambda}{d_{p,\text{Stk}}} \left( 2.514 + 0.80 \exp\left(-\frac{0.55 d_{p,\text{Stk}}}{\lambda}\right) \right) \quad 34.20$$

A particle will become saturated if it remains in a strong electric field sufficiently long. The *equilibrium charge* is found from the number of electron charges on a

saturated spherical particle. The charging electric field is not necessarily the same as the drift electric field.

$$N_{\text{sat,spherical}} = \frac{3\epsilon\epsilon_0\pi E_{\text{charging}} d_p^2}{(\epsilon + 2)q_e} \quad 34.21$$

In practice, the theoretical drift velocity is seldom used. Rather, an *effective drift velocity*,  $w_e$ , is used. Although it shares the “velocity” name and units, the effective drift velocity is not an actual velocity, but is an empirical design parameter derived from pilot tests of collection efficiency.

The *Deutsch-Anderson equation* predicts the single-particle fractional *collection efficiency* (*removal efficiency*),  $\eta$ , of an electrostatic precipitator with total collection area,  $A$ , of all plates. The exponent,  $y$ , is 1 for fly ash and for anything else in the absence of specific knowledge otherwise. *Penetration*,  $Pt$ , is the fraction of particles that pass through the ESP uncollected. Penetration is the complement of collection efficiency.

$$\eta = \frac{C_{\text{in}} - C_{\text{out}}}{C_{\text{in}}} = \frac{\dot{m}_{\text{in}} - \dot{m}_{\text{out}}}{\dot{m}_{\text{in}}} = 1 - \exp\left(\frac{-Aw_e}{Q}\right)^y \quad 34.22$$

$$Pt = 1 - \eta \quad 34.23$$

The effect of flow rate on the collection efficiency is predicted by Eq. 34.24.

$$\frac{Q_1}{Q_2} = \ln(\eta_1 - \eta_2) \quad 34.24$$

Collection efficiency can also be expressed as a function of the *residence time*.  $K$  is the ratio of collection plate area to internal volume.

$$\eta = 1 - \exp(-Kw_e t_r) = 1 - \exp\left(-\left(\frac{A}{WHL}\right)w_e t_r\right) \quad 34.25$$

One of the most important factors affecting the collection efficiency is the *specific collection area*, SCA, which is the ratio of the total collection surface area to the gas flow rate into the collector, usually reported in  $\text{ft}^2/1000 \text{ ft}^3\text{-min}$  ( $\text{m}^2/1000 \text{ m}^3\text{-h}$ ). The higher the SCA, the higher the collection efficiency will be.

$$\text{SCA} = \frac{A}{Q} \quad 34.26$$

<sup>13</sup>The dielectric constant of fly ash depends greatly on the temperature and amount of unburned carbon.

Using units common to the industry, the instantaneous collection efficiency of an ESP collector is

$$\eta = 1 - \exp(-0.06 w_{e,\text{ft/sec}} \text{SCA}_{\text{ft}^2}/1000 \text{ACFM}) \quad 34.27$$

The *corona power ratio*, CPR, is the power consumed by the corona in developing the electric field divided by the airflow. Generally, collection efficiency increases with increased CPR. The *corona current ratio*, CCR, is the current per unit plate area. The *power density*,  $P_A$ , is the power per unit plate area.

$$\text{CPR}_{\text{W-min}/\text{ft}^3} = \frac{P_{c,W}}{Q_{\text{ft}^3/\text{min}}} = \frac{I_{c,A} V_V}{Q_{\text{ft}^3/\text{min}}} \quad 34.28$$

$$\text{CCR}_{\mu\text{A}/\text{ft}^2} = \frac{I_{c,\mu\text{A}}}{A_{\text{ft}^2}} \quad 34.29$$

$$P_{A,W/\text{ft}^2} = \frac{P}{A} \quad 34.30$$

Typical values for ESP design parameters are given in Table 34.5.

**Table 34.5 Typical ESP Design Parameters**

design parameter	typical value
particle effective drift velocity	0.05–1.0 ft/sec (0.015–0.3 m/s)
gas velocity	2–5 ft/sec typical; 15 ft/sec max (0.6–1.5 m/s typical; 4.5 m/s max)
number of stages	1–7
total specific collection area	100–1000 ft <sup>2</sup> /1000 ACFM (5.5–55 m <sup>2</sup> /1000 m <sup>3</sup> ·h)
pressure drop	> 0.5 in wg (0.13 kPa)

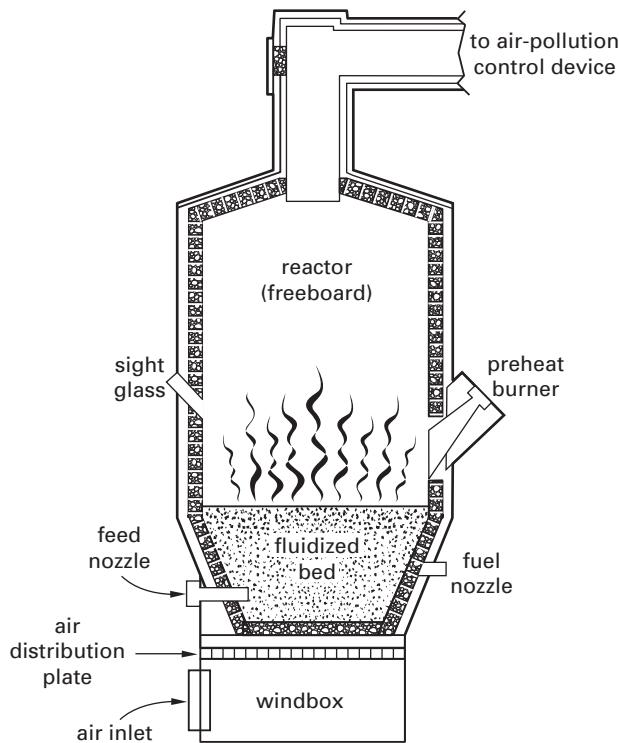

## 19. FLUE GAS RECIRCULATION

NO<sub>x</sub> emissions can be reduced when thermal dissociation is the primary NO<sub>x</sub> source (as it is when low-nitrogen fuels such as natural gas are burned) by recirculating a portion (15% to 25%) of the flue gas back into the furnace. This process is known as *flue gas recirculation* (FGR). The recirculated gas absorbs heat energy from the flame and lowers the peak temperature. Thermal NO<sub>x</sub> formation can be reduced by up to 50%. The recirculated gas should not be more than 600°F (315°C).

## 20. FLUIDIZED-BED COMBUSTORS

*Fluidized-bed combustors* (FBCs) are increasingly being used in steam/electric generation systems and for destruction of hazardous wastes. A *bubbling bed FBC*, as shown in Fig. 34.6, consists of four major components: (1) a windbox (plenum) that receives the fluidizing/combustion air, (2) an air distribution plate that transmits the air at 10 ft/sec to 30 ft/sec (3 m/s to 9 m/s) from the windbox to the bed and prevents the

**Figure 34.6 Fluidized-Bed Combustor**

bed material from sifting into the windbox, (3) the fluid bed of inert material (usually sand or product ash), and (4) the freeboard area above the bed.

During the operation of a bubbling bed fluidized-bed combustor, the inert bed is levitated by the upcoming air, taking on many characteristics of a fluid (hence, the name FBC). The bed “boils” vigorously, offering an extremely large heat-transfer area, resulting in the thorough mixing of feed combustibles and air. Combustible material usually represents less than 1% of the bed mass, so the rest of the bed acts as a large thermal flywheel.

Combustion of volatile materials is completed in the freeboard area. Ash is generally reduced to small size so that it exits with the flue gas. In some cases (e.g., deliberate pelletization or wastes with high ash content), ash can accumulate in the bed. The fluid nature of the bed allows the ash to float on its surface, where it is removed through an overflow drain.

Most FBC systems use forced air with a single blower at the front end. If there are significant losses due to heat recovery or pollution control systems, an exhaust fan may also be used. In that case, the *null (balanced draft) point* should be in the freeboard area.

Large variations in the composition of the flue gases (known as *puffing*) is minimized by the long residence time and the large heat reservoir of the bed. Air pollution control equipment common to most boilers and

incinerators is used with fluidized-bed combustors. Either wet scrubbers or baghouses can be used.

The temperature of the bed can be as high as approximately 1900°F (1040°C), though in most applications, temperatures this high are neither required nor desirable.<sup>14</sup> Most systems operate in the 1400°F to 1650°F (760°C to 900°C) range.

Three main options exist for reducing temperatures with overautogeneous fuels:<sup>15</sup> (1) water can be injected into the bed, which has the disadvantage of reducing downstream heat recovery; (2) excess air can be injected, requiring the entire system to be sized for the excess air, increasing its cost; (3) and heat-exchange coils can be placed within the bed itself, in which case, the name *fluidized-bed boiler* is applicable.

Air can be preheated to approximately 1000°F to 1250°F (540°C to 680°C) for use with subautogenous fuels, or auxiliary fuel can be used.

Contemporary FBC boilers for steam/electricity generation are typically of the *circulating fluidized-bed boiler design*. An important aspect of FBC boiler operation is the in-bed gas desulfurization and dechlorination that occurs when limestone and other solid reagents are injected into the combustion area. In addition, circulating fluidized-bed boilers have very low NOx emissions (i.e., less than 200 ppm).

## 21. INJECTION WELLS

Properly treated and stabilized liquid and low-viscosity wastes can be injected under high pressure into appropriate strata 2000 ft to 6000 ft (600 m to 1800 m) below the surface. The wastes displace natural fluids, and the injection well is capped to maintain the pressure. Injection wells fail primarily by waste plumes through fractures, cracks, fault slips, and seepage around the well casing. Figure 34.7 shows a typical injection well installation.

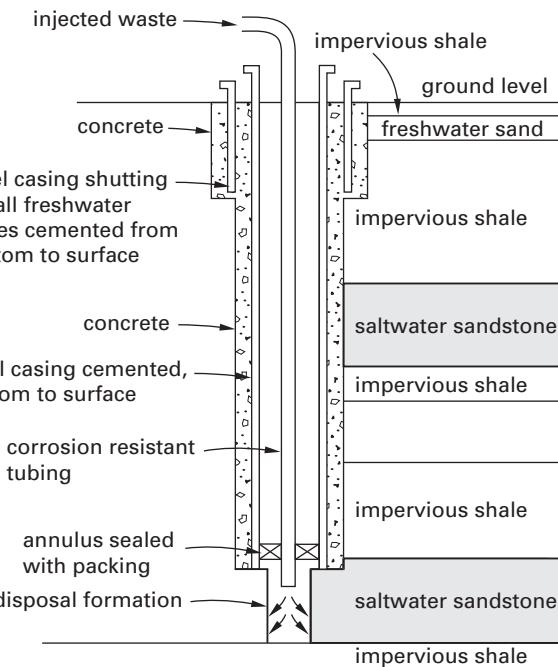

## 22. INCINERATORS, FLUIDIZED-BED COMBUSTION

In an FBC, combustion is efficient and excess air required is low (e.g., 25% to 50%). Destruction is essentially complete due to the long residence time (5 sec to 8 sec for gases, and even longer for solids), high turbulence, and exposure to oxygen. Combustion control is simple, and combustion is often maintained within a 15°F (8°C) band. Both overautogeneous and subautogenous feeds can be handled. Due to the thermal mass of the bed, the FBC temperature drops slowly—at the rate of about 10°F/hr (5°C/h) after shutdown. Start-up is fast and operation can be intermittent.

<sup>14</sup>It is a common misconception that extremely high temperatures are required to destroy hazardous waste.

<sup>15</sup>A *subautogenous waste* has a heating value too low to sustain combustion and requires a supplemental fuel. Conversely, an *overautogeneous waste* has a heating value in excess of what is required to sustain combustion and requires temperature control.

**Figure 34.7** Typical Injection Well Installation

Relative to other hazardous waste disposal methods, NOx and metal emissions are low, and the organic content of the ash is very low (e.g., below 1%). Because of the long residence time, FBC systems do not usually require afterburners or secondary combustion chambers (SCCs). Due to the turbulent combustion process, the combustion temperature can be 200°F to 300°F (110°C to 170°C) lower than in rotary kilns. These factors translate into fuel savings, fewer or no NOx emissions, and lower metal emissions.

Most limitations of FBC systems relate to the feed. The feed must be of a form (small size and roughly regular in shape) that can be fluidized. This makes FBCs ideal for non-atomizable liquids, slurries, sludges, tars, and granular solids. It is more appropriate (and economical) to destroy atomizable liquid wastes in a boiler or special injection furnace and large bulky wastes in a rotary kiln or incinerator.

FBCs are usually inapplicable when the feed material or its ash melts below the bed temperature.<sup>16</sup> If the feed melts, it will agglomerate and defluidize the bed. When it is necessary to burn a feed with low melting temperature, two methods can be used. The bed can be operated as a *chemically active bed*, where operation is close to but below the ash melting point of 1350°F to 1450°F (730°C to 790°C). A small amount of controlled melting is permitted to occur, and the agglomerated ash is removed.

When a higher temperature is desirable in order to destroy hazardous materials, the melting point of feed

<sup>16</sup>The melting temperature of a eutectic mixture of two components may be lower than the individual melting temperatures.

can be increased by injecting low-cost additives (e.g., calcium hydroxide or kaolin clay). These combine with salts of alkali metals to form refractory-like materials with melting points in the 1950°F to 2350°F (1070°C to 1290°C) range.

The design of a fluidizing-bed incinerator starts with a heat balance. Energy enters the FBC during combustion of the feed and auxiliary fuel and from sensible heat contributions of the air and fuel. Some of the heat is recovered and reused. The remainder of the heat is lost through sensible heating of the combustion products, water vapor, excess air, and ash, and through radiation from the combustor vessel and associated equipment. Since these items may not all be known in advance, the following assumptions are reasonable.

- Radiation losses are approximately 5%.
- Sensible heat losses from the ash are minimal, particularly if the feed contains significant amounts of moisture.
- Excess air will be approximately 40%.
- Combustion temperature will be approximately 1400°F (760°C).
- If air is preheated, the preheat temperature will be approximately 1000°F (540°C).

The fuel's *specific feed characteristic* (SFC) is the ratio of the higher (gross) heating value to the moisture content.

$$SFC = \frac{\text{total heat of combustion}}{\text{mass of water}} = \frac{m_{\text{solid}} \text{HHV}}{m_w} \quad 34.31$$

Typical values of the specific feed characteristic range from a low of approximately 1000 Btu/lbm (2300 kJ/kg) for wastewater treatment plant biosolids, to more than 60,000 Btu/lbm (140 MJ/kg) for barks, sawdust, and RDF.<sup>17</sup> Making the previous assumptions and using the SFC as an indicator, the following generalizations can be made.

- Fuels with SFCs that are less than 2600 Btu/lbm (6060 kJ/kg) require a 1000°F (540°C) hot windbox, and are autogenous at that value and subautogenous below that value. The SFC drops to 2400 Btu/lbm (5600 kJ/kg) with air preheated to 1200°F (650°C). Below the subautogenous SFC, water evaporation is the controlling design factor, and auxiliary fuel is required.
- Fuels with an SFC of 4000 Btu/lbm (9300 kJ/kg) are autogenous with a cold windbox and are overautogenous above that value. Combustion is the controlling design factor for overautogenous SFCs.

<sup>17</sup>Although the units are the same, the specific feed characteristic is not the same as the heating value.

### Example 34.1

A wastewater treatment sludge is dewatered to 75% water by weight. The solids have a heating value of 6500 Btu/lbm (15 000 kJ/kg). The dewatered sludge enters a fluidized-bed combustor with a 1000°F (540°C) windbox at the rate of 15,000 lbm/hr (1.9 kg/s). (a) What is the specific feed characteristic? (b) Approximately what energy (in Btu/hr) must the auxiliary fuel supply?

#### SI Solution

(a) The dewatered sludge consists of 25% combustible solids and 75% moisture. The total mass of sludge required to contain 1.0 kg water is

$$m_{\text{sludge}} = \frac{m_w}{x_w} = \frac{1 \text{ kg}}{0.75} = 1.333 \text{ kg}$$

The mass of combustible solids per kilogram of water is

$$\begin{aligned} m_{\text{solids}} &= 0.25 m_{\text{sludge}} = (0.25)(1.333 \text{ kg}) \\ &= 0.3333 \text{ kg} \end{aligned}$$

From Eq. 34.31, the specific feed characteristic is

$$\begin{aligned} SFC &= \frac{\text{total heat of combustion}}{m_w} = \frac{m_{\text{solid}} \text{HHV}}{m_w} \\ &= \frac{(0.3333 \text{ kg}) \left( 15 000 \frac{\text{kJ}}{\text{kg}} \right) \left( 1000 \frac{\text{J}}{\text{kJ}} \right)}{1 \text{ kg}} \\ &= 5.0 \times 10^6 \text{ J/kg} \end{aligned}$$

(b) Making the listed assumptions, operation with a 540°C hot windbox requires an SFC of approximately 6060 kJ/kg. Therefore, the energy per kilogram of water in the fuel that an auxiliary fuel must provide is

$$(6060 \text{ kJ}) \left( 1000 \frac{\text{J}}{\text{kJ}} \right) - 5 \times 10^6 \text{ J} = 1.06 \times 10^6 \text{ J}$$

The energy supplied by the auxiliary fuel is

$$\begin{aligned} \dot{m}_{\text{fuel}} x_w \times \text{SFC deficit} \\ &= \left( 1.9 \frac{\text{kg}}{\text{s}} \right) (0.75) \left( 1.06 \times 10^6 \frac{\text{J}}{\text{kg}} \right) \\ &= 1.51 \times 10^6 \text{ J/s} \quad (1.5 \text{ MW}) \end{aligned}$$

#### Customary U.S. Solution

(a) The dewatered sludge consists of 25% combustible solids and 75% moisture. The total mass of sludge required to contain 1.0 lbm water is

$$m_{\text{sludge}} = \frac{m_w}{x_w} = \frac{1 \text{ lbm}}{0.75} = 1.333 \text{ lbm}$$

The mass of combustible solids per pound of water is

$$\begin{aligned}m_{\text{solids}} &= 0.25m_{\text{sludge}} = (0.25)(1.333 \text{ lbm}) \\&= 0.3333 \text{ lbm}\end{aligned}$$

From Eq. 34.31, the specific feed characteristic is

$$\begin{aligned}\text{SFC} &= \frac{\text{total heat of combustion}}{m_w} = \frac{m_{\text{solid}} \text{HHV}}{m_w} \\&= \frac{(0.3333 \text{ lbm})(6500 \frac{\text{Btu}}{\text{lbm}})}{1 \text{ lbm}} \\&= 2166 \text{ Btu/lbm}\end{aligned}$$

(b) Making the listed assumptions, operation with a 1000°F hot windbox requires an autogenous SFC of approximately 2600 Btu/lbm. Therefore, the energy per pound of water in the fuel that an auxiliary fuel must provide is

$$2600 \text{ Btu} - 2166 \text{ Btu} = 434 \text{ Btu}$$

The energy supplied by the auxiliary fuel is

$$\begin{aligned}\dot{m}_{\text{fuel}}x_w \times \text{SFC deficit} &= (15,000 \frac{\text{lbm}}{\text{hr}})(0.75)(434 \frac{\text{Btu}}{\text{lbm}}) \\&= 4.88 \times 10^6 \text{ Btu/hr}\end{aligned}$$

### 23. INCINERATION, GENERAL

Most rotary kiln and liquid injection incinerators have *primary* and *secondary combustion chambers* (SCCs). Kiln temperatures are approximately 1200°F to 1400°F (650°C to 760°C) for soil incineration and up to 1700°F (930°C) for other waste types.<sup>18</sup> SCC temperatures are higher—1800°F (980°C) for most hazardous wastes and 2200°F (1200°C) for liquid PCBs. The waste heat may be recovered in a boiler, but the combustion gas must be cooled prior to further processing. *Thermal ballast* can be accomplished by injecting large amounts of excess air (typical when liquid fuels are burned) or by quenching with a water spray (typical in rotary kilns).

SCCs are necessary to destroy toxics in the off-gases. SCCs are vertical units with high-swirl, vortex-type burners. These produce high *destruction removal efficiencies* (DREs) with low retention times (e.g., 0.5 sec) and moderate-to-high temperatures, even for chlorinated compounds. When soil with fine clay is incinerated, fines can build up in the SCC, causing slagging and other problems. A refractory-lined cyclone located

<sup>18</sup>Temperatures higher than 1400°F (760°C) may cause incinerated soil to vitrify and clog the incinerator.

after the primary combustion chamber can be used to reduce particle carryover to the SCC.

Prior to full operation, incinerators must be tested in a trial burn with a *principal organic hazardous constituent* (POHC) that is in or has been added to the waste. The POHC must be destroyed with a DRE of at least 99.99% by weight.

For nontoxic organics, a DRE of 95% is a common requirement. Hazardous wastes require a DRE of 99.99%. Certain hazardous wastes, including PCBs and dioxins, require a 99.9999% DRE. This is known as the *six nines rule*.

Emission limitations of some pollutants depend on the incoming concentration and the height of the stack.<sup>19</sup> Thus, in certain circumstances, raising the stack is the most effective method of being in compliance. This is considered justified on the basis that ground-level concentrations will be lower with higher stacks.

Rules of thumb regarding incinerator performance are as follows.

- Stoichiometric combustion requires approximately 725 lbm (330 kg) of air for each million Btu of fuel or waste burned.
- 100% excess air is required.
- Stack gas dew point is approximately 180°F (80°C).
- Water-spray-quenched flue gas is approximately 40% moisture by weight.

Table 34.6 gives performance parameters typical of incinerators.

**Table 34.6 Representative Incinerator Performance**

	type of incinerator/use				
	rotary kiln	liquid injection	soil incinerators		
			hazardous	nonhazardous	
<b>waste heating value</b>					
(Btu/lbm)	15,000	20,000	0	0	
(MJ/kg)	35	46	0	0	
<b>kiln temp</b>					
(°F)	1700	—	1650	850	
(°C)	925	—	900	450	
<b>SCC temp</b>					
(°F)	1800–2200	2000–2200	1800	1400	
(°C)	980–1200	1100–1200	980	750	
<b>SCC mean residence time (sec)</b>					
O <sub>2</sub> in stack gas (%)	2	2	2	1	
	10%	12%	9%	6%	

<sup>19</sup>Some of the metallic pollutants treated this way include antimony, arsenic, barium, beryllium, cadmium, chromium, lead, mercury, silver, and thallium.

**Example 34.2**

If no additional fuel is added to the incinerator, what is the mass (in lbm/hr) of water required to spray-quench combustion gases from the incineration of hazardous waste with a heating rate of 50 MBtu/hr?

*Solution*

Use the rules of thumb. Assume 100% excess air is required. The total dry air required is

$$m_a = \frac{(2)(50 \times 10^6 \frac{\text{Btu}}{\text{hr}})(725 \text{ lbm})}{10^6 \frac{\text{Btu}}{\text{hr}}} \\ = 72,500 \text{ lbm/hr [dry]}$$

Since the quenched combustion gas is 40% water by weight, it is 60% dry air by weight. The total mass of wet combustion gas produced per hour is

$$m_t = \frac{m_a}{x_a} = \frac{72,500 \frac{\text{lbm}}{\text{hr}}}{0.6} \\ = 1.21 \times 10^5 \text{ lbm/hr}$$

The required mass of quenching water is

$$m_w = x_w m_t = (0.4)(1.21 \times 10^5 \frac{\text{lbm}}{\text{hr}}) \\ = 4.84 \times 10^4 \text{ lbm/hr}$$

**24. INCINERATION, HAZARDOUS WASTES**

Most hazardous waste incinerators use rotary kilns. Waste in solid and paste form enters a rotating drum where it is burned at 1850°F to 2200°F (1000°C to 1200°C). (See Table 34.6 for other representative performance characteristics.) Slag is removed at the bottom, and toxic gases exit to a tall, vortex secondary combustion chamber (SCC). Gases remain in the SCC for 2 sec to 4 sec where they are completely burned at approximately 1850°F (1000°C). Liquid wastes are introduced into and destroyed by the SCC as well. Heat from off-gases may be recovered in a boiler. Typical flue gas cleaning processes include electrostatic precipitation, two-stage scrubbing, and NOx removal.

Common problems with hazardous waste incinerators include (1) inadequate combustion efficiency (easily caused by air leakage in the drum and uneven fuel loading) resulting in incomplete combustion of the primary organic hazardous component (POHC), emission of CO, NOx, and *products of incomplete combustion* (also known as *partially incinerated compounds* or PICs) and metals, (2) meeting low dioxin limits, and (3) minimizing the toxicity of slag and fly ash.

These problems are addressed by (1) reducing air leaks in the drum and (2) introducing air to the SCC through multiple sets of ports at specific levels. Gas is burned in

the SCC in substoichiometric conditions, with the vortex ensuring adequate mixing to obtain complete combustion. Dioxin formation can be reduced by eliminating the waste-heat recovery process, since the lower temperatures present near waste-heat boilers are ideal for dioxin formation. Once formed, dioxin is removed by traditional end-of-pipe methods. Figure 34.8 shows a large-scale hazardous waste incinerator.

**25. INCINERATION, INFRARED**

Infrared incineration (II) is effective for reducing dioxins to undetectable levels. The basic II system consists of a waste feed conveyor, an electrical-heated primary chamber, a gas-fired afterburner, and a typical flue gas cleanup (FGC) system (i.e., scrubber, electrostatic precipitator, and/or baghouse). Electrical heating elements heat organic wastes to their combustion temperatures. Off-gas is burned in a secondary combustion chamber (SCC).

**26. INCINERATION, LIQUIDS**

Liquid-injection incinerators can be used for atomizable liquids. Such incinerators have burners that fire directly into a refractory-lined chamber. If the liquid waste contains salts or metals, a downfired liquid-injection incinerator is used with a submerged quench to capture the molten material. A typical flue gas cleanup (FGC) system (i.e., scrubber, electrostatic precipitator, and/or baghouse) completes the system.

Incineration of organic liquid wastes usually requires little external fuel, since the wastes are overautogenous and have good heating values. The heating value is approximately 20,000 Btu/lbm (47 MJ/kg) for solvents and approximately 8000 Btu/lbm to 18,000 Btu/lbm (19 MJ/kg to 42 MJ/kg) for chlorinated compounds.

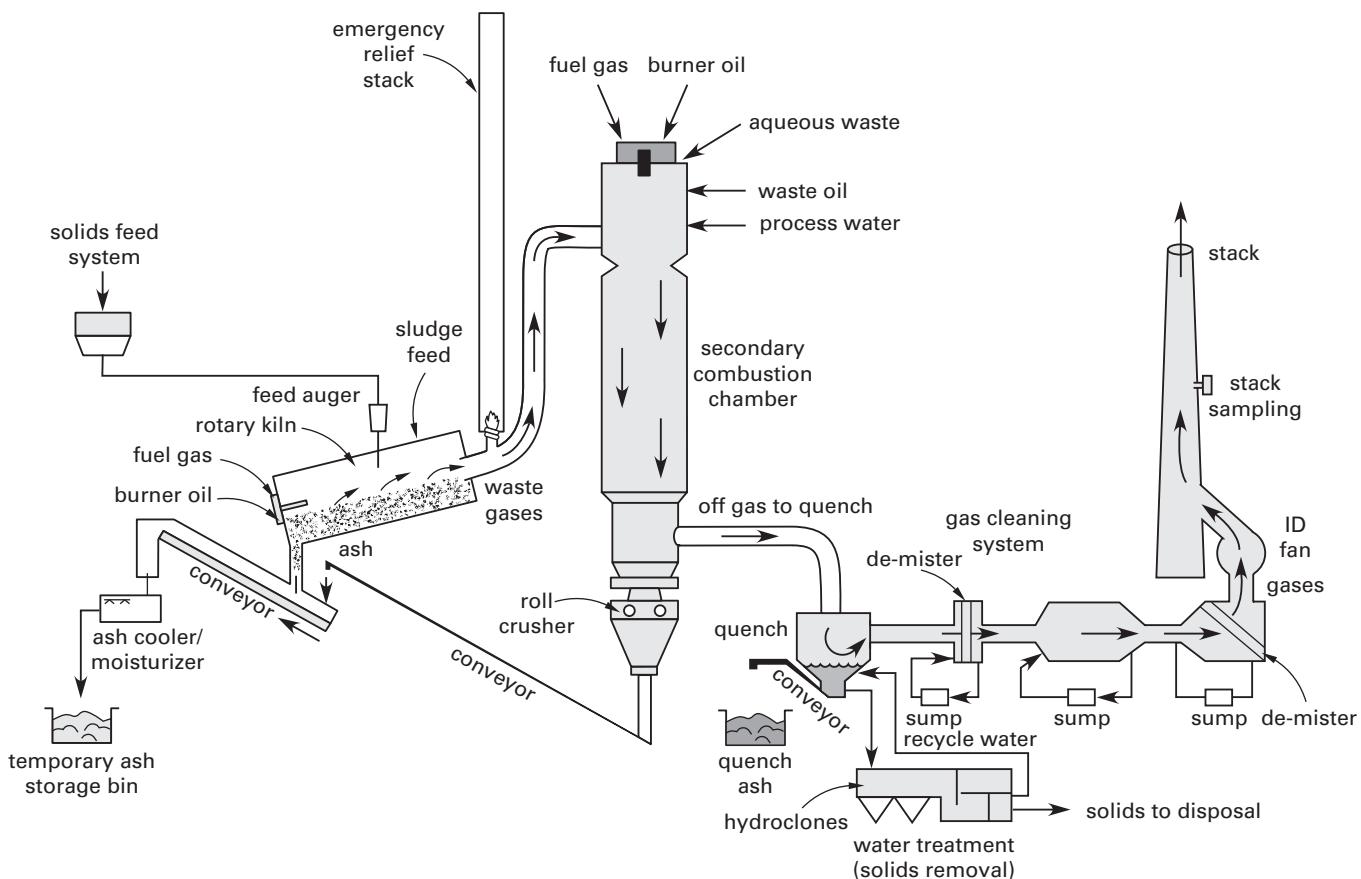

**27. INCINERATION, OXYGEN-ENRICHED**

*Oxygen-enriched incineration* is intended primarily for dioxin removal and is operationally similar to that of a rotary kiln. However, the burner includes oxidant jets. The jets aspirate furnace gases to provide more oxygen for combustion. Apparent advantages are low NOx production and increased incinerator feed rates.

**28. INCINERATION, PLASMA**

A wide variety of solid, liquid, and gaseous wastes can be treated in a *plasma incinerator*. Wastes are heated by an electric arc to higher than 5000°F (2760°C), dissociating them into component atoms. Upon cooling, atoms recombine into hydrogen gas, nitrogen gas, carbon monoxide, hydrochloric acid, and particulate carbon. The ash cools to a nonleachable, vitrified matrix. Off-gases pass through a normal train of cyclone, baghouse, and scrubbing operations. The process has a very high DRE. However, energy requirements are high.

**Figure 34.8** Large-Scale Hazardous Waste Incinerator

## 29. INCINERATION, SOIL

Incineration can completely decontaminate soil. Incinerators are often thought of as being fixed facilities, as are cement kilns and special-use (e.g., Superfund) incinerators. However, mobile incinerators can be brought to sites when the soil quantities are large (e.g., 2000 tons to 100,000 tons (1800 Mg to 90,000 Mg)) and enough setup space is available.<sup>20</sup> (See also Sec. 34.30.)

## 30. INCINERATION, SOLIDS AND SLUDGES

Rotary kilns and fluidized-bed incinerators are commonly used to incinerate solids and sludges. The feed system depends on the waste's physical characteristics. Ram feeders are used for boxed or drummed solids. Bulk solids are fed via chutes or screw feeders. Sludges are fed via lances or by premixing with solids.

The constant rotation of the shell moves wastes through rotary kilns and promotes incineration. External fuel is required in rotary kilns if the heating value of the waste is below 1200 Btu/lbm (2800 kJ/mg) (i.e., is subauto-  
genous). Additional fuel is required in the secondary chamber, as well.

<sup>20</sup>Modified asphalt batch processing plants can be used to incinerate soils contaminated with low-heating value, nonchlorinated hydrocarbons.

Fluidized-bed incinerators work best when the waste is consistent in size and texture. An important benefit is the ability to introduce limestone and other solid reagents to the bed in order to remove HCl and SO<sub>2</sub>.

## 31. INCINERATION, VAPORS

Vapor incinerators, also known as *afterburners* and *flares*, convert combustible materials (gases, vapors, and particulate matter) in the stack gas to carbon dioxide and water. Afterburners can be either direct-flame or catalytic in operation.

## 32. LOW EXCESS-AIR BURNERS

NO<sub>x</sub> formation in gas-fired boilers can be reduced by maintaining excess air below 5%.<sup>21</sup> Low excess-air burners use a forced-draft and self-recirculating combustion chamber configuration to approximate multistaged combustion.

## 33. LOW-NOX BURNERS

Low (or ultra-low) NO<sub>x</sub> burners (LNB) in gas-fired applications use a combination of staged-fuel burning

<sup>21</sup>Reducing excess air from 30% to 10%, for example, can reduce NO<sub>x</sub> emissions by 30%.

and internal flue gas recirculation (FGR). Recirculation within a burner is induced by either the pressure of the fuel gas or other agents (e.g., medium-pressure steam or compressed air).

### 34. MECHANICAL SEALS

*Fugitive emissions* from pumps and other rotating equipment can be reduced or eliminated using current technology by the proper selection and installation of mechanical seals. The three major classes of mechanical seals are single seals, tandem seals (dual seals placed next to each other), and double seals (dual seals mounted back to back or face to face).

The most economical and reliable sealing device is a *single seal*. It has a minimum number of parts and requires no support devices. However, since the pumped product is usually the lubricant for the seal face, small amounts of the product escape into the environment. Emissions are generally below 1000 ppmv, and are often below 100 ppmv.

*Tandem seals* consist of two seal assemblies separated by a buffer fluid at a pressure lower than the seal-chamber liquid. The primary inner seal operates at full pump pressure. The outer seal operates in the buffer fluid. Tandem seals can achieve zero emissions when used with a vapor recovery system, provided that the pumped product's specific gravity is less than that of the buffer fluid and the product is immiscible with the buffer fluid.

If the buffer fluid used in a tandem dual seal is a controlled substance, emissions from the outer seal must also meet the emission limits. Seals using glycol as the buffer fluid typically achieve zero emissions. Seals using diesel oil or kerosene have emissions in the 25 ppmv to 100 ppmv range.

*Double seals* are recommended for hazardous fluids with specific gravities less than 0.4 and are a good choice when a vapor recovery system is not available. (Liquids with low specific gravities do not lubricate the seal well.) Double seals consist of two seal assemblies connected by a common collar; they operate with a barrier fluid kept at a pressure higher than that of the pumped product. Double seals can reduce the emission rate to zero.

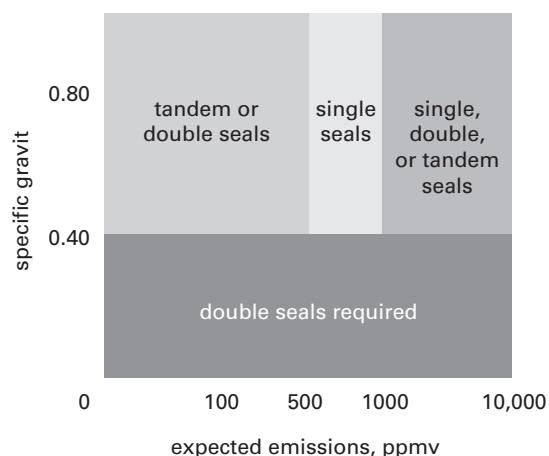

Figure 34.9 shows the relationship between typical emissions and specific gravity for the different seal types.

### 35. MULTIPLE PIPE CONTAINMENT

The U.S. Environmental Protection Agency (EPA) requires *multiple pipe containment* (MPC) in the storage and transmission of hazardous fluids.<sup>22</sup> MPC systems consist of a carrier pipe or bundle of pipes, a

<sup>22</sup>In addition to multiple pipe containment, other factors that contribute to reduction of fugitive emissions are (1) the use of tongue-in-groove flanges, and (2) the reduction of as many nozzles as possible from storage tanks and reactor vessels.

**Figure 34.9** Representative Emissions to Atmosphere for Mechanical Seals\* (1 cm from source)

\*maximum seal size, 6 in (153 mm); maximum pressure, 600 psig (40 bar); maximum speed, 3600 rpm.

common casing, and a leak detector consisting of redundant instrumentation with automatic shutdown features. Casings are generally not pressurized. If one of the pipes within the bundle develops a leak, the fluid will remain in the casing and the detector will signal an alarm and automatically shut off the liquid flow.

Some of the many factors that go into the design of an MPC system are (1) the number of pipes to be grouped together; (2) the weight and strength of the pipes, carrier, and supports; (3) the compatibility of pipe materials and fluids; (4) differential expansion of the container and carrier pipes; and (5) a method of leak detection.

Carrier pipes within the casing should be supported and separated from each other by internal supports (i.e., perforated baffles within the casing). Carrier pipes pass through oval-shaped holes in the internal supports. Holes are oval and oversized to allow flexing of the carrier pipes due to expansion. Other holes through the internal supports allow venting and draining of the casing in the event of a leak. If multiple detectors are used, isolation baffles can be included to separate the casing into smaller sections.

When a pipe bundle changes elevation as well as direction, the carrier pipes may change their positions relative to one another. A pipe on the outside (i.e., at 3 o'clock) may end up being the lower pipe (i.e., at 6 o'clock).<sup>23</sup> This change in relative positioning is known as *rotation*. Rotation complicates the accommodation of pipes that must enter and exit the bundle at specific locations.

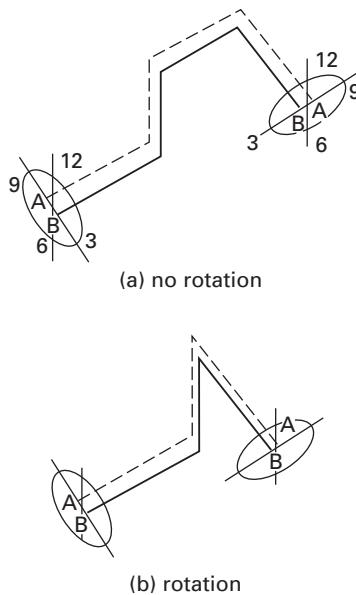

Rotation occurs when a change in direction is located at the top or bottom of an elevation change. Therefore, unless rotation can be tolerated, changes in direction

<sup>23</sup>It is important to consistently "face" the same way (e.g., in the direction of flow).

should not be combined with changes in elevation. In Fig. 34.10(a), pipe A remains to the left of pipe B. In Fig. 34.10(b), pipe A starts out to the left of pipe B and ends up above pipe B.

Another problem associated with MPC systems is expansion of the containment casing and carrier pipes caused by differences in ambient and fluid temperatures and the use of different pipe materials. For pipes containing direct changes, there must be space at each elbow to permit the pipe expansion. If both ends of a pipe are fixed, expansion and contraction will cause the pipes to flex unless Z-bends or loops are included.

**Figure 34.10** Rotation in Pipe Bundles

Differential expansion must be calculated from the largest expected temperature difference using Eq. 34.32.  $\alpha$  is the coefficient of thermal expansion found from Table 34.7.

$$\Delta L = \alpha L \Delta T \quad 34.32$$

Computer programs are commonly used to design pipe networks. These programs are helpful in locating guides and anchors and in performing stress analyses on the final design. Drains, purge points, baffles, and joints are generally chosen by experience.

## 36. OZONATION

*Ozonation* is one of several advanced oxidation methods capable of reducing pollutants from water. Ozone is a powerful oxidant produced by electric discharge through liquid oxygen. Ozone is routinely used in the water treatment industry for disinfection. Table 34.8 shows reactions used for oxidation of several common industrial wastewater pollutants.

**Table 34.7** Approximate Coefficients of Thermal Expansion of Piping Materials (at 70°F (21°C))

pipe material	U.S. (ft/ft·°F)	SI (m/m·°C)
carbon steel	$6.1 \times 10^{-6}$	$1.1 \times 10^{-5}$
chlorinated polyvinyl chloride (CPVC)	$3.8 \times 10^{-5}$	$6.8 \times 10^{-5}$
copper	$9.5 \times 10^{-6}$	$1.7 \times 10^{-5}$
fiberglass-reinforced polyethylene (FRP)	$8.5 \times 10^{-6}$	$1.5 \times 10^{-5}$
Polyethylene (PE)	$8.3 \times 10^{-5}$	$1.5 \times 10^{-4}$
Polyvinyl chloride (PVC)	$3.0 \times 10^{-5}$	$5.4 \times 10^{-5}$
stainless steel	$9.1 \times 10^{-6}$	$1.6 \times 10^{-5}$

## 37. SCRUBBING, GENERAL

Scrubbing is the act of removing particulate matter from a gaseous stream, although substances in gaseous and liquid forms may also be removed.<sup>24</sup>

## 38. SCRUBBING, CHEMICAL

*Chemical scrubbing* using oxidizing compounds such as chlorine, ozone, hypochlorite, or permanganate rapidly destroys volatile organic compounds (VOCs). Efficiencies are typically 95% for highly reactive substances, but are lower for hydrocarbons and substances with low reactivities.

## 39. SCRUBBING, DRY

*Dry scrubbing*, also known as *dry absorption* and *semi-dry scrubbing*, is one form of sorbent injection. It is commonly used to remove SO<sub>2</sub> from flue gas. In operation, flue gases pass through a scrubbing chamber where

<sup>24</sup>As it relates to air pollution control, the term *scrubbing* is loosely used. The term may be used in reference to any process that removes any substance from flue gas. In particular, any process that removes SO<sub>2</sub> by passing flue gas through lime or limestone is referred to as *scrubbing*.

a slurry of lime and water is sprayed through them.<sup>25</sup> The slurry is produced by high-speed rotary atomizers. The sorbent (a reagent such as lime, limestone, hydrated lime, sodium bicarbonate, or trona, also called sodium sesquicarbonate) is injected into the flue gas in either dry or slurry form. The flue gas heat drives off the water. In either case, a dry powder is carried through the flue gas system. An electrostatic precipitator or baghouse captures the fly ash and calcium sulfate particulates.

Dry scrubbers do not saturate the gas stream, even when some moisture is used as a carrier. The moisture that is added is evaporated and does not condense, so unlike wet scrubbers, there is no visible moisture plume.

Dry scrubbing has an SO<sub>2</sub> removal efficiency of approximately 50% to 75%, with some installations reporting 90% efficiencies. NOx removal is not usually intended and is essentially zero. Though the removal efficiency is lower than with wet scrubbing, an advantage of dry scrubbing is that the waste is dry, requiring no sludge-handling equipment. The lower efficiency may be sufficient in older power plants with less stringent regulations. (See also Sec. 34.44.)

Particulate removal efficiencies of 90% can be achieved. Since wet scrubbers normally have a lower particulate removal efficiency than baghouses, they are usually combined with electrostatic precipitators.

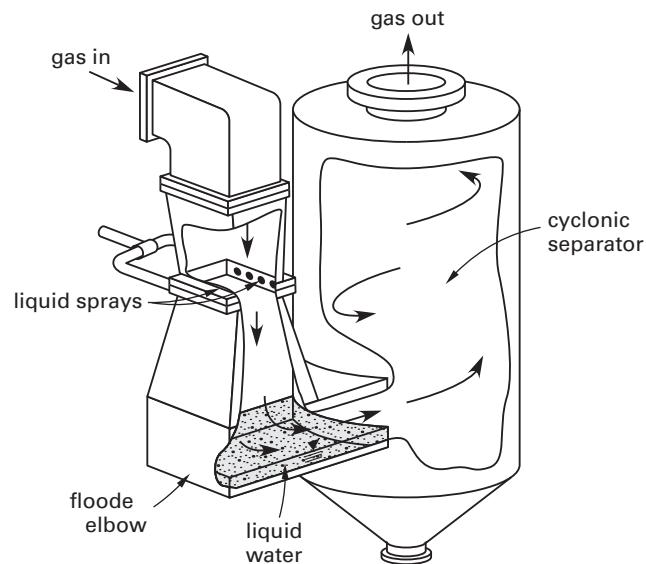

#### 40. SCRUBBING, VENTURI

*Venturi scrubbers* (also known as *atomizing scrubbers*) are effective with particle sizes greater than 0.2 μm. In a fixed-throat venturi scrubber, the gas stream enters a converging section and is accelerated toward the throat. In the throat section, the high velocity gas stream strikes liquid streams that are injected at right angles to the gas flow, shattering the liquid into small droplets. The particles impact the slower moving high-mass droplets and are collected in the droplets. Some particles are also collected in the diverging section where the gas stream slows and the droplets agglomerate. The droplet-entrained particles are collected in the flooded elbow and cyclonic separator. (See Fig. 34.11.)

The pressure drop between the entrance of the converging section and the exit of the diverging section is proportional to the square of the gas velocity at the throat.  $Q_w/Q_g$  is known as the *liquid-gas ratio*,  $L/G$ . Typical operating ranges are:  $\Delta p$ , less than 60 in wg maximum, 5–25 in wg typical (less than 15 kPa maximum, 1.2–6.2

<sup>25</sup>Limestone, sodium carbonate, and magnesium oxide can also be used instead of lime. Because they cost less, lime and limestone are the most common.

Figure 34.11 Wet Venturi Scrubber

typical);  $v_{g,\text{throat}}$ , 18–45 ft/sec (60–150 m/s);  $Q_w/Q_g$ , 10–30 gal/1000 ACFM (80–240 L·h/1000 m<sup>3</sup>). The high pressure drop results in a high operating cost.

$$\Delta p \propto \frac{Q_w v_{g,\text{throat}}^2}{Q_g} \quad 34.33$$

The gas is considered incompressible and in a saturated condition at the throat. The throat velocity can be calculated from basic principles.

$$v_{g,\text{throat}} = \frac{Q_{\text{sat}}}{A_{\text{throat}}} = K_{\text{Calvert}} \sqrt{\frac{\Delta p}{\rho_{\text{sat}}}} \quad 34.34$$

$$A_{\text{throat}} = \frac{A_{\text{inlet}} v_{g,\text{inlet}}}{v_{g,\text{throat}}} \quad 34.35$$

$$\begin{aligned} \rho_{\text{sat}} &= \rho_{\text{dry air}} + \rho_w = \frac{p_{\text{air}}}{R_{\text{air}} T} + \frac{p_w}{R_w T} \\ &= \rho_{\text{dry air}} \left( \frac{1+x}{1+1.609x} \right) \end{aligned} \quad 34.36$$

For  $v$  in ft/sec,  $\Delta p$  in in wg, and  $\rho$  in lbm/ft<sup>3</sup>, *Calvert's constant* is

$$K_{\text{Calvert}} = \sqrt{\frac{1850}{\frac{L}{G}}} \quad 34.37$$

The derivation of an explicit equation for venturi scrubber efficiency is dependent on the assumptions made about the extent of liquid atomization, droplet sizes, acceleration and velocity of the droplets, coefficient of drag, and location of impaction. Accordingly, there are numerous models of varying complexities, none of which are generically applicable or particularly accurate. For example, the common *Calvert model* assumes an

infinitely long throat section where all droplets travel at the throat velocity. The Calvert model incorporates an *impaction parameter*,  $K_{\text{impaction}}$ , defined as the ratio of particle stopping distance,  $s_{p,\text{stopping}}$ , to droplet diameter,  $d_d$ . The predicted efficiency is

$$\eta = \left( \frac{K_{\text{impaction}}}{K_{\text{impaction}} + 0.35} \right)^2 \quad 34.38$$

$$K_{\text{impaction}} = \frac{s_{p,\text{stopping}}}{d_d} = \frac{C_c \rho_s d_p^2 |v_g - v_d|}{18 \mu_g g_c d_d} \quad 34.39$$

Equation 34.40 is a generic equation for calculating collection efficiency for many collection system types, including scrubbers.  $K'$  is based on observation and is unique to the characteristics of the process and equipment. It is determined from pilot tests or actual performance measurements.  $L$  is a characteristic length, such as the height of a tower or length or width of a chamber, and may or may not be incorporated into  $K'$ .

$$\eta = 1 - \exp\left(\frac{K' L}{d_p}\right) \quad 34.40$$

Collection efficiency may be expressed in terms of penetration. *Penetration*,  $Pt$ , is the fraction of particles that pass through the scrubber uncollected. Penetration is the complement of collection efficiency.

$$Pt = 1 - \eta \quad 34.41$$

In order to compare relative (not absolute) changes in collection operations, penetration can be expressed in terms of the *number of transfer units*, NTU.

$$\text{NTU} = -\ln(Pt) \quad 34.42$$

## 41. SELECTIVE CATALYTIC REDUCTION

*Selective catalytic reduction* (SCR) uses ammonia in combination with a catalyst to reduce nitrogen oxides (NOx) to nitrogen gas and water.<sup>26</sup> Vaporized ammonia is injected into the flue gas; the mixture passes through a catalytic reaction bed approximately 0.5 sec to 1.0 sec later. The reaction bed can be constructed from honeycomb plates or parallel-ridged plates. Alternatively, the reaction bed may consist of a packed bed of rings, pellets, or other shapes. The catalyst lowers the NOx decomposition activation energy. NOx and NH<sub>3</sub> combine on the catalyst's surface, producing nitrogen and water.

One mole of ammonia is required for every mole of NOx removed. However, in order to maximize the reduction efficiency, approximately 5 ppm to 10 ppm

<sup>26</sup>Vanadium oxide, titanium, and platinum are metallic catalysts; zeolites and ceramic catalysts are also used.

of unreacted ammonia is left behind.<sup>27</sup> The chemical reaction is

The optimum temperature for SCR is 600°F to 700°F (315°C to 370°C). Gas velocities are typically around 20 ft/sec (6 m/s). The pressure drop is 3 in wg to 4 in wg (0.75 kPa to 1 kPa). NOx removal efficiency is typically 90% but can range from 70% to 95% depending on the application.<sup>28</sup> SCR produces no liquid waste.

Several conditions can cause deactivation of the catalyst. *Poisoning* occurs when trace quantities of specific materials (e.g., arsenic, lead, phosphorous, other heavy metals, silicon, and sulfur from SO<sub>2</sub>) react with the catalyst and lower its activity. Poisoning by SO<sub>2</sub> can be reduced by keeping the flue gas temperature above 608°F (320°C) and/or using poison-resisting compounds. *Masking* (or *plugging*) occurs when the catalytic surface becomes covered with fine particle dust, unburned solids, or ammonium salts. Internal cleaning devices remove surface contaminants such as ash deposits and are used to increase the activity of the equipment.

## 42. SELECTIVE NONCATALYTIC REDUCTION

*Selective noncatalytic reduction* (SNCR) involves injecting ammonia or urea into the upper parts of the combustion chamber (or into a thermally favorable location downstream of the combustion chamber) to reduce NOx.<sup>29</sup> SNCR is effective when the oxygen content is low (e.g., 1%) and the combustion temperature is controlled. If the temperature is too high, the NH<sub>3</sub> will react more with oxygen than with NOx, forming even more NOx. If the temperature is too low, the reactions slow and unreacted ammonia enters the flue gas. The optimal temperature range is 1600°F to 1750°F (870°C to 950°C) for NH<sub>3</sub> injection and up to 1900°F (1040°C) for urea. (In general, the temperature ranges for NH<sub>3</sub> and urea are similar. However, various hydrocarbon

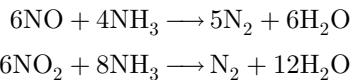

<sup>27</sup>Leftover ammonia in the flue gas is referred to as *ammonia slip* and is usually measured in ppm. 50 ppm to 100 ppm would be considered an excessive ammonia slip. Since NOx and NH<sub>3</sub> react on a 1:1 molar basis, slip is easily calculated. In the following equations, the units can be either molar or volumetric (ppmvd, lbm/hr, mol/hr, scfm, etc.), but they must be consistent.

$$\begin{aligned} \text{NH}_{3,\text{slip}} &= \text{NH}_{3,\text{feed}} - \text{NH}_{3,\text{reacted}} \\ &= \text{NH}_{3,\text{feed}} - (\text{NOx}_{\text{in}} - \text{NOx}_{\text{out}}) \\ &= \text{NH}_{3,\text{feed}} - (\text{NOx}_{\text{in}})(\text{removal efficiency}) \end{aligned}$$

<sup>28</sup>Removal efficiencies of 95% to 99% are possible when SCR is used for VOC removal.

<sup>29</sup>Urea, which decomposes to NH<sub>3</sub> and carbon dioxide inside the combustion chamber, is safer and easier to handle.

additives can be used with urea to lower the temperature range.) The reactions are

The NOx reduction efficiency is approximately 20% to 50% with an ammonia slip of 20 ppm to 30 ppm. The actual efficiency is highly dependent on the injection geometries and interrelations between ammonia slip, ash, and sulfur.

Since the NOx reduction efficiency is relatively low, the SNCR process cannot usually satisfy NOx regulations by itself. The use of urea must be balanced against the potential for ammonia slip and the conversion of NO to nitrous oxide. These and other problems relating to formation of ammonium salts have kept SNCR from gaining widespread popularity in small installations.

### 43. SOIL WASHING

*Soil washing* is effective in removing heavy metals, wood preserving wastes (PAHs), and BTEX compounds from contaminated soil. Soil washing is a two-step process. In the first step, soil is mixed with water to dissolve the contaminants. Additives are used as required to improve solubility. In the second step, additional water is used to flush the soil and to separate the fine soil from coarser particles. (Semi-volatile materials concentrate in the fines.) Metals are extracted by adding chelating agents to the wash water.<sup>30</sup> The contaminated wash water is subsequently treated.

### 44. SORBENT INJECTION

*Sorbent injection* (FSI) involves injecting a limestone slurry directly into the upper parts of the combustion chamber (or into a thermally favorable location downstream) to reduce SOx. Heat calcines the limestone into reactive lime. Fast drying prevents wet particles from building up in the duct. Lime particles are captured in a scrubber with or without an electrostatic precipitator (ESP). With only an ESP, the SOx removal efficiency is approximately 50%.

### 45. SPARGING

*Sparging* is the process of using air injection wells to bubble air through groundwater. The air pushes volatile contaminants into the overlying soil above the aquifer where they can be captured by vacuum extraction.

<sup>30</sup>A *chelate* is a ring-like molecular structure formed by unshared electrons of neighboring atoms. A *chelating agent* (*chelant*) is an organic compound in which atoms form bonds with metals in solution. By combining with metal ions, chelates control the damaging effects of trace metal contamination. Ethylenediaminetetraacetic acid (EDTA) types are the leading industrial chelants.

### 46. STAGED COMBUSTION

*Staged combustion* methods are primarily used with gas-fired burners to reduce formation of nitrogen oxides (NOx). Both staged-air burner and staged-fuel burner systems are used. *Staged-air burner systems* reduce NOx production 20% to 35% by admitting the combustion air through primary and secondary paths around each fuel nozzle. The fuel burns partially in the fuel-rich zone. Fuel-borne nitrogen is converted to compounds that are subsequently oxidized to nitrogen gas. Secondary air completes combustion and controls the flame size and shape. Combustion temperature is lowered by recirculation of combustion products within the burner. Staged burners have few disadvantages, the main one being longer flames.

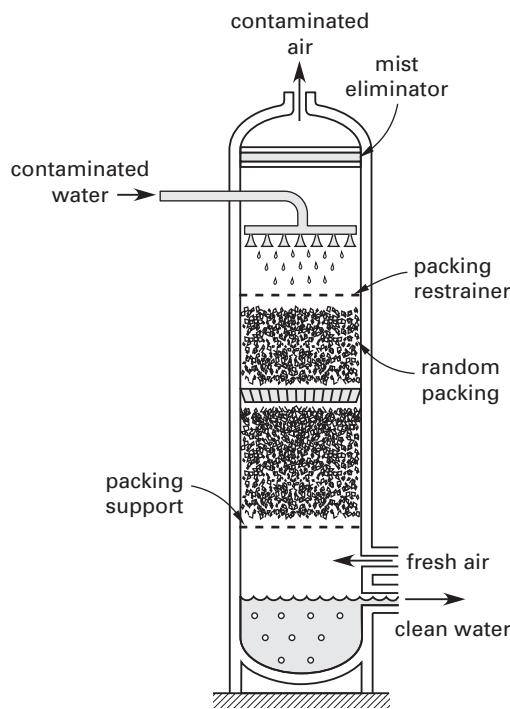

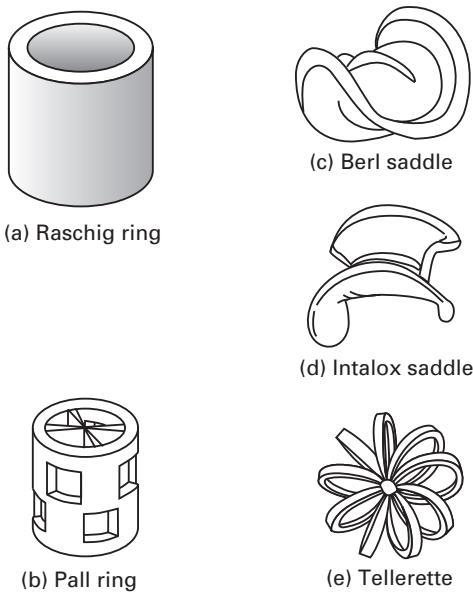

In *staged-fuel burner systems*, a portion of the fuel gas is initially burned in a fuel-lean (air-rich) combustion. The peak flame temperature is reduced, with a corresponding reduction in thermal NOx production. The remainder of the fuel is injected through secondary nozzles. Combustion gases from the first stage dilute the combustion in the second stage, reducing peak temperature and oxygen content. Reductions in NOx formation of 50% to 60% are possible. Flame length is less than with staged-air burners, and the required excess air is lower.

### 47. STRIPPING, AIR

*Air strippers* are primarily used to remove volatile organic compounds (VOCs) or other target substances from water. In operation, contaminated water enters a stripping tower at the top, and fresh air enters at the bottom. The effectiveness of the process depends on the volatility of the compound, its temperature and concentration, and the liquid-air contact area. However, removal efficiencies of 80% to 90% (and above) are common for VOCs. Figure 34.12 shows a typical air stripping operation.

There are three types of stripping towers—*packed towers* filled with synthetic *packing media* (polypropylene balls, rings, saddles, etc.) like those shown in Fig. 34.13, *spray towers*, and (less frequently for VOC removal) *tray towers* with horizontal trays arranged in layers vertically. *Redistribution rings (wall wipers)* prevent channeling down the inside of the tower. (*Channeling* is the flow of liquid through a few narrow paths rather than an over-the-bed packing.) The stripping air is generated by a small blower at the column base. A mist eliminator at the top eliminates entrained water from the air.

As the contaminated water passes over packing media in a packed tower, the target substance leaves the liquid and enters the air where the concentration is lower. The mole fraction of the target substance in the water, *x*, decreases; the mole fraction of the target substance in the air, *y*, increases.

**Figure 34.12** Schematic of Air Stripping Operation**Figure 34.13** Packing Media Types

The discharged air, known as *off-gas*, is discharged to a process that destroys or recovers the target substance. (Since the quantities are small, recovery is rarer.) Destruction of the target substance can be accomplished by flaring, carbon absorption, and incineration. Since flaring is dangerous and carbon absorption creates a secondary waste if the AC is not regenerated, incineration is often preferred.

*Henry's law*, as it applies to water treatment, states that at equilibrium, the vapor pressure of target substance A is directly proportional to the target substance's mole fraction,  $x_A$ . (The maximum mole fraction is the substance's *solubility*.) Table 34.9 lists representative values of Henry's law constant,  $H$ .<sup>31</sup> When multiple compounds are present in the water, the *key component* is the one that is the most difficult to remove (i.e., the component with the highest concentration and lowest Henry's constant).

$$p_A = H_A x_A \quad 34.43$$

**Table 34.9** Typical Henry's Law Constants for Selected Volatile Organic Compounds (at low pressures and 25°C)

VOC	Henry's law constant, $H$ (atm)*
1,1,2,2-tetrachloroethane	24.02
1,1,2-trichloroethane	47.0
propylene dichloride	156.8
methylene chloride	177.4
chloroform	188.5
1,1,1-trichloroethane	273.56
1,2-dichloroethene	295.8
1,1-dichloroethane	303.0
hexachloroethane	547.7
hexachlorobutadiene	572.7
trichloroethylene	651.0
1,1-dichloroethene	834.03
perchloroethane	1596.0
carbon tetrachloride	1679.17

(Multiply atm by 101.3 to obtain kPa.)

\*Henry's law indicates that the units of  $H$  are atmospheres per mole fraction. Mole fraction is dimensionless and does not appear in the units for  $H$ .

The liquid *mass-transfer coefficient*,  $K_L a$ , is the product of the *coefficient of liquid mass transfer*,  $K$ , and the *interfacial area* per volume of packing,  $a$ . The mass transfer coefficient is a measure of the efficiency of the air stripper as a whole. The higher the mass transfer coefficient, the higher the efficiency. The  $K_L a$  value is largely a function of the size and shape of the packing material, and it is usually obtained from the packing manufacturer or theoretical correlations. For some types of packing, the gas-phase resistance is greater than the liquid-phase resistance, and the gas mass-transfer coefficient,  $K_G a$ , may be given.

The *stripping factor*,  $R$  (the reciprocal of the *absorption factor*), is given by Eq. 34.44. Units for the gas and liquid flow rates,  $G$  and  $L$ , depend on the correlations used to solve the stripping equations. The air flow rate is

<sup>31</sup>Henry's law is fairly accurate for most gases when the partial pressure is less than 1 atm. If the partial pressure is greater than 1 atm, Henry's law constants will vary with partial pressure.

limited by the acceptable pressure drop through the tower.

$$R = \frac{HG}{L} \quad 34.44$$

The *transfer unit method* is a convenient way of designing and analyzing the performance of stripping towers. A *transfer unit* is a measure of the difficulty of the mass-transfer operation and depends on the solubility and concentrations. The overall number of transfer units is expressed as NTU<sub>OG</sub> or NTU<sub>OL</sub> (alternatively, N<sub>OG</sub> or N<sub>OL</sub>), depending on whether the gas or liquid resistance dominates.<sup>32</sup> The NTU value depends on the incoming and desired concentrations and the material flow rates.<sup>33</sup>

The *height of the packing*, z, is the effective height of the tower. It is calculated from the NTUs and the *height of a transfer unit*, HTU, using Eq. 34.45. The HTU value depends on the packing media.

$$z = (\text{HTU}_{\text{OG}})(\text{NTU}_{\text{OG}}) = (\text{HTU}_{\text{OL}})(\text{NTU}_{\text{OL}}) \quad 34.45$$

10% of additional height should be added to the theoretical value as a safety factor. Packing heights greater than 30 ft to 40 ft (9.1 m to 12.2 m) are not recommended since the packing might be crushed, and greater heights produce little or no increase in removal efficiency.

The blower power depends on the packing shape and size and the air-to-water ratio. Typical pressure drops are 0.5 in wg to 1.0 in wg per vertical foot (0.38 kPa/m to 0.75 kPa/m) of packing. To minimize the blower power requirement, the ratio of tower diameter to gross packing dimension should be between 8 and 15. Blower fan power increases with increasing air-to-water ratios.

A significant problem for air strippers removing contaminants from water is fouling of the packing media through biological growth and solids (e.g., iron complexes) deposition. Biological growth can be inhibited by continuous or batch use of a *biocide* that does not interfere with the off-gas system.<sup>34</sup> Another problem is *flooding*, which occurs when excess liquid flow rates impede the flow of the air.

<sup>32</sup>The gas film resistance controls when the solubility of the target substance in the liquid is high. Conversely, when the solubility is low, the liquid film resistance controls. In flue gas cleanup (FGC) work, the gas film resistance usually controls.

<sup>33</sup>Stripping is one of many mass-transfer operations studied by chemical engineers. Determining the number of transfer units required and the height of a single transfer unit are typical chemical engineering calculations.

<sup>34</sup>A *biocide* is a chemical that kills living things, particularly microorganisms. Biocide categories include chlorinated isocyanurates (used in swimming pool disinfectants and dishwashing detergents), sodium bromide, inorganics (used in wood treatments), quaternaries ("quats") used in hard-surface cleaners and sanitizers, and iodophors (used in human-skin disinfectants). By comparison, *biostats* do not kill microorganisms already present, but they retard further growth of microorganisms from the moment they are incorporated. Biostats are organic acids and salts (e.g., sodium and potassium benzoate, sorbic acid, and potassium sorbate used "to preserve freshness" in foods).

## 48. STRIPPING, STEAM

*Steam stripping* is more effective than air stripping for removing semi- and non-volatile compounds, such as diesel fuel, oil, and other organic compounds with boiling points up to approximately 400°F (200°C). Operation of a steam stripper is similar to that of an air stripper, except that steam is used in place of the air. Steam strippers can be operated at or below atmospheric pressure. Higher vacuums will remove greater amounts of the compound.

## 49. THERMAL DESORPTION

*Thermal desorption* is primarily used to remove volatile organic compounds (VOCs) from contaminated soil. The soil is heated directly or indirectly to approximately 1000°F (540°C) to evaporate the volatiles. This method differs from incineration in that the released gases are not burned but are captured in a subsequent process step (e.g., activated carbon filtration).

## 50. VACUUM EXTRACTION

*Vacuum extraction* is used to remove many types of volatile organic compounds (VOCs) from soil. The VOCs are pulled from the soil through a well dug in the contaminated area. Air is withdrawn from the well, vacuuming volatile substances with it.

## 51. VAPOR CONDENSING

Some vapors can be removed simply by cooling them to below their dew points. Traditional contact (open) and surface (closed) condensers can be used.

## 52. VITRIFICATION

*Vitrification* melts and forms slag and ash wastes into glass-like pellets. Heavy metals and toxic compounds cannot leach out, and the pellets can be disposed of in hazardous waste landfills. Vitrification can occur in the incineration furnace or in a stand-alone process. Stand-alone vitrification occurs in an electrically heated vessel where the temperature is maintained at 2200°F to 2370°F (1200°C to 1300°C) for up to 20 hr or so. Since the electric heating is nonturbulent, flue gas cleaning systems are not needed.

## 53. WASTEWATER TREATMENT PROCESSES

Many industrial processes use water for cooling, rinsing, or mixing. Such water must be treated prior to being discharged to *publicly owned treatment works* (POTWs).<sup>35</sup> Table 34.10 lists some of the polluting characteristics of industrial wastewaters.

<sup>35</sup>Rainwater runoff from some industrial plants can also be a hazardous waste.

**Table 34.10** Types of Pollution from Industrial Wastewater

ammonia
biochemical oxygen demand (BOD)

whole-effluent toxicity (LC <sub>50</sub> )

Most large-volume industrial wastewaters go through the following processes: (1) flow equalization, (2) neutralization, (3) oil and grease removal, (4) suspended solids removal, (5) metals removal, and (6) VOC removal. These processes are similar, in many cases, to processes with the same names used to treat municipal wastewater in a POTW.

*Flow equalization* reduces the chance of under- and overloading a treatment process. Equalization of both hydraulic and chemical loading is required. *Hydraulic loading* is usually equalized by storing wastewater during high flow periods and discharging it during periods of low flow. *Chemical loading* is equalized by use of an equalization basin with mechanical mixing or air agitation. Mixing with air has the added advantages of oxidizing reducing compounds, stripping away volatiles, and eliminating odors.

There are two reasons for water *neutralization*. First, the pH of water is regulated and must be between 6.0 and 9.0 when discharged. Second, water that is too acidic or alkaline may not be properly processed by subsequent, particularly biological, processes. The optimum pH for biological processes is between 6.5 and 7.5. The effectiveness of the processes is greatly reduced with pHs below 4.0 and above 9.5.

Acidic water is neutralized by adding lime (oxides and hydroxides of calcium and magnesium), limestone, or some other caustic solution. Alkaline waters are treated with sulfuric or hydrochloric acid or carbon dioxide gas.<sup>36</sup> Large volumes of oil and grease float to the surface and are skimmed off. Smaller volumes may require a dissolved-air process. Removing emulsified oil is more complex and may require use of chemical coagulants.

<sup>36</sup>In water, carbon dioxide gas forms *carbonic acid*.

The method used to remove suspended solids depends on the solid size. Most industrial plants do not require strainers, bar screens, or fine screens to remove large solids (i.e., those larger than 1 in (25 mm)). *Grit* (i.e., sand and gravel) is removed in grit chambers by simple sedimentation. Fine solids are categorized into *settleable solids* (diameters more than 1  $\mu\text{m}$ ) and *colloids* (diameters between 0.001  $\mu\text{m}$  and 1  $\mu\text{m}$ ). Settleable solids and colloids are removed in a sedimentation tank, with chemical coagulants or dissolved-air flotation being used to assist colloidal particles in settling out.

Most metal (e.g., lead) removal occurs by precipitating its hydroxide, although precipitation as carbonates or sulfides is also used.<sup>37</sup> A caustic substance (e.g., lime) is added to the water to raise the pH below the solubility limit of the metal ion. When they come out of solution, the metallic compounds are *flocculated* into larger flakes that ultimately settle out. Floc is mechanically removed as inorganic heavy-metal sludge, which has a 96% to 99% water content by weight. The sludge is dewatered in a drying bed, vacuum filter, or filter press to 65% to 85% water. Depending on its composition, the sludge can be landfilled or treated as a hazardous waste by incineration or other methods.

VOCs such as benzene and toluene are removed by air stripping or adsorption in activated charcoal (AC) towers. Nonvolatile organic compounds (NVOCs) are removed by biological processes such as lagooning, trickle filtration, and activated sludge.

Although destruction of biological health hazards is not always needed for industrial wastewater, chemical oxidants are still needed to destroy odors, control bacterial growth downstream, and eliminate sulfur compounds.<sup>38</sup> (See Table 34.1.) Chemical oxidants can also reduce heavy metals (e.g., iron, manganese, silver, and lead) that were not removed in previous operations.

<sup>37</sup>Ion exchange, activated charcoal, and reverse osmosis methods can be used but may be more expensive.

<sup>38</sup>Meat packing and dairy (e.g., cheese) plants are examples of industrial processes that require chlorination to destroy bacteria in wastewater.

**1. SOIL PARTICLE SIZE DISTRIBUTION**

*Soil* is an aggregate of loose mineral and organic particles. *Rock*, on the other hand, exhibits strong and permanent cohesive forces between the mineral particles. From an engineering perspective, the distinction between soil and rock relates to the workability of materials. For example, one practical definition is that soil can be excavated with a backhoe while rock needs to be blasted. The distinction between soil and rock can also be made based on strength, density, and other quantifiable parameters. A geologist or soil scientist might be more interested in how a material has been formed than its workability, and thus might distinguish between soil and rock differently.

**Table 35.1** Classification of Soil Particle Sizes

system	date	sizes (mm)			
		gravel	sand	silt	clay
Bureau of Soils	1890	1–100	0.05–1	0.005–0.05	< 0.005
Atterberg	1905	2–100	0.2–2	0.002–0.2	< 0.002
MIT	1931	2–100	0.06–2	0.002–0.06	< 0.002
USDA	1938	2–100	0.05–2	0.002–0.05	< 0.002
Unified (or USCS)	1953	4.75–75	0.075–4.75	< 0.075	
ASTM	1967	4.75–75	0.075–4.75	< 0.075	
AASHTO	1970	2–75	0.075–2	0.002–0.075	0.001–0.002

(Divide mm by 25.4 to obtain in.)

The primary mineral components of any soil are gravel, sand, silt, and clay. Organic material can also be present in surface samples. Gravel and sand are classified as coarse-grained soils, while inorganic silt and clay are classified as fine-grained soils. Particle size limits for defining gravel, sand, silt, and clay used in different classification schemes are given in Table 35.1.

The particle size distribution for a coarse soil is found from a sieve test. In a *sieve test*, the soil is passed through a set of sieves of consecutively smaller openings. (See Table 35.2.) The particle size distribution for the finer particles of a soil is determined from a *hydrometer test*. This test is based on Stokes' Law, which relates the speed of a particle falling out of suspension to its diameter and solid density. The results of both the sieve and hydrometer tests are graphed as a *particle size distribution*, as shown in Fig. 35.1.

The *Hazen uniformity coefficient*,  $C_u$ , given by Eq. 35.1, indicates the general shape of the particle size distribution. The diameter for which only 10% of the particles are finer is designated as  $D_{10}$  and is known as the *effective grain size*. The diameter for which 60% of the particles are finer is designated as  $D_{60}$ .

$$C_u = \frac{D_{60}}{D_{10}} \quad 35.1$$

If the uniformity coefficient is less than 4 or 5, the soil is considered uniform in particle size, which means that all particle sizes fall within a narrow range. *Well-graded soils* have uniformity coefficients greater than 10 and have a continuous, wide range of particle sizes. *Gap-graded soils* are missing one or more ranges of particle sizes. Table 35.3 gives typical uniformity coefficients, and Fig. 35.2 illustrates uniformity in particle size distributions.

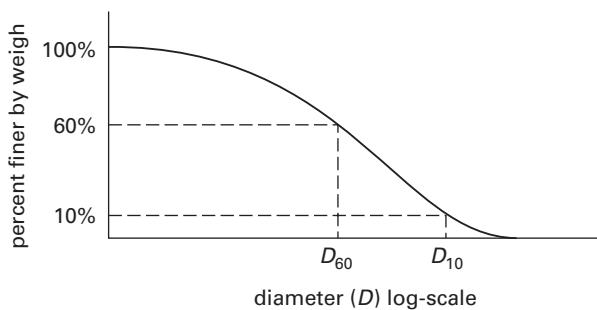

Another index of distribution shape is the *coefficient of curvature* (also known as the *coefficient of gradation*),  $C_z$ , given by Eq. 35.2. The diameter for which 30% of the particles are finer is designated as  $D_{30}$ . Typical shape parameters are listed in Table 35.3.

$$C_z = \frac{D_{30}^2}{D_{10} D_{60}} \quad 35.2$$

**Table 35.2** Sieve Size Designations (nominal)\*

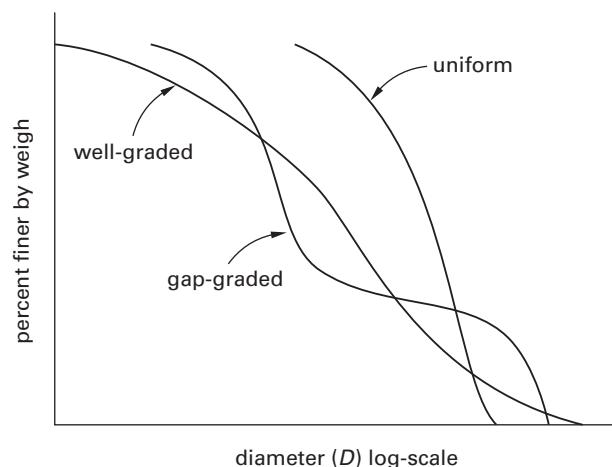

alternative designation	standard designation (mm)

no. 30	0.600
no. 40	0.425
no. 50	0.300
no. 60	0.250
no. 70	0.212
no. 100	0.150
no. 140	0.106
no. 200	0.075

\*Actual opening dimensions specified in ASTM E-11 differ slightly from the nominal designations.

**Figure 35.1** Typical Particle Size Distribution**Table 35.3** Typical Uniformity Coefficients

soil	$C_u$	$C_z$
gravel	>4	1–3
fine sand	5–10	1–3
coarse sand	4–6	—
mixture of silty sand and gravel	15–300	—
mixture of clay, sand, silt, and gravel	25–1000	—

Equation 35.1 and Eq. 35.2, as well as various soil classification schemes, require knowing percentages of soil passing through specific sieve sizes. When sieve data are incomplete, the needed values can be interpolated by plotting known data on a *particle size distribution chart*, such as Fig. 35.3.

**Figure 35.2** Uniformity in Particle Size Distributions

## 2. SOIL CLASSIFICATION

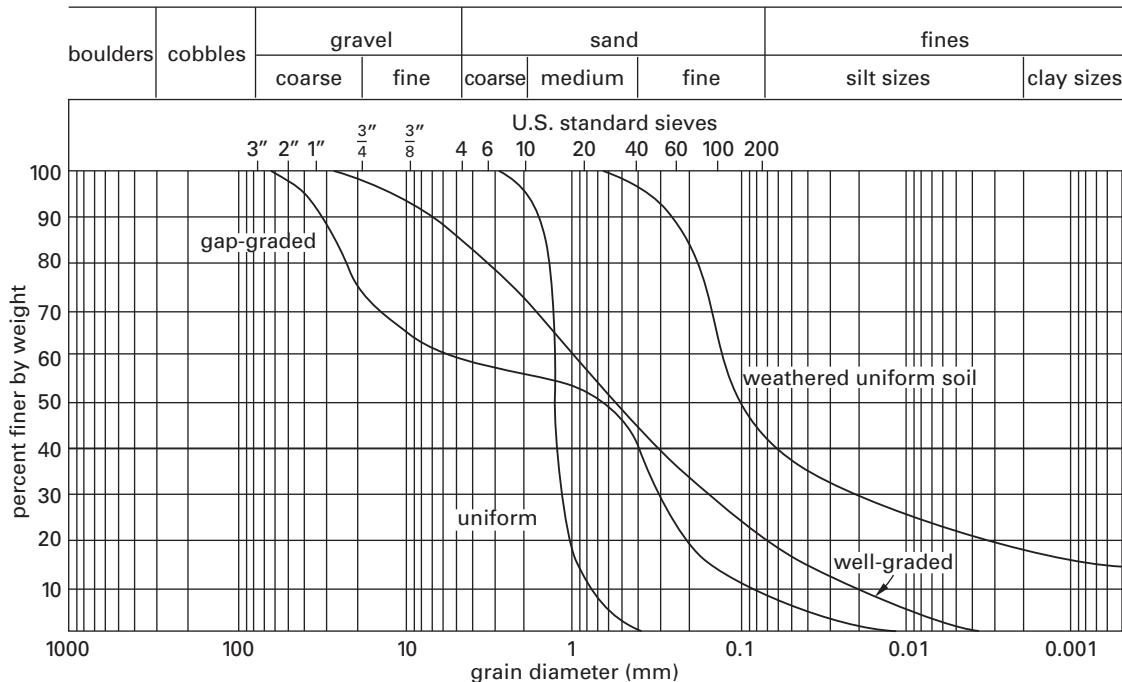

Formal soil classification schemes have been established by a number of organizations. These schemes standardize the way that soils are described and group similar soils by the characteristics that are important in determining behavior. The classification of a soil depends mostly on the percentages of gravel, sand, silt, and clay. Usually it will also depend on special characteristics of the silt and clay fractions.

A distinction is made between silt and clay. What are called *clays* for classification purposes depends on the existence of clay minerals in the *fines fraction* (silt and clay sizes) of the soil, as well as size of the particles. These clay minerals have different compositions and behaviors than silts and coarse-grained soils.

Clays display the characteristic of *plasticity*. For the most part, particles that are clay size are also clay minerals. The plasticity characteristics of the fines fraction of a soil is measured in the laboratory by the *Atterberg limit tests*. (See Sec. 35.14.) The Atterberg limits used most in classification are the liquid limit and plasticity index. In the field, where laboratory tests are not available, clays can be informally distinguished from silts by using the following simple “visual identification” tests.

*Dry strength test:* A small brick of soil is molded and allowed to air dry. The brick is broken and a small ( $\frac{1}{8}$  in or 3 mm) fragment is taken between thumb and finger. A silt fragment will break easily, whereas clay will not.

*Dilatancy test:* A small sample is mixed with water to form a thick slurry. When the sample is squeezed, water will flow back into a silty sample quickly. The return rate will be much lower for clay.

**Figure 35.3** Particle Size Distribution Chart

**Plasticity test:** A moist soil sample is rolled into a thin ( $\frac{1}{8}$  in or 3 mm) thread. As the thread dries, silt will be weak and friable, but clay will be tough.

**Dispersion test:** A sample of soil is dispersed in water. The time for the particles to settle is measured. Sand settles in 30–60 sec. Silt settles in 15–60 min, and clay remains in suspension for a long time.

**Organic matter** can also be present in soil. Generally, the greater the organic content, the darker the soil color. Organic matter can have a significant effect (usually negative) on the mechanical properties of the soil.

### 3. AASHTO SOIL CLASSIFICATION

The American Association of State Highway Transportation Officials' (AASHTO) classification system is based on the sieve analysis, liquid limit, and plasticity index. The best soils suitable for use as roadway subgrades are classified as A-1. Highly organic soils not suitable for roadway subgrades are classified as A-8. Soils can also be classified into subgroups. The AASHTO classification methodology is given in Table 35.4.

The *group index*, given by Eq. 35.3, may be added to the group classification. The group index is a means of comparing soils within a group, not between groups. A soil with a group index of zero is a good subgrade material within its particular group. Group indexes of 20 or higher represent poor subgrade materials. The

group index,  $I_g$ , is reported to the nearest whole number but is reported as zero if it is calculated to be negative. (The liquid limit, LL, and plasticity index, PI, are discussed in Sec. 35.14.)

$$I_g = (F_{200} - 35)(0.2 + 0.005(LL - 40)) \\ + 0.01(F_{200} - 15)(PI - 10) \quad 35.3$$

$F_{200}$  in Eq. 35.3 is the percentage of soil that passes through a no. 200 sieve. Both the quantities  $LL - 40$  and  $PI - 10$  may be negative. For the A-2-6 and A-2-7 subgroups, only the second term in Eq. 35.3 is used in calculating the group index.

### 4. UNIFIED SOIL CLASSIFICATION

The *Unified Soil Classification System* (USCS) is described in Table 35.5. Like the AASHTO system, it is based on the grain size distribution, liquid limit, and plasticity index of the soil.

Soils are classified into USCS groups that are designated by a group symbol and a corresponding group name. The symbols each contain two letters: The first represents the most significant particle size fraction, and the second is a descriptive modifier. Some categories require dual symbols.

**Table 35.4** AASHTO Soil Classification System\*

	granular materials (35% or less passing no. 200 sieve)								silt-clay materials (more than 35% passing no. 200 sieve)				
	A-1		A-3	A-2				A-4	A-5	A-6	A-7	A-8	
	A-1-a	A-1-b		A-2-4	A-2-5	A-2-6	A-2-7						
sieve analysis: % passing no. 10 no. 40 no. 200	50 max 30 max 15 max	50 max 25 max	51 min 10 max	35 max 35 max	35 max 35 max	35 max 35 max	36 min	36 min	36 min	36 min	36 min		
characteristics of fraction passing no. 40: LL: liquid limit PI: plasticity index	6 max	NP	40 max 10 max	41 min 10 max	40 max 11 min	41 min 11 min	40 max 10 max	41 min 10 max	40 max 11 min	41 min 11 min			
usual types of significant constituents	stone fragments gravel and sand	fine sand	silty or clayey gravel and sand				silty soils		clayey soils		peat, highly organic soils		
general subgrade rating	excellent to good				fair to poor				unsatisfactory				

\*Classification procedure: Using the test data, proceed from left to right in the chart. The correct group will be found by process of elimination. The first group from the left consistent with the test data is the correct classification. The A-7 group is subdivided into A-7-5 or A-7-6, depending on the plastic limit. For plastic limit PL = LL - PI less than 30, the classification is A-7-6. For plastic limit PL = LL - PI greater than or equal to 30, it is A-7-5. NP means nonplastic.

Coarse-grained soils are divided into two categories: gravel soils (symbol G) and sand soils (symbol S). Sands and gravels are further subdivided into four subcategories as follows.

- symbol W: well-graded, fairly clean
- symbol C: significant amounts of clay
- symbol P: poorly graded, fairly clean
- symbol M: significant amounts of silt

Fine-grained soils are divided into three categories: inorganic silts (symbol M), inorganic clays (symbol C), and organic silts and clays (symbol O).<sup>2</sup> These three are subdivided into two subcategories as follows.

- symbol L: low compressibilities (LL less than 50)
- symbol H: high compressibilities (LL 50 or greater)

### Example 35.1

Determine the classification of an inorganic soil with the characteristics listed using (a) the AASHTO and (b) the USCS classification systems.

soil size (mm)	fraction retained on sieve	
<0.002	0.19	LL = 53
0.002–0.005	0.12	PL = 22
0.005–0.05	0.36	
0.05–0.075	0.04	$F_{200} = (1 - 0.29)(100)$
0.075–2.0	0.29	= 71
>2.0	0	

### Solution

The plasticity index is given by Eq. 35.23.

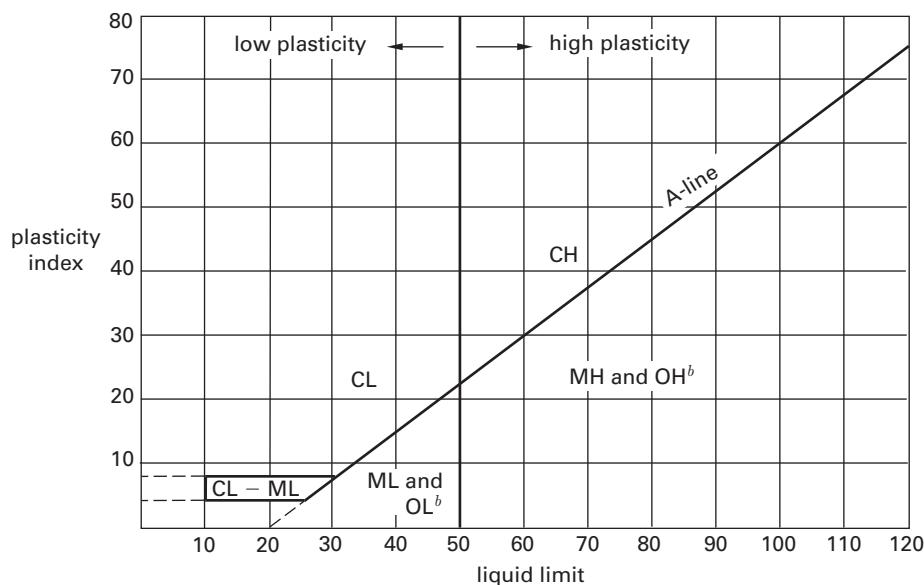

$$PI = LL - PL = 53 - 22 = 31$$

- (a) From Table 35.2, the no. 200 sieve has an opening of 0.075 mm.  $F_{200}$  is 71, so from Table 35.4, the soil is first classified as a silt-clay material (more than 35% passing a no. 200 sieve). For a liquid limit of 53 and a plasticity index of 31, the classification is A-7-5 or A-7-6. Since the

<sup>2</sup>The symbol M comes from the Swedish *mjala* (meaning silt) and *mo* (meaning very fine sand).

**Table 35.5** Unified Soil Classification System

major division		group symbol	laboratory classification criteria		soil description
			finer than 200 sieve (%)	supplementary requirements	
coarse-grained (over 50% by weight coarser than no. 200 sieve)	gravelly soils (over half of coarse fraction larger than no. 4)	GW	0–5 <sup>a</sup>	$D_{60}/D_{10}$ greater than 4 $D_{30}^2/(D_{60}D_{10})$ between 1 and 3	well-graded gravels, sandy gravels
		GP	0–5 <sup>a</sup>	not meeting above gradation for GW	gap-graded or uniform gravels, sandy gravels
		GM	12 or more <sup>a</sup>	PI less than 4 or below A-line	silty gravels, silty sandy gravels
		GC	12 or more <sup>a</sup>	PI over 7 and above A-line	clayey gravels, clayey sandy gravels
	sandy soils (over half of coarse fraction finer than no. 4)	SW	0–5 <sup>a</sup>	$D_{60}/D_{10}$ greater than 6 $D_{30}^2/(D_{60}D_{10})$ between 1 and 3	well-graded, gravelly sands
		SP	0–5 <sup>a</sup>	not meeting above gradation requirements	gap-graded or uniform sands, gravelly sands
		SM	12 or more <sup>a</sup>	PI less than 4 or below A-line	silty sand
		SC	12 or more <sup>a</sup>	PI over 7 and above A-line	clayey sands, clayey gravelly sands
fine-grained (over 50% by weight finer than no. 200 sieve)	low compressibility (liquid limit less than 50)	ML	plasticity chart		
		CL	plasticity chart		
		OL	plasticity chart, organic odor or color		
	high compressibility (liquid limit 50 or more)	MH	plasticity chart		
		CH	plasticity chart		
		OH	plasticity chart, organic odor or color		
soils with fibrous organic matter	Pt	fibrous organic matter; will char, burn, or glow			peat, sandy peats, and clayey peat

Note: Plasticity chart for the classification of fine-grained soils. Tests made on fraction finer than no. 40 sieve, 0.425 mm

<sup>a</sup>For soils having 5–12% passing the no. 200 sieve, use a dual symbol such as GW-GC.

<sup>b</sup>Distinguishing between M and O classifications requires identifying organic components by observation, odor, or other testing.

plastic limit is 22 (less than 30), the classification is A-7-6. From Eq. 35.3, the group index is

$$\begin{aligned} I_g &= (F_{200} - 35)(0.2 + 0.005(LL - 40)) \\ &\quad + 0.01(F_{200} - 15)(PI - 10) \\ &= (71 - 35)(0.2 + (0.005)(53 - 40)) \\ &\quad + (0.01)(71 - 15)(31 - 10) \\ &= 21.3 \end{aligned}$$

Round 21.3 to the nearest whole number. The soil classification is A-7-6 (21).

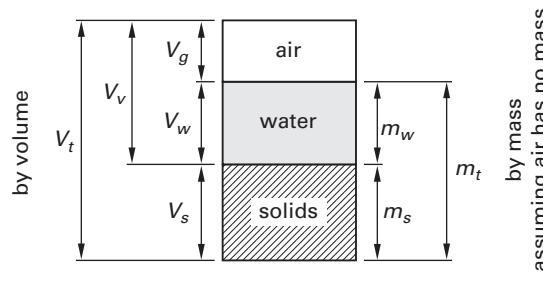

(b) From Table 35.5, the soil is first classified as a fine-grained soil (more than 50% passing the no. 200 sieve). The liquid limit is greater than 50 (LL = 53).

Since the soil plots above the A-line, it is classified as CH: a highly plastic clay.

## 5. MASS-VOLUME RELATIONSHIPS

Soil consists of solid soil particles separated by voids. The voids can be filled with either air or water. Thus, soil is a three-phase material (solids, water, and air), as shown in Fig. 35.4. The percentages by volume, mass, and weight of these three constituents are used to calculate the aggregate properties.

**Figure 35.4** Soil Phases

The *porosity*,  $n$ , is the ratio of the volume of voids to the total volume.

$$n = \frac{V_v}{V_t} = \frac{V_g + V_w}{V_g + V_w + V_s} \quad 35.4$$

The *void ratio*,  $e$ , is the ratio of the volume of voids to the volume of solids.

$$e = \frac{V_v}{V_s} = \frac{V_g + V_w}{V_s} \quad 35.5$$

The *moisture content (water content)*,  $w$ , is the ratio of the mass of water to the mass of solids, usually expressed in percent.<sup>3</sup>

$$w = \frac{m_w}{m_s} \times 100\% \quad 35.6$$

The *degree of saturation*,  $S$ , is the percentage of the volume of water to the total volume of voids. This indicates how much of the void space is filled with water. If all the voids are filled with water, then the volume of air is zero and the sample's degree of saturation is 100%. The sample is said to be fully saturated.

$$\begin{aligned} S &= \frac{V_w}{V_v} \times 100\% \\ &= \frac{V_w}{V_g + V_w} \times 100\% \end{aligned} \quad 35.7$$

The *density (also called the total density)*,  $\rho$ , is the ratio of the total mass to the total volume. The total density may be referred to as the *moist density (wet density)* above the water table and as the *saturated density* below the water table.

$$\rho = \frac{m_t}{V_t} = \frac{m_w + m_s}{V_g + V_w + V_s} \quad 35.8$$

In the United States, weight is commonly used in soil calculations instead of mass. The corresponding density is called *unit weight*,  $\gamma$ . Weight is calculated from the formula  $W = mg/g_c$ , where  $g_c$  is the gravitational constant, 32.2 ft-lbm/lbf-sec<sup>2</sup>. In Eq. 35.8 and Eq. 35.10 through Eq. 35.14,  $\gamma$  can be substituted for  $\rho$  whenever convenient.<sup>4</sup>

$$\gamma = \rho g \quad [\text{SI}] \quad 35.9(a)$$

$$\gamma = \frac{\rho g}{g_c} \quad [\text{U.S.}] \quad 35.9(b)$$

The *dry density*,  $\rho_d$ , is the ratio of the solid mass to the total volume.

$$\rho_d = \frac{m_s}{V_t} = \frac{m_s}{V_g + V_w + V_s} \quad 35.10$$

<sup>3</sup>Both water content and saturation are reported as percentages; however, it is easiest to use the decimal form when working problems.

<sup>4</sup>There is no concept of weight in SI units. The choice to work in weight or mass in U.S. units is somewhat arbitrary, because as long as the local gravitational field is essentially standard, the mass in lbm is numerically equal to the weight in lbf.

If the water content is known, the dry density of a moist sample can be found from Eq. 35.11.

$$\rho_d = \frac{m_t}{(1+w)V_t} = \frac{\rho}{1+w} \quad 35.11$$

The *buoyant density (submerged density)*,  $\rho_b$ , is the difference between the total density and the density of water.

$$\rho_b = \rho - \rho_w \quad 35.12$$

The density of the solid constituents,  $\rho_s$ , is the ratio of the mass of the solids to the volume of the solids. This would also be the density of soil if there were no voids. For that reason,  $\rho_s$  is also known as the *solid density* and *zero-voids density*.

$$\rho_s = \frac{m_s}{V_s} \quad 35.13$$

The *percent pore space*, PPS, is the ratio of the volume of the voids to the total volume, in percent.

$$\begin{aligned} \text{PPS} &= \frac{V_v}{V_t} \times 100\% \\ &= \left(1 - \frac{V_s}{V_t}\right) \times 100\% \\ &= \left(1 - \frac{\rho_d}{\rho_s}\right) \times 100\% \end{aligned} \quad 35.14$$

The *specific gravity*, SG, of the solid constituents is given by Eq. 35.15. For practical purposes, the density of water,  $\rho_w$ , is 62.4 lbm/ft<sup>3</sup> (1000 kg/m<sup>3</sup>). The specific gravity of most soils is within the range of 2.65–2.70, with clays as high as 2.9 and organic soils as low as 2.5.

$$\text{SG} = \frac{\rho_s}{\rho_w} \quad 35.15$$

The *relative density*,  $D_r$  (also denoted as the *density index*,  $I_d$ ), is the density of a granular soil relative to the minimum and maximum densities achieved for that soil in a laboratory test. This index is not applicable to clays because clays do not densify in this particular laboratory test. The relative density is equal to 1 for a very dense soil and 0 for a very loose soil.

$$D_r = \frac{e_{\max} - e}{e_{\max} - e_{\min}} \quad 35.16$$

Typical values of some of these soil parameters are given in Table 35.6. Useful relationships for computing the soil indexes are summarized in Table 35.7.

**Table 35.6** Typical Soil Characteristics

description	$n$	$e$	$w_{\text{sat}}$	$\rho_d$		$\rho_{\text{sat}}$	
				(lbm/ft <sup>3</sup> )	(kg/m <sup>3</sup> )	(lbm/ft <sup>3</sup> )	(kg/m <sup>3</sup> )
sand, loose and uniform	0.46	0.85	0.32	90	(1440)	118	(1890)
sand, dense and uniform	0.34	0.51	0.19	109	(1750)	130	(2080)
sand, loose and mixed	0.40	0.67	0.25	99	(1590)	124	(1990)
sand, dense and mixed	0.30	0.43	0.16	116	(1860)	135	(2160)
glacial clay, soft	0.55	1.20	0.45	76	(1200)	110	(1760)
glacial clay, stiff	0.37	0.60	0.22	106	(1700)	125	(2000)

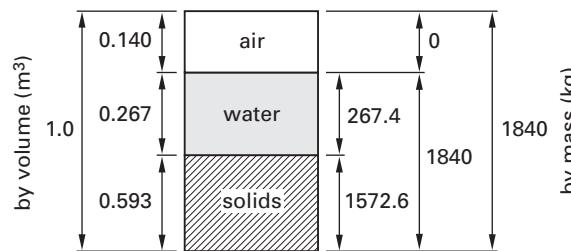

(Multiply lbm/ft<sup>3</sup> by 16.02 to obtain kg/m<sup>3</sup>.)

### Example 35.2

What is the degree of saturation for a sand sample with SG = 2.65,  $\rho = 115$  lbm/ft<sup>3</sup> (1840 kg/m<sup>3</sup>), and  $w = 17\%$ ?

#### SI Solution

Draw the various mass and volume phases on a phase diagram. Since an actual mass or volume of soil is not specified, arbitrarily assume any convenient volume, usually 1.0 m<sup>3</sup>.

From Eq. 35.6,

$$m_w = w m_s = 0.17 m_s$$

However,  $m_t = m_w + m_s = 1840$  kg. (The mass of any air voids is negligible.)

$$0.17 m_s + m_s = 1840 \text{ kg}$$

$$m_s = 1572.6 \text{ kg}$$

$$m_w = 267.4 \text{ kg}$$

**Table 35.7** Soil Indexing Formulas

$\rho_w$  is the density of water. Where noted with an asterisk (\*), use the actual density of water at the recorded temperature. In other cases, use 62.4 lbm/ft<sup>3</sup> or 1000 kg/m<sup>3</sup>.

The solids volume is given by Eq. 35.13.

$$\begin{aligned} V_s &= \frac{m_s}{\rho_s} = \frac{m_s}{(\text{SG})\rho_w} \\ &= \frac{1572.6 \text{ kg}}{(2.65)\left(1000 \frac{\text{kg}}{\text{m}^3}\right)} \\ &= 0.593 \text{ m}^3 \end{aligned}$$

Similarly, the water volume is

$$\begin{aligned} V_w &= \frac{m_w}{\rho_w} \\ &= \frac{267.4 \text{ kg}}{1000 \frac{\text{kg}}{\text{m}^3}} \\ &= 0.267 \text{ m}^3 \end{aligned}$$

The air volume is

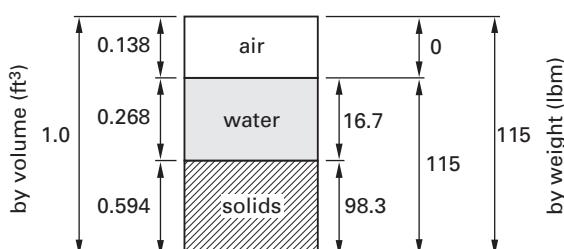

$$\begin{aligned} V_g &= V_t - V_s - V_w \\ &= 1 \text{ m}^3 - 0.593 \text{ m}^3 - 0.267 \text{ m}^3 \\ &= 0.140 \text{ m}^3 \end{aligned}$$

The degree of saturation is given by Eq. 35.7.

$$\begin{aligned} S &= \frac{V_w}{V_g + V_w} \times 100\% \\ &= \frac{0.267 \text{ m}^3}{0.140 \text{ m}^3 + 0.267 \text{ m}^3} \times 100\% \\ &= 66\% \end{aligned}$$

#### Customary U.S. Solution

Draw the various mass and volume phases on a phase diagram. Since an actual mass or volume of soil is not specified, arbitrarily assume any convenient volume, usually 1.0 ft<sup>3</sup>.

From Eq. 35.6,

$$m_w = w m_s = 0.17 m_s$$

However,  $m_t = m_w + m_s = 115$  lbm. (The mass of any air voids is negligible.)

$$0.17 m_s + m_s = 115 \text{ lbm}$$

$$m_s = 98.3 \text{ lbm}$$

$$m_w = 16.7 \text{ lbm}$$

The solids volume is given by Eq. 35.13 and Eq. 35.15.

$$\begin{aligned} V_s &= \frac{m_s}{\rho_s} = \frac{m_s}{(\text{SG})\rho_w} \\ &= \frac{98.3 \text{ lbm}}{(2.65)\left(62.4 \frac{\text{lbm}}{\text{ft}^3}\right)} \\ &= 0.594 \text{ ft}^3 \end{aligned}$$

Similarly, the water volume is

$$\begin{aligned} V_w &= \frac{m_w}{\rho_w} \\ &= \frac{16.7 \text{ lbm}}{62.4 \frac{\text{lbm}}{\text{ft}^3}} \\ &= 0.268 \text{ ft}^3 \end{aligned}$$

The air volume is

$$\begin{aligned} V_g &= V_t - V_s - V_w \\ &= 1 \text{ ft}^3 - 0.594 \text{ ft}^3 - 0.268 \text{ ft}^3 \\ &= 0.138 \text{ ft}^3 \end{aligned}$$

The degree of saturation is given by Eq. 35.7.

$$\begin{aligned} S &= \frac{V_w}{V_g + V_w} \times 100\% \\ &= \frac{0.268 \text{ ft}^3}{0.138 \text{ ft}^3 + 0.268 \text{ ft}^3} \times 100\% \\ &= 66\% \end{aligned}$$

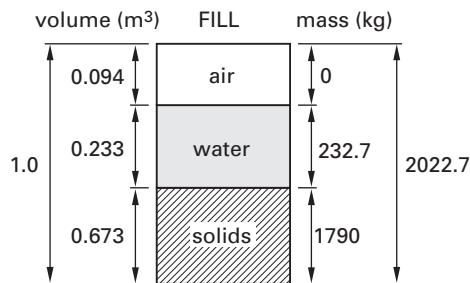

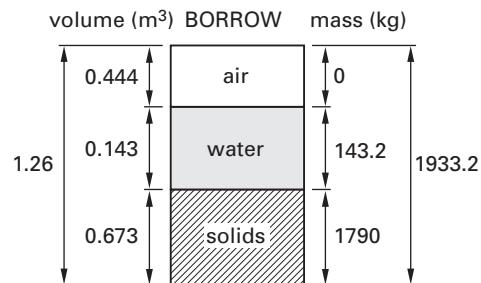

#### Example 35.3

Borrow soil is used to fill a 100,000 yd<sup>3</sup> (75,000 m<sup>3</sup>) depression. The borrow soil has the following characteristics: density = 96.0 lbm/ft<sup>3</sup> (1540 kg/m<sup>3</sup>), water content = 8%, and specific gravity of the solids = 2.66. The final in-place dry density should be 112.0 lbm/ft<sup>3</sup> (1790 kg/m<sup>3</sup>), and the final water content should be 13%.

- (a) How many cubic yards (cubic meters) of borrow soil are needed? (b) Assuming no evaporation loss, what water mass is needed to achieve 13% moisture? (c) What will be the density of the in-place fill after a long rain?

*SI Solution*

Draw the phase diagrams for both the borrow and compacted fill soils. Use subscript *B* for borrow soil and *F* for fill soil, and work with 1 m<sup>3</sup> of fill material.

*step 1:* The air has no mass. The soil content (mass) is the same at both locations. (That is, getting 1790 kg of soil solids in the fill requires taking 1790 kg of borrow soil solids.) Per cubic meter of fill, the mass of borrow soil solids is

$$m_{s,B} = m_{s,F} \\ = 1790 \text{ kg}$$

*step 2:* The mass of the water in 1 m<sup>3</sup> of fill is found from Eq. 35.6.

$$m_{w,F} = w m_{s,F} \\ = (0.13)(1790 \text{ kg}) \\ = 232.7 \text{ kg}$$

*step 3:* The total mass and density of the fill are

$$m_{t,F} = m_{s,F} + m_{w,F} \\ = 1790 \text{ kg} + 232.7 \text{ kg} \\ = 2022.7 \text{ kg} \\ \rho_F = \frac{m_{t,F}}{V_t} \\ = \frac{2022.7 \text{ kg}}{1 \text{ m}^3} \\ = 2022.7 \text{ kg/m}^3 \text{ fill}$$

*step 4:* Since  $\rho_s = m_s/V_s$ , the volume of the solids in the fill is

$$V_{s,F} = \frac{m_{s,F}}{\rho_{s,F}} \\ = \frac{1790 \text{ kg}}{(2.66)\left(1000 \frac{\text{kg}}{\text{m}^3}\right)} \\ = 0.673 \text{ m}^3$$

*step 5:* Similarly, the volume of the water in the fill is

$$V_{w,F} = \frac{m_{w,F}}{\rho_{w,F}} \\ = \frac{232.7 \text{ kg}}{1000 \frac{\text{kg}}{\text{m}^3}} \\ = 0.233 \text{ m}^3$$

*step 6:* The air volume in the fill is

$$V_g = V_t - V_s - V_w \\ = 1 \text{ m}^3 - 0.673 \text{ m}^3 - 0.233 \text{ m}^3 \\ = 0.094 \text{ m}^3$$

*step 7:* The mass of the water per cubic meter of fill in the borrow soil is given by Eq. 35.6.

$$m_{w,B} = w m_{s,B} \\ = (0.08)(1790 \text{ kg}) \\ = 143.2 \text{ kg}$$

*step 8:* The total mass of the borrow soil per cubic meter of fill is

$$m_{t,B} = m_{s,B} + m_{w,B} = 1790 \text{ kg} + 143.2 \text{ kg} \\ = 1933.2 \text{ kg}$$

*step 9:* The total volume of the borrow soil per cubic meter of fill is

$$V_{t,B} = \frac{m_{t,B}}{\rho_B} \\ = \frac{1933.2 \text{ kg}}{1540 \frac{\text{kg}}{\text{m}^3}} \\ = 1.26 \text{ m}^3$$

*step 10:* The mass of solids in 1 m<sup>3</sup> of fill is the same as the mass of solids in 1.26 m<sup>3</sup> of borrow soil. Since the mass is the same, the volume of solids is also the same, even though the total soil density is different. The volume of solids was calculated in step 4.

$$V_{s,B} = V_{s,F} = 0.673 \text{ m}^3$$

*step 11:* The volume of water in the borrow soil per cubic meter of fill is

$$V_{w,B} = \frac{m_{w,B}}{\rho_w} \\ = \frac{143.2 \text{ kg}}{1000 \frac{\text{kg}}{\text{m}^3}} \\ = 0.143 \text{ m}^3$$

*step 12:* The air volume in the borrow soil per cubic foot of fill is

$$V_{g,B} = V_{t,B} - V_{s,B} - V_{w,B} \\ = 1.26 \text{ m}^3 - 0.143 \text{ m}^3 - 0.673 \text{ m}^3 \\ = 0.444 \text{ m}^3$$

*step 13:* Since 1.26 m<sup>3</sup> of borrow soil is required for every 1 m<sup>3</sup> of fill, the volume of borrow soil required to fill the depression is

$$V_{\text{required},B} = \left( \frac{1.26 \text{ m}^3}{1 \text{ m}^3} \right) (75000 \text{ m}^3) \\ = 94500 \text{ m}^3$$

*step 14:* The amount of water needed to achieve 13% moisture is the difference in mass of water between the fill and borrow soil. The actual moisture in the compacted borrow soil is

$$m_{B,\text{total}} = V_{B,\text{total}} \left( \frac{m_{w,B}}{V_{t,B}} \right) \\ = \frac{(94500 \text{ m}^3)(143.2 \text{ kg})}{1.26 \text{ m}^3} \\ = 1.074 \times 10^7 \text{ kg}$$

The required moisture in the fill soil is

$$m_{F,\text{total}} = V_{F,\text{total}} \left( \frac{m_{w,F}}{V_{t,F}} \right) \\ = \frac{(75000 \text{ m}^3)(232.7 \text{ kg})}{1 \text{ m}^3} \\ = 1.745 \times 10^7 \text{ kg}$$

The required additional moisture is

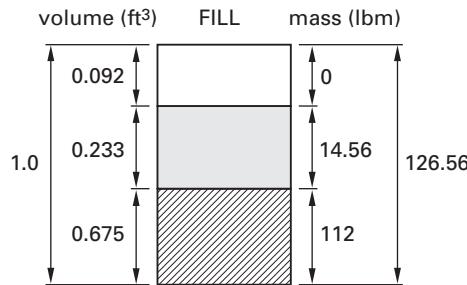

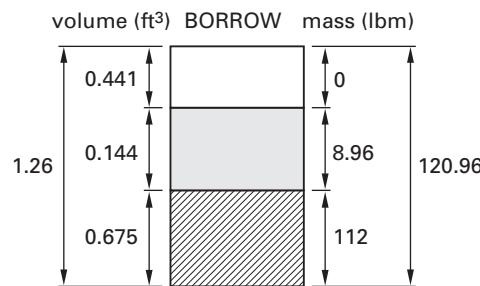

$$m_{w,\text{required}} = m_{F,\text{total}} - m_{B,\text{total}} \\ = 1.745 \times 10^7 \text{ kg} - 1.074 \times 10^7 \text{ kg} \\ = 6.71 \times 10^6 \text{ kg}$$

*step 15:* After a rain, all the void spaces will be filled with water and the density will be the saturated density.

$$m_w = (V_w + V_g)\rho_w \\ = (0.233 \text{ m}^3 + 0.094 \text{ m}^3) \left( 1000 \frac{\text{kg}}{\text{m}^3} \right) \\ = 327.0 \text{ kg} \\ \rho = \frac{m_t}{V_t} = \frac{m_s + m_w}{V_t} \\ = \frac{1790 \text{ kg} + 327.0 \text{ kg}}{1 \text{ m}^3} \\ = 2117 \text{ kg/m}^3$$

#### Customary U.S. Solution

Draw the phase diagrams for both the borrow and compacted fill soils. Use subscript *B* for borrow soil and *F* for fill soil, and work with 1 ft<sup>3</sup> of fill material.

*step 1:* The air has no mass. The soil content (mass) is the same at both locations. (That is, getting 112 lbm of soil solids in the fill requires taking 112 lbm of borrow soil solids.) Per cubic foot of fill, the mass of borrow soil solids is

$$m_{s,B} = m_{s,F} = 112 \text{ lbm}$$

*step 2:* The mass of the water in 1 ft<sup>3</sup> of fill is given by Eq. 35.6.

$$m_{w,F} = w m_{s,F} = (0.13)(112 \text{ lbm}) = 14.56 \text{ lbm}$$

*step 3:* The total mass and density of the fill are

$$\begin{aligned} m_{t,F} &= m_{s,F} + m_{w,F} = 112 \text{ lbm} + 14.56 \text{ lbm} \\ &= 126.56 \text{ lbm} \\ \rho_F &= \frac{m_{t,F}}{V_t} = \frac{126.56 \text{ lbm}}{1 \text{ ft}^3} \\ &= 126.56 \text{ lbm/ft}^3 \text{ fill} \end{aligned}$$

*step 4:* Since  $\rho_s = m_s/V_s$ , the volume of the solids in the fill is

$$\begin{aligned} V_{s,F} &= \frac{m_{s,F}}{\rho_{s,F}} \\ &= \frac{112 \text{ lbm}}{(2.66)\left(62.4 \frac{\text{lbm}}{\text{ft}^3}\right)} \\ &= 0.675 \text{ ft}^3 \end{aligned}$$

*step 5:* Similarly, the volume of the water in the fill is

$$\begin{aligned} V_{w,F} &= \frac{m_{w,F}}{\rho_{w,F}} \\ &= \frac{14.56 \text{ lbm}}{62.4 \frac{\text{lbm}}{\text{ft}^3}} \\ &= 0.233 \text{ ft}^3 \end{aligned}$$

*step 6:* The air volume in the fill is

$$\begin{aligned} V_g &= V_t - V_s - V_w \\ &= 1 \text{ ft}^3 - 0.675 \text{ ft}^3 - 0.233 \text{ ft}^3 \\ &= 0.092 \text{ ft}^3 \end{aligned}$$

*step 7:* The mass of the water per cubic foot of fill in the borrow soil is given by Eq. 35.6.

$$\begin{aligned} m_{w,B} &= w m_{s,B} = (0.08)(112 \text{ lbm}) \\ &= 8.96 \text{ lbm} \end{aligned}$$

*step 8:* The total mass of the borrow soil per cubic foot of fill is

$$\begin{aligned} m_{t,B} &= m_{s,B} + m_{w,B} = 112 \text{ lbm} + 8.96 \text{ lbm} \\ &= 120.96 \text{ lbm} \end{aligned}$$

*step 9:* The total volume of the borrow soil per cubic foot of fill is

$$\begin{aligned} V_{t,B} &= \frac{m_{t,B}}{\rho_B} \\ &= \frac{120.96 \text{ lbm}}{96 \frac{\text{lbm}}{\text{ft}^3}} \\ &= 1.26 \text{ ft}^3 \end{aligned}$$

*step 10:* The mass of solids in 1 ft<sup>3</sup> of fill is the same as the mass of solids in 1.26 ft<sup>3</sup> of borrow soil. Since the mass is the same, the volume of solids is also the same, even though the total soil density is different. The volume of solids was calculated in step 4.

$$V_{s,B} = V_{s,F} = 0.675 \text{ ft}^3$$

*step 11:* The volume of water in the borrow soil per cubic foot of fill is

$$\begin{aligned} V_{w,B} &= \frac{m_{w,B}}{\rho_w} \\ &= \frac{8.96 \text{ lbm}}{62.4 \frac{\text{lbm}}{\text{ft}^3}} \\ &= 0.144 \text{ ft}^3 \end{aligned}$$

*step 12:* The air volume in the borrow soil per cubic foot of fill is

$$\begin{aligned} V_{g,B} &= V_{t,B} - V_{s,B} - V_{w,B} \\ &= 1.26 \text{ ft}^3 - 0.675 \text{ ft}^3 - 0.144 \text{ ft}^3 \\ &= 0.441 \text{ ft}^3 \end{aligned}$$

*step 13:* Since 1.26 ft<sup>3</sup> of borrow soil is required for every 1 ft<sup>3</sup> of fill, the volume of borrow soil required to fill the depression is

$$\begin{aligned} V_{\text{required},B} &= \left( \frac{1.26 \text{ ft}^3}{1 \text{ ft}^3} \right) (100,000 \text{ yd}^3) \\ &= 126,000 \text{ yd}^3 \end{aligned}$$

*step 14:* The amount of water needed to achieve 13% moisture is the difference in mass of water between the fill and borrow soil. The actual moisture in the compacted borrow soil is

$$\begin{aligned} m_{B,\text{total}} &= V_{B,\text{total}} \left( \frac{m_{w,B}}{V_{t,B}} \right) \\ &= \frac{(126,000 \text{ yd}^3) \left( 27 \frac{\text{ft}^3}{\text{yd}^3} \right) (8.96 \text{ lbm})}{1.26 \text{ ft}^3} \\ &= 2.42 \times 10^7 \text{ lbm} \end{aligned}$$

The required moisture in the fill soil is

$$\begin{aligned} m_{F,\text{total}} &= V_{F,\text{total}} \left( \frac{m_{w,F}}{V_{t,F}} \right) \\ &= (100,000 \text{ yd}^3) \left( 27 \frac{\text{ft}^3}{\text{yd}^3} \right) \left( 14.56 \frac{\text{lbm}}{\text{ft}^3} \right) \\ &= 3.93 \times 10^7 \text{ lbm} \end{aligned}$$

The required additional moisture is

$$\begin{aligned} m_{w,\text{required}} &= m_{F,\text{total}} - m_{B,\text{total}} \\ &= 3.93 \times 10^7 \text{ lbm} - 2.42 \times 10^7 \text{ lbm} \\ &= 1.51 \times 10^7 \text{ lbm} \end{aligned}$$

*step 15:* After a rain, all the void spaces will be filled with water and the density will be the saturated density.

$$\begin{aligned} m_w &= (V_w + V_g)\rho_w \\ &= (0.233 \text{ ft}^3 + 0.092 \text{ ft}^3) \left( 62.4 \frac{\text{lbm}}{\text{ft}^3} \right) \\ &= 20.28 \text{ lbm} \\ \rho &= \frac{m_t}{V_t} = \frac{m_s + m_w}{V_t} \\ &= \frac{112.0 \text{ lbm} + 20.28 \text{ lbm}}{1.0 \text{ ft}^3} \\ &= 132.3 \text{ lbm/ft}^3 \end{aligned}$$

## 6. SWELL

*Swell* occurs when clayey soils are used at lower loadings and/or higher moisture contents than existed prior to excavation. A small percentage may need to be added to calculated borrow-soil volumes to account for swell. Actual swell percentages are difficult to predict, but are typically less than 5%. Soils with large swell percentages are probably not suitable for foundation fill.

## 7. EFFECTIVE STRESS

Each of the three phases (solids, water, and air) in soil have different characteristics. Unlike other construction materials that essentially perform as homogeneous media, the three phases in soil interact with each other: Water and air can enter or leave the soil, and the soil grains can be pushed closer together. The water and air in the soil voids cannot support shear stress, so shear is supported entirely through grain-to-grain contact.

The *effective stress*,  $\sigma'$ , is the portion of the total stress that is supported through grain contact. It is the difference between the *total stress*,  $\sigma$ , and the *pore water pressure*,  $u$ . (The pore water pressure is sometimes called the *neutral stress* because it is equal in all directions; that is, it has no shear stress component.) The effective stress is the average stress on a plane through

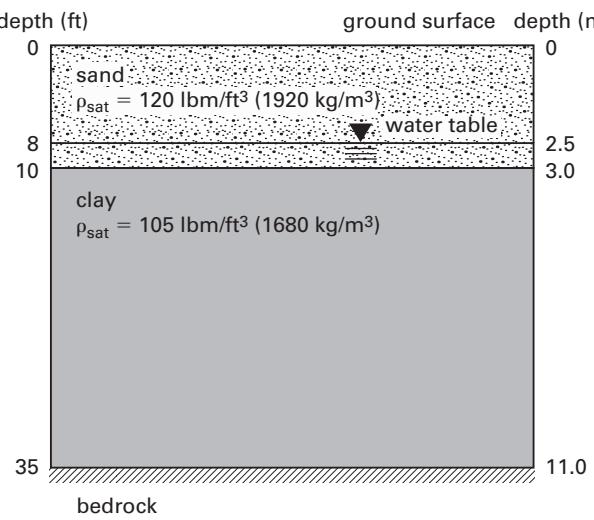

the soil, not the actual contact stress between two soil particles (which can be much higher).

$$\sigma' = \sigma - u \quad 35.17$$

The stresses in a soil element at depth  $z$  below the ground surface include those due to the weight above that element (called the *overburden stress*) and any buoyant forces that the water in the soil voids exerts. The stress in a soil column can be divided into total stress, effective stress, and pore pressure components. Above the water table, total and effective stresses are equal. Below the water table, the pore water exerts a buoyant force, and this hydrostatic stress is subtracted from the total stress to obtain the effective stress.

#### Example 35.4

The sand in the profile illustrated is saturated above the water table by virtue of capillary action. Given the soil properties illustrated, draw the total stress, effective stress, and pore pressure diagrams.

#### SI Solution

The total stress profile is a profile of the total weight of the soil column with depth. The total stress at a depth of 3 m is

$$\begin{aligned}\sigma_{3\text{m}} &= \rho g z \\ &= \left(1920 \frac{\text{kg}}{\text{m}^3}\right) \left(9.81 \frac{\text{m}}{\text{s}^2}\right) (3 \text{ m}) \\ &= 56505 \text{ Pa} \quad (56.5 \text{ kPa})\end{aligned}$$

At a depth of 11 m, the total stress is

$$\begin{aligned}\sigma_{11\text{m}} &= \sigma_{3\text{m}} + \rho g z \\ &= 56505 \text{ Pa} + \left(1680 \frac{\text{kg}}{\text{m}^3}\right) \left(9.81 \frac{\text{m}}{\text{s}^2}\right) \\ &\quad \times (11 \text{ m} - 3 \text{ m}) \\ &= 188351 \text{ Pa} \quad (188.4 \text{ kPa})\end{aligned}$$

The pore water pressure above the water table is zero. Below the water table, the pore water pressure is equal to the weight of the water column. At a depth of 11 m, the pore water pressure is

$$\begin{aligned}u_{11\text{m}} &= \rho_w g z \\ &= \left(1000 \frac{\text{kg}}{\text{m}^3}\right) \left(9.81 \frac{\text{m}}{\text{s}^2}\right) (8.5 \text{ m}) \\ &= 83385 \text{ Pa} \quad (83.4 \text{ kPa})\end{aligned}$$

The effective stress profile is determined by subtracting the pore water pressure from the total stress, or by using buoyant weights below the water table. Above the water table, the total and effective stresses are equal.

At a depth of 2.5 m, the effective stress is

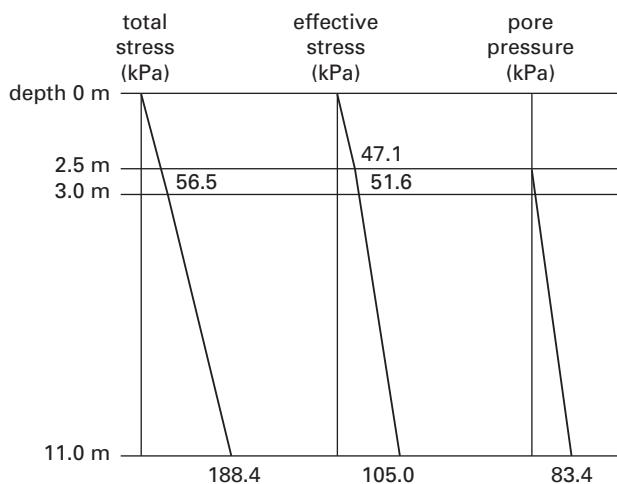

$$\begin{aligned}\sigma'_{2.5\text{m}} &= \rho g z \\ &= \left(1920 \frac{\text{kg}}{\text{m}^3}\right) \left(9.81 \frac{\text{m}}{\text{s}^2}\right) (2.5 \text{ m}) \\ &= 47088 \text{ Pa} \quad (47.1 \text{ kPa})\end{aligned}$$

At a depth of 3 m, the effective stress is

$$\begin{aligned}\sigma'_{3\text{m}} &= \sigma_{2.5\text{m}} + \rho g z \\ &= 47088 \text{ Pa} + \left(1920 \frac{\text{kg}}{\text{m}^3} - 1000 \frac{\text{kg}}{\text{m}^3}\right) \\ &\quad \times (0.5 \text{ m}) \left(9.81 \frac{\text{m}}{\text{s}^2}\right) \\ &= 51601 \text{ Pa} \quad (51.6 \text{ kPa})\end{aligned}$$

At a depth of 11 m, the effective stress is

$$\begin{aligned}\sigma'_{11\text{m}} &= 51601 \text{ Pa} + \left(1680 \frac{\text{kg}}{\text{m}^3} - 1000 \frac{\text{kg}}{\text{m}^3}\right) \\ &\quad \times \left(9.81 \frac{\text{m}}{\text{s}^2}\right) (8 \text{ m}) \\ &= 104967 \text{ Pa} \quad (105.0 \text{ kPa})\end{aligned}$$

*Customary U.S. Solution*

The total stress profile is a profile of the total weight of the soil column with depth. The total stress at a depth of 10 ft is

$$\begin{aligned}\sigma_{10 \text{ ft}} &= \gamma z \\ &= \left(120 \frac{\text{lbf}}{\text{ft}^3}\right)(10 \text{ ft}) \\ &= 1200 \text{ lbf/ft}^2\end{aligned}$$

At a depth of 35 ft, the total stress is

$$\begin{aligned}\sigma_{35 \text{ ft}} &= \sigma_{10 \text{ ft}} + \gamma z \\ &= 1200 \frac{\text{lbf}}{\text{ft}^2} + \left(105 \frac{\text{lbf}}{\text{ft}^3}\right)(25 \text{ ft}) \\ &= 3825 \text{ lbf/ft}^2\end{aligned}$$

The pore water pressure above the water table is zero. Below the water table, the pore water pressure is equal to the weight of the water column. At a depth of 35 ft, the pore water pressure is

$$\begin{aligned}u_{35 \text{ ft}} &= \left(62.4 \frac{\text{lbf}}{\text{ft}^3}\right)(35 \text{ ft} - 8 \text{ ft}) \\ &= 1684.8 \text{ lbf/ft}^2\end{aligned}$$

The effective stress profile is determined by subtracting the pore water pressure from the total stress, or by using buoyant densities below the water table. Above the water table, the total and effective stresses are equal.

At a depth of 8 ft, the effective stress is

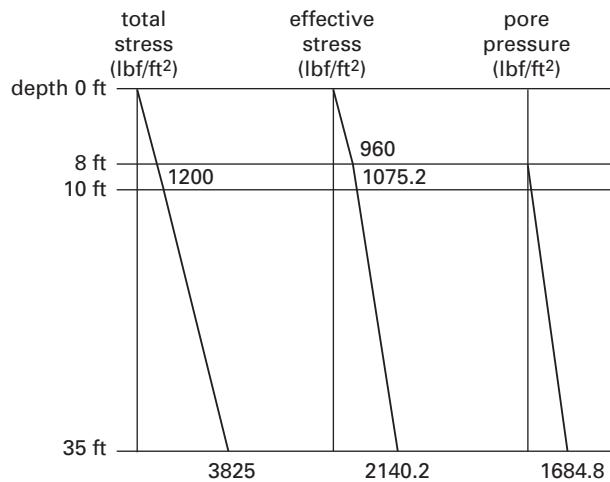

$$\begin{aligned}\sigma'_{8 \text{ ft}} &= \gamma z = \left(120 \frac{\text{lbf}}{\text{ft}^3}\right)(8 \text{ ft}) \\ &= 960 \text{ lbf/ft}^2\end{aligned}$$

At a depth of 10 ft, the effective stress is

$$\begin{aligned}\sigma'_{10 \text{ ft}} &= 960 \frac{\text{lbf}}{\text{ft}^2} + \left(120 \frac{\text{lbf}}{\text{ft}^3} - 62.4 \frac{\text{lbf}}{\text{ft}^3}\right)(2 \text{ ft}) \\ &= 1075.2 \text{ lbf/ft}^2\end{aligned}$$

At a depth of 35 ft, the effective stress is

$$\begin{aligned}\sigma'_{35 \text{ ft}} &= 1075.2 \frac{\text{lbf}}{\text{ft}^2} + \left(105 \frac{\text{lbf}}{\text{ft}^3} - 62.4 \frac{\text{lbf}}{\text{ft}^3}\right)(25 \text{ ft}) \\ &= 2140.2 \text{ lbf/ft}^2\end{aligned}$$

**8. STANDARDIZED SOIL TESTING PROCEDURES**

Soil testing procedures and equipment vary from laboratory to laboratory and depend on specific project needs. To compare results, consistent methodologies are necessary. For this reason, government and professional agencies have developed standards for commonly performed tests. Table 35.8 lists some of the soil tests that have been standardized by ASTM International. Most of the procedures referred to in this chapter have been chosen in accordance with ASTM standards.

**9. STANDARD PENETRATION TEST**

A common soil test is the *standard penetration test* (SPT), which is performed in situ as part of the drilling and sampling operation. (The term “in situ” is synonymous with “in place.”) The SPT measures resistance to the penetration of a standard split-spoon sampler that is driven by a 140 lbm (63.5 kg) hammer dropped from a height of 30 in (0.76 m). The number of blows required to drive the sampler a distance of 12 in (0.305 m) after an initial penetration of 6 in (0.15 m) is referred to as the *N-value* or *standard penetration resistance* in blows per foot.

**Table 35.8** ASTM Standard Soil Tests

test	ASTM designation	title (abbreviated)
AASHTO Soil Classification	D3282	Classification of Soils and Soil-Aggregate Mixtures for Highway Construction Purposes
USCS Soil Classification	D2487	Classification of Soils for Engineering Purposes
Standard Penetration Test	D1586	Penetration Test and Split-Barrel Sampling of Soils
Cone Penetrometer Test	D3441	Mechanical Cone Penetration Tests of Soil
Proctor/Modified Proctor Test	D698 D1557	Laboratory Compaction Characteristics —Using Standard Effort —Using Modified Effort
In-Place Density Test	D6938 D2167 D1556	Nuclear Methods (Shallow Depth) Rubber-Balloon Method Sand-Cone Method
Atterberg Limit Tests	D4318	Liquid Limit, Plastic Limit, and Plasticity Index of Soils
Permeability Tests	D2434	Permeability of Granular Soils (Constant Head)
Consolidation Tests	D2435	One-Dimensional Consolidation Properties of Soils Using Incremental Loading
Direct Shear Tests	D3080	Direct Shear Test of Soils Under Consolidated Drained Conditions
Triaxial Stress Tests	D2850 D4767	Unconsolidated-Undrained Triaxial Compression Tests, Cohesive Soils Consolidated-Undrained Triaxial Compression Tests, Cohesive Soils
Unconfined Compressive Strength Test	D2166	Unconfined Compressive Strength of Cohesive Soil
CBR Test	D1883	CBR (California Bearing Ratio) of Laboratory-Compacted Soils
Plate Bearing Value Test	D1195	Repetitive Static Plate Load Tests of Soils and Flexible Pavement Components
Hveem's Resistance Value Test	D2844	Resistance R-Value and Expansion Pressure of Compacted Soils

The measured value of  $N$  is inconsistent from operator to operator because different drill rig systems deliver energy input that deviates from the theoretical value. Therefore, the  $N$ -value obtained in the field is converted to a standardized  $N$ -value,  $N'$ . In addition, because the  $N$ -value is sensitive to overburden pressure, corrections are applied to reference the value to a standard overburden stress, usually 2000 lbf/ft<sup>2</sup> (95.76 kPa).

The  $N$ -value has been correlated with many other mechanical properties, including shear modulus, unconfined compressive strength, angle of internal friction, and relative density. The correlations work best with cohesionless soils. Table 35.9 relates  $N$  to the relative density and friction angle.

**Table 35.9** Relationship Between SPT ( $N$ ), Relative Density ( $D_r$ ), and Angle of Internal Friction ( $\phi$ ) (cohesionless soils)

type of soil	SPT, $N$	relative density, $D_r$	angle of internal friction, $\phi$	
			Peck, et al., 1974	Meyerhof, 1956
very loose sand	< 4	< 0.02	< 29	< 30
loose sand	4–10	0.2–0.4	29–30	30–35

## 10. CONE PENETROMETER TEST

The *cone penetrometer test* (CPT) has gained popularity as an alternative or adjunct to the standard penetration test. The standard cone penetrometer is a cylinder with an area of 1.55 in<sup>2</sup> (10 cm<sup>2</sup>), tipped with a cone that has a 60° point. The cone is pushed into the soil at a continuous rate of 2–4 ft/min (10–20 mm/s). Resistance is measured separately at the tip of the cone (tip resistance,  $q_c$ , in lbf/ft<sup>2</sup> or kPa) and along the sides (sleeve friction resistance,  $q_s$ , in lbf/ft<sup>2</sup> or kPa). A data acquisition system collects nearly continuous data with depth.

One advantage of the cone penetration test is that a continuous record is obtained with depth, in contrast with the standard penetration test that is performed usually once every few feet. The cone penetration test is quite good for classifying both sands and clays. The cone can also be altered to measure pore water pressure or shear wave velocity.

The disadvantages to the cone test are: (a) No sample is retrieved, so some additional borings are usually required to confirm classification results or to obtain samples for further tests; (b) the cone and its accompanying equipment require a high initial investment to acquire; (c) the cone is easily damaged and immobilized; and (d) the cone cannot be used in very stiff or gravelly soils.

For sands, the *friction ratio*,  $f_R$ , is less than 1%; for clays,  $f_R$  is larger, up to 5% or more.

$$f_R = \frac{q_s}{q_c} \times 100\% \quad 35.18$$

## 11. PROCTOR TEST

Soils are compacted to increase stability and strength, enhance resistance to erosion, decrease permeability, and decrease compressibility. This is usually accomplished by placing the soil in *lifts* (i.e., layers) of a few inches to a few feet thick, and then mechanically compacting the lifts. Compaction equipment can densify the soil by static loading, impact, vibration, and/or kneading actions. *Grid rollers* can be used to break up and compact rocky soil. Cohesive soils respond best to the kneading action that is provided by a *sheepsfoot roller*. *Rubber-tired* or *smooth-wheeled rollers* are especially useful for final finishes. Roller compactors with vibration capabilities are well-suited for cohesionless soils. These types of compaction equipment are shown in Fig. 35.5.

The specification given to the grading contractor sets forth the minimum acceptable density as well as a range of acceptable water content values. The minimum density is specified as a *relative compaction* (RC), the

percentage of the maximum value determined in the laboratory,  $\rho_d^*$ <sup>5</sup>.

$$RC = \frac{\rho_d}{\rho_d^*} \times 100\% \quad 35.19$$

The basic laboratory test used to determine the maximum dry density of compacted soils is the *Proctor test*. In this procedure, a soil sample is compacted into a 1/30 ft<sup>3</sup> (944 cm<sup>3</sup>) mold in 3 layers by 25 hammer blows on each layer. The hammer has a mass of 5.5 lbm (2.5 kg) and is dropped 12 in (305 mm). The dry density of the sample can be found from Eq. 35.10. This procedure is repeated for various water contents, and a graph similar to Fig. 35.6 is obtained.  $\rho_d^*$  is known as the *maximum dry density*, or density at 100% compaction.  $w^*$  is known as the *optimum water content*.

Soils close to the optimum water content require less compactive effort to achieve the required relative compaction. Usually a range of acceptable water contents, bracketing the optimum water content, is specified in addition to the relative compaction.

## 12. MODIFIED PROCTOR TEST

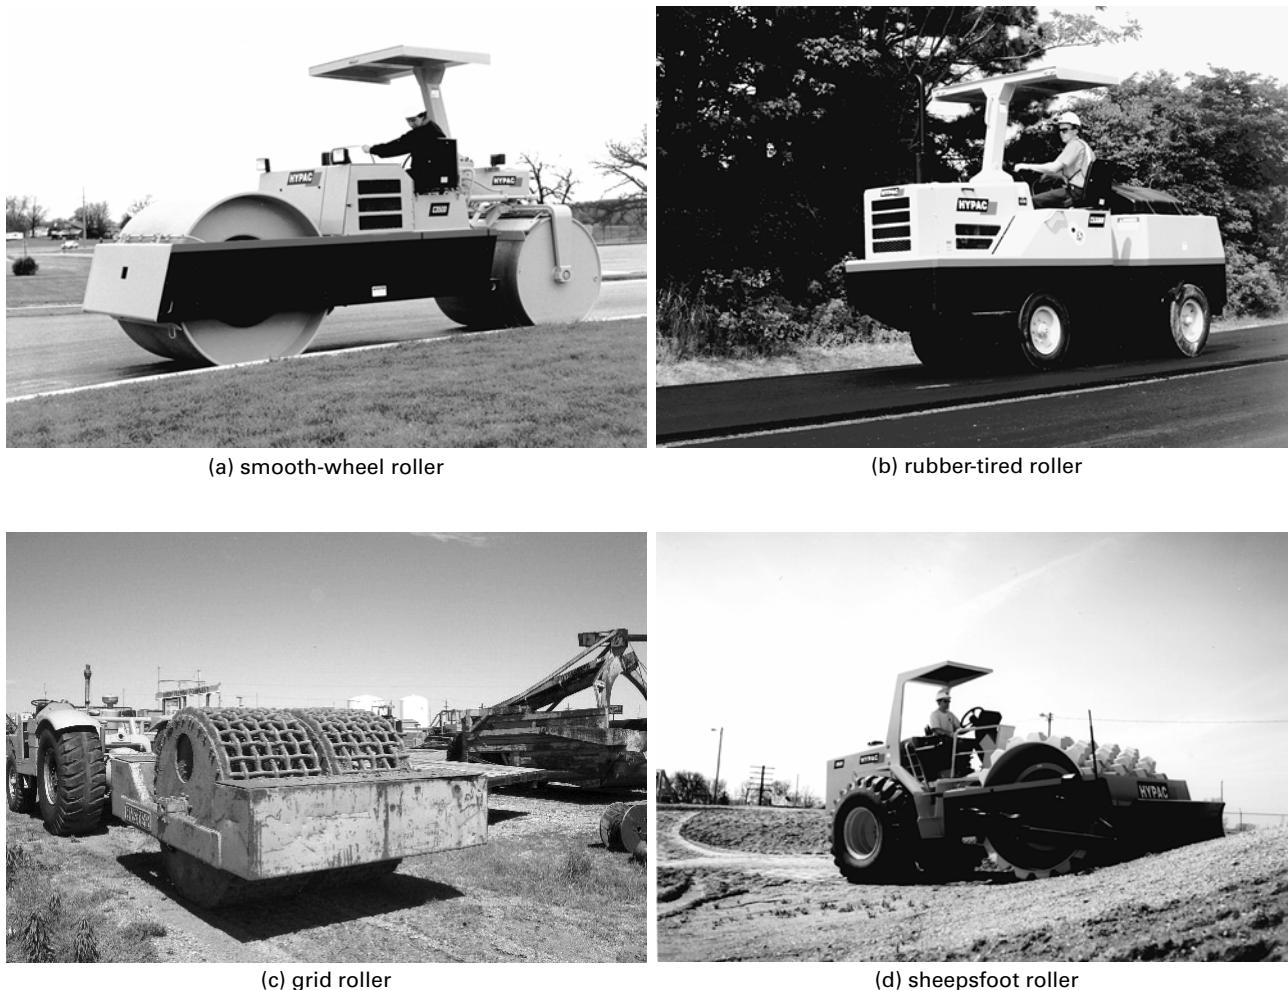

The *modified Proctor test* is similar to the Proctor test except that the soil is compacted in five layers with a 10 lbm (4.5 kg) hammer falling 18 in (457 mm). The result is a denser soil that is more representative of the compaction densities that can be achieved with modern equipment. The modified Proctor curve for a soil always lies above and to the left of the standard Proctor curve. Table 35.10 can be used by adding 10–20 lbm/ft<sup>3</sup> to the densities and subtracting 3–10% from the moisture contents.

For a given water content, perfect compaction will result in saturation, since all air will be removed. The dry densities corresponding to saturation at each water content can be plotted versus water content, and the result is known as a *zero air voids curve*, as shown in Fig. 35.7. The zero air voids curve always lies above the Proctor test curve, since that test cannot expel all air.

The *zero air voids density* (i.e., *dry unit weight at zero air voids*) is the ratio of the mass of the solids to the total volume if the sample is fully compacted (i.e., there is no air in the voids).

$$\rho_z = \frac{m_s}{V_w + V_s} \quad 35.20$$

<sup>5</sup>Relative compaction is not the same as relative density (see Eq. 35.16).

**Figure 35.5** Compaction Equipment

Figures reproduced with permission of Compaction America, Inc.

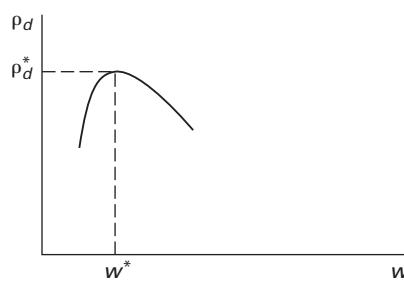

The theoretical dry density of the zero air voids curve is calculated from Eq. 35.21.

$$\rho_z = \frac{\rho_w}{w + \frac{1}{SG}} \quad 35.21$$

The maximum value of the zero air voids density occurs at  $w = 0$ . At that point, the maximum zero air voids density is equal to the density of the solid itself (as calculated from the solid specific gravity).

$$\rho_s = (SG)\rho_w \quad 35.22$$

$\rho_s$  and  $\rho_d^*$  are not the same, however, since air voids exist in the  $\rho_d^*$  case and  $\rho_d^*$  occurs at  $w^*$ .

**Figure 35.6** Proctor Test Curve

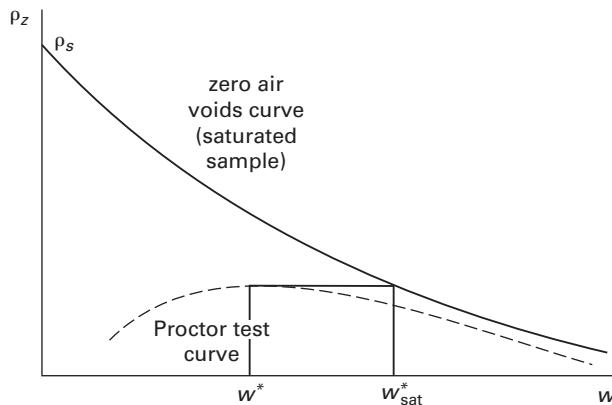

**Table 35.10** Typical Values of Optimum Moisture Content and Suggested Relative Compactions  
(based on standard Proctor test)

class group symbol	description	range of maximum dry densities (lbm/ft <sup>3</sup> )	range of optimum moisture content (%)	recommended percentage of Proctor maximum class (%) <sup>*</sup>		
				1	2	3
GW	well-graded, clean gravels, gravel-sand mixtures	125–135	11–8	97	94	90
GP	poorly graded clean gravels, gravel-sand mixtures	115–125	14–11	97	94	90

OL	organic silts and silt-clays, low plasticity	80–100	33–21	—	96	93
MH	inorganic clayey silts, elastic silts	70–95	40–24	—	97	93
CH	inorganic clays of high plasticity	75–105	36–19	—	—	93
OH	organic and silty clays	65–100	45–21	—	97	93

(Multiply lbm/ft<sup>3</sup> by 16.02 to obtain kg/m<sup>3</sup>.)

\*Class 1 uses include the upper 9 ft (2.7 m) of fills supporting one- and two-story buildings, the upper 3 ft (0.9 m) of subgrade under pavements, and the upper 1 ft (0.3 m) of subgrade under floors. Class 2 uses include deeper parts of fills under buildings and pavements, as well as earth dams. All other fills requiring some degree of strength or incompressibility are classified as class 3.

**Figure 35.7** Typical Zero Air Voids Curve

### Example 35.5

A Proctor test using a  $1/30$  ft<sup>3</sup> (0.9443 L) mold is performed on a sample of soil.

If 0.032 ft<sup>3</sup> (0.00091 m<sup>3</sup>) of compacted soil tested at a construction site had a mass of 3.87 lbm (1.755 kg) wet and 3.74 lbm (1.696 kg) dry, what is the percentage of compaction?

### SI Solution

From Eq. 35.11, the dry density of sample 1 is

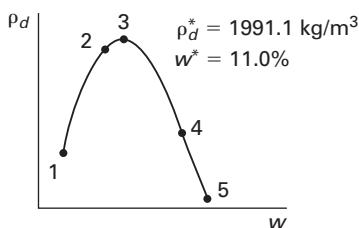

$$\rho_d = \frac{m_t}{(1+w)V_t}$$

$$= \frac{1.941 \text{ kg}}{(1+0.073)(0.9443 \text{ L}) \left( 0.001 \frac{\text{m}^3}{\text{L}} \right)}$$

$$= 1915.7 \text{ kg/m}^3$$

The following table is constructed from the results of all five tests.

test no.	sample net mass (lbm)	water content (%)	dry density (kg/m <sup>3</sup> )	
			test no.	1
1	4.28	7.3		1915.7
2	4.52	9.7	2	1979.0
3	4.60	11.0	3	1991.1
4	4.55	12.8	4	1937.7
5	4.50	14.4	5	1889.4

Since the peak is near point 3, take the maximum dry density to be  $1991.1 \text{ kg/m}^3$ . The sample dry density is

$$\begin{aligned}\rho_d &= \frac{m_d}{V} = \frac{1.696 \text{ kg}}{0.00091 \text{ m}^3} \\ &= 1863.7 \text{ kg/m}^3\end{aligned}$$

The percentage of compaction is

$$\frac{1863.7 \frac{\text{kg}}{\text{m}^3}}{1991.1 \frac{\text{kg}}{\text{m}^3}} \times 100\% = 93.6\%$$

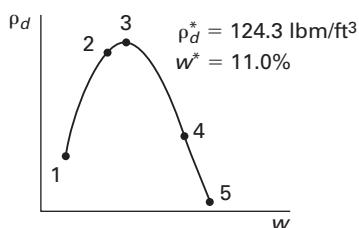

#### Customary U.S. Solution

From Eq. 35.11, the dry density of sample 1 is

$$\begin{aligned}\rho_d &= \frac{m_t}{(1+w)V_t} \\ &= \frac{4.28 \text{ lbm}}{(1+0.073)\left(\frac{1}{30} \text{ ft}^3\right)} \\ &= 119.7 \text{ lbm/ft}^3\end{aligned}$$

The following table is constructed from the results of all five tests.

test no.	dry density (lbm/ft <sup>3</sup> )
1	119.7
2	123.6
3	124.3
4	121.0
5	118.0

Since the peak is near point 3, take the maximum dry density to be  $124.3 \text{ lbm/ft}^3$ . The sample dry density is

$$\begin{aligned}\rho_d &= \frac{m_d}{V} = \frac{3.74 \text{ lbm}}{0.032 \text{ ft}^3} \\ &= 116.9 \text{ lbm/ft}^3\end{aligned}$$

The percentage of compaction is

$$\frac{116.9 \frac{\text{lbm}}{\text{ft}^3}}{124.3 \frac{\text{lbm}}{\text{ft}^3}} \times 100\% = 94\%$$

#### 13. IN-PLACE DENSITY TESTS

The *in-place density test*, also known as the *field density test*, determines the density of a compacted fill to see if it meets specifications. A 3–5 in (8–13 cm) deep hole with smooth sides is dug into the compacted soil. All soil taken from the hole is saved and weighed before the water content can change. The hole is filled with sand or a water-filled rubber balloon. The volume of the hole is calculated from the known mass and density of the sand or water. The required densities of the compacted soil are given by Eq. 35.8 and Eq. 35.11.

A more convenient way to determine the density of in-place soil is by using a *nuclear gauge (nuclear moisture/density gauge)*. This device has a probe containing radioactive material that is inserted into a hole punched into the compacted soil. The rate of radiation penetration through the soil is detected and used to determine both the wet density and the water content of the soil. The dry density can be calculated with Eq. 35.11.

#### 14. ATTERBERG LIMIT TESTS

A clay soil can behave like a solid, semi-solid, plastic solid, or liquid, depending on the water content. The water contents corresponding to the transitions between these states are known as the *Atterberg limits*.<sup>6</sup> Each of the Atterberg limits varies with the clay content, type of clay mineral, and ions (cations) contained in the clay. Tests that determine two of these Atterberg limits—the plastic limit and the liquid limit—are frequently used to classify clay soils.

The *plastic limit (PL or  $w_p$ )* is the water content corresponding to the transition between the semi-solid and plastic state. The *liquid limit (LL or  $w_l$ )* is the water content corresponding to the transition between the plastic and liquid state. A third limit that is occasionally used in soils engineering is the *shrinkage limit (SL or  $w_s$ )*, which is the water content corresponding to the transition between a brittle solid and a semi-solid.<sup>7</sup>

The liquid limit test is performed with a special apparatus. A soil sample is placed in a shallow container and the sample is parted in half with a grooving tool. The

<sup>6</sup>Although standard practice varies, it is suggested that Atterberg limits be reported as whole numbers rather than as percentages, to emphasize that they are an index of behavior, not a soil characteristic.

<sup>7</sup>The Atterberg limits are sometimes given the symbols  $w_L$  (liquid limit),  $w_P$  (plastic limit), and  $w_S$  (shrinkage limit).

container is dropped a distance of 0.4 in (10 mm) repeatedly until the sample has rejoined for a length of  $1/2$  in (13 mm). The liquid limit is defined as the water content at which the soil rejoins at exactly 25 blows. The test is repeated at different water contents, and the water content corresponding to the liquid limit is found by interpolation using a *flow curve* (a plot of water content versus logarithm of number of blows,  $N$ ).

When a soil has a liquid limit of 100, the weight of water equals the weight of the dry soil (i.e.,  $w = 100\%$ ). A liquid limit of 50 means that the soil at the liquid limit is two-thirds soil and one-third water.

Sandy soils have low liquid limits—on the order of 20. In such soils, the test is of little significance in judging load-carrying capacities. Silts and clays can have significant liquid limits—most clays have liquid limits less than 100, but they can be as high as 1000.

The plastic limit test consists of rolling a soil sample into a  $1/8$  in (3 mm) thread. The sample will crumble at that diameter when it is at the plastic limit. The sample is remolded to remove moisture and rolled into a thread repeatedly until the plastic limit is reached. The water content is determined for three such samples, and the average value is the plastic limit.

Sands and most silts have no plastic limit at all. They are known as *nonplastic soils*. The test is of little significance in judging the relative load-carrying capacities of such soils. The plastic limit of clays and plastic silts can be from 0 to 100 or more, but it is usually less than 40.

The difference between the liquid and plastic limits is known as the *plasticity index*, PI. The plasticity index indicates the range in moisture content over which the soil is in a plastic condition. In this condition it can be deformed and still hold together without crumbling. A large plasticity index (i.e., greater than 20) shows that considerable water can be added before the soil becomes liquid. The plasticity index correlates with strength, deformation properties, and insensitivity.

$$\text{PI} = \text{LL} - \text{PL} \quad 35.23$$

The shrinkage limit, SL, is the water content at which further drying out of the soil does not decrease the volume of the soil. Below the shrinkage limit, air enters the voids and water content decreases are not accompanied by decreases in volume. The test consists of drying a brick of soil to remove all interstitial (removable) water, and then adding water until all the voids are filled. The difference between the plastic and shrinkage limits is known as the *shrinkage index*, SI. The shrinkage index indicates the range in moisture content over which the soil is in a semi-solid condition.

$$\text{SI} = \text{PL} - \text{SL} \quad 35.24$$

The *consistency* of a clay is the water content relative to the Atterberg limits. This is represented by the *liquidity index*, LI.<sup>8</sup> A liquidity index between 0 and 1 indicates that the water content is between the plastic limit and the liquid limit; a liquidity index greater than one indicates that the water content is above the liquid limit.

$$\text{LI} = \frac{w - \text{PL}}{\text{PI}} \quad 35.25$$

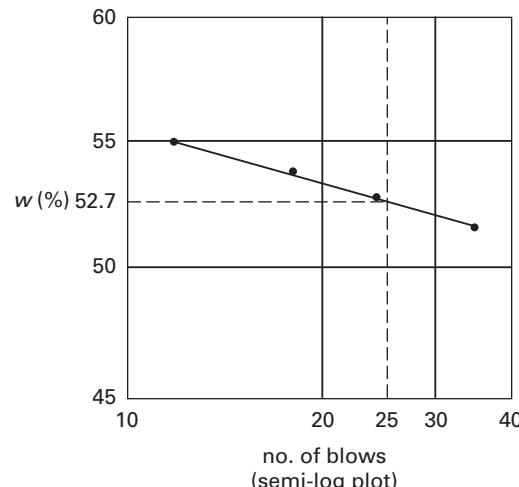

### Example 35.6

Atterberg limit tests were performed on a silty clay. The water contents obtained in the plastic limit test were 31.6%, 33.5%, and 30.9%. The following data were obtained in the liquid limit test. What are the (a) liquid limit, (b) plastic limit, and (c) plasticity index?

no. of blows	water content
12	54.8%
18	54.2%
23	52.9%
35	51.9%

*Solution*

(a) For the liquid limit, plot the logarithm of the number of blows versus the water content. The liquid limit corresponding to the water content at 25 blows is 52.7%. Round to whole number 53%.

(b) The plastic limit is the average of the three test results.

$$\text{PL} = \frac{31.6 + 33.5 + 30.9}{3} = 32$$

(c) The plasticity index is given by Eq. 35.23.

$$\text{PI} = \text{LL} - \text{PL} = 53 - 32 = 21$$

<sup>8</sup>Alternative symbols are IL for liquidity index and IP for plasticity index.

## 15. PERMEABILITY TESTS

*Permeability* of a soil is a measure of continuous voids. It is not enough for a soil to have large voids. The voids must also be connected for water to flow through them. A permeable material supports a flow of water. The flow of water through a permeable aquifer or soil is given by Eq. 35.26, known as *Darcy's law*.

$$Q = vA_{\text{gross}} \quad 35.26$$

$$v = Ki \quad 35.27$$

The gross area in Eq. 35.26 is the total cross-sectional area of the aquifer, not the actual area in flow. Water can only flow through the open spaces between the solids. This open space area is  $nA_{\text{gross}}$ .

Typical values of the coefficient of permeability,  $K$ , are given in Table 35.11. Clays are considered relatively impervious, while sands and gravels are pervious. For comparison, the permeability of concrete is approximately  $10^{-10}$  cm/s.

**Table 35.11** Typical Permeabilities

group symbol	typical coefficient of permeability (cm/s)
GW	$2.5 \times 10^{-2}$
GP	$5 \times 10^{-2}$
GM	$> 5 \times 10^{-7}$
GC	$> 5 \times 10^{-8}$
SW	$> 5 \times 10^{-4}$
SP	$> 5 \times 10^{-4}$
SM	$> 2.5 \times 10^{-5}$
SM-SC	$> 10^{-6}$
SC	$> 2.5 \times 10^{-7}$
ML	$> 5 \times 10^{-6}$
ML-CL	$> 2.5 \times 10^{-7}$
CL	$> 5 \times 10^{-8}$
OL	—
MH	$> 2.5 \times 10^{-7}$
CH	$> 5 \times 10^{-8}$
OH	—

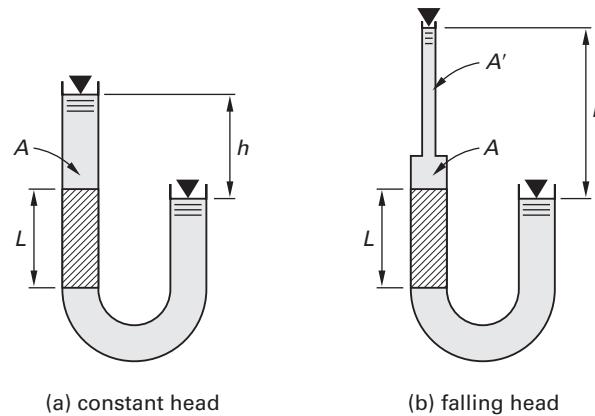

For uniform sands that have  $0.1 \text{ mm} \leq D_{10} \leq 3 \text{ mm}$  and  $C_u \leq 5$ , permeability is approximately given by *Hazen's formula*, Eq. 35.28.  $D_{10}$  is the *effective grain size*—the diameter for which only 10% of the particles are finer. The coefficient  $C$  is 0.4–0.8 for very fine sand (poorly sorted) or fine sand with appreciable fines; 0.8–1.2 for medium sand (well sorted) or coarse sand (poorly sorted); and 1.2–1.5 for coarse sand (well sorted and clean).

$$K_{\text{cm/s}} \approx CD_{10,\text{mm}}^2 \quad 35.28$$

Hazen's formula provides only a crude estimate, and actual values can vary by two orders of magnitude. Accurate values are calculated from controlled permeability tests using constant- or falling-head *permeameters*. (See Fig. 35.8.) In a *constant-head test*, the volume of water,  $V$ , percolating through the soil over time is measured. The test is applicable to coarse-grained soils with  $K > 10^{-3}$  cm/s.

$$K = \frac{VL}{hAt} \quad [\text{constant head}] \quad 35.29$$

**Figure 35.8** Permeameters

In a *falling-head test*, the change in head over time is measured as the water percolates through the soil. The test is applicable to fine-grained soils with  $K < 10^{-3}$  cm/s.

$$K = \frac{A'L}{At} \ln \frac{h_i}{h_f} \quad [\text{falling head}] \quad 35.30$$

The permeability can also be determined with an in situ test in the field. For the *auger-hole method* (a falling-head test), the combination of area and length variables may be known as the *shape factor* or *conductivity coefficient*,  $F$ . For example, for a cased hole below the water table of length  $L$  and radius  $r$  whose impervious casing extends all the way to the hole bottom and whose liquid level rises from  $h_i$  to  $h_f$  in time  $t$  (approaching the water table level), the shape factor and permeability are

$$F = \frac{11r}{2} \quad 35.31$$

$$\begin{aligned} K &= \frac{\pi r^2}{Ft} \ln \frac{h_i}{h_f} \\ &= \frac{2\pi r}{11t} \ln \frac{h_i}{h_f} \quad [\text{auger hole}] \end{aligned} \quad 35.32$$

Other in-field tests can use cased holes with constant head or uncased holes with constant and variable head. The shape factors for these tests are not the same as that in Eq. 35.31.

### Example 35.7

The permeability of a semi-impervious soil was evaluated in a falling-head permeameter whose head decreased from 40 in to 15 in (100 cm to 38 cm) in 5 min. The body diameter was 5 in (13 cm), the standpipe diameter was 0.1 in (0.3 cm), and the sample length was 2 in (5 cm). What was the permeability of the soil?

*SI Solution*

Use Eq. 35.30.

$$\begin{aligned} K &= \frac{A'L}{At} \ln \frac{h_i}{h_f} \\ &= \left( \frac{\frac{1}{4}\pi(0.3 \text{ cm})^2(5 \text{ cm})}{\frac{1}{4}\pi(13 \text{ cm})^2(5 \text{ min})(60 \frac{\text{s}}{\text{min}})} \right) \\ &\quad \times \ln \frac{100 \text{ cm}}{38 \text{ cm}} \\ &= 8.6 \times 10^{-6} \text{ cm/s} \end{aligned}$$

*Customary U.S. Solution*

Use Eq. 35.30.

$$\begin{aligned} K &= \frac{A'L}{At} \ln \frac{h_i}{h_f} \\ &= \left( \frac{\frac{1}{4}\pi(0.1 \text{ in})^2(2 \text{ in})}{\frac{1}{4}\pi(5 \text{ in})^2(5 \text{ min})(60 \frac{\text{sec}}{\text{min}})} \right) \\ &\quad \times \ln \frac{40 \text{ in}}{15 \text{ in}} \\ &= 2.6 \times 10^{-6} \text{ in/sec} \end{aligned}$$

## 16. CONSOLIDATION TESTS

Consolidation tests (also known as *confined compression tests* and *oedometer tests*) start with a disc of soil (usually clay) confined by a metal ring. (See Fig. 35.9.) The faces of the disc are covered with porous plates. The disc sandwich is loaded and submerged in water. Static loads are applied in increments, and the vertical displacement is measured with time for each load increment. The testing time is very long, usually 24 hr per load increment, since seepage through clay soils is very slow. When

the displacement rate levels off, the final void ratio is determined for that increment. The load versus the void ratio for all increments is plotted together as an *e-log p curve*.<sup>9</sup>

Figure 35.9 Consolidation Test Apparatus

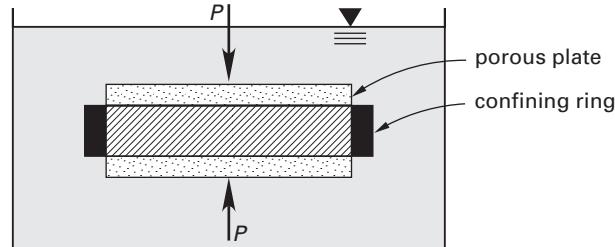

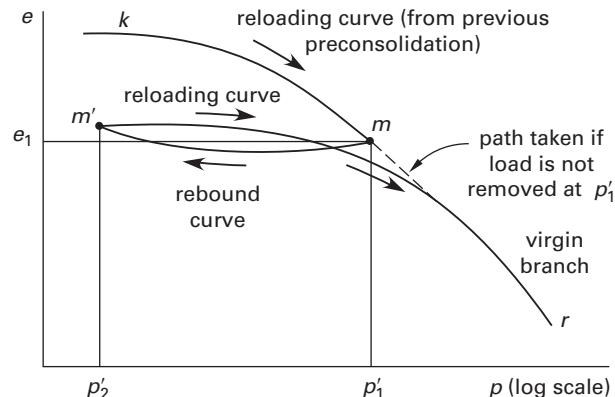

Figure 35.10 shows an *e-log p* curve for a soil sample from which the load has been removed at point *m*, allowing the clay to recover.

Figure 35.10 *e-log p* Curve

The line segment *m-r* is known as the *virgin compression line* or *virgin consolidation line*. In this region, the clay is considered to be *normally consolidated*, which means that the present load has never been exceeded.

Line *m-m'* is a *rebound curve*. Line *m'-r* is known as a *reloading curve*. Such curves result when a normally consolidated clay is unloaded and then reloaded. Since it has carried a higher load in the past, the soil is considered to be *overconsolidated* or *preloaded* in the rebound-reload region.

Notice that point *m'* can only be reached by loading the soil to a pressure of *p*' and then removing the pressure. Although the pressure of the clay at *p*' is essentially the

<sup>9</sup>The use of pressure, *p*, instead of stress, *σ*, for the discussion on consolidation follows convention. Pressure refers to the external forces on the soil. Some soils texts substitute stress for pressure to emphasize that the soil response is dependent on internal forces in the soil, but otherwise the methodology is exactly the same.

same as at the start of the test, the void ratio has been reduced.

The *overconsolidation ratio*, OCR, is defined by Eq. 35.33.  $p'_o$  is the present or in situ overburden pressure;  $p'_{\max}$  is the maximum past pressure or *preconsolidation pressure*. An overconsolidation ratio of 1 means that the soil is normally consolidated; an overconsolidation ratio greater than 1 means that the soil is overconsolidated. In rare circumstances, such as during construction or rapid underwater deposition, a soil may be “underconsolidated”; that is, it has not yet come to equilibrium with its present load.

$$\text{OCR} = \frac{p'_{\max}}{p'_o} \quad 35.33$$

The shape of the  $e$ -log  $p$  curve will depend on the degree of remolding or disturbance, as shown in Fig. 35.11. A highly disturbed soil will show a gradual transition between overconsolidated and normally consolidated behavior.

Laboratory results can be used to find the preconsolidation pressure (point  $m$  in Fig. 35.10). One procedure is the *Casagrande Method*, as illustrated in Fig. 35.12. This procedure starts by drawing two lines—a tangent line and a horizontal line—through the point of maximum curvature, which is determined by eye. The resulting angle is bisected. Then a tangent extension (line  $k$ ) is drawn to the virgin compression line. The intersection of this tangent and the bisection line defines the preconsolidation pressure,  $p'_{\max}$ .

The field virgin compression line, line  $k$  in Fig. 35.12, can be used to predict consolidation of the soil under any loading greater than  $p'_{\max}$ . The *compression index*,  $C_c$ , or *compressibility index*, is the negative of the logarithmic slope of line  $k$  and is given by Eq. 35.34, where points 1 and 2 correspond to any two points on line  $k$ .<sup>10</sup>

$$C_c = -\frac{e_1 - e_2}{\log_{10} \frac{p'_1}{p'_2}} \quad 35.34$$

It is common practice to plot strain,  $\epsilon$ , versus log  $p$  for consolidation test data, as well as void ratio versus log  $p$ , as shown in Fig. 35.10. The slope of the  $e$ -log  $p$  line is  $C_{\epsilon c}$  and is related to the compression index,  $C_c$ .

$$C_{\epsilon c} = \frac{C_c}{1 + e_0} \quad 35.35$$

If the clay is soft and near its liquid limit, the compression index can be approximated by Eq. 35.36.

$$C_c \approx 0.009(\text{LL} - 10) \quad 35.36$$

<sup>10</sup>Although the compression index is, strictly speaking, the slope of the virgin compression line and therefore negative, it is typically reported and used as a positive number. Equation 35.34 is a convenient form for calculating  $C_c$  as a positive number.

When the loading is removed from a soil sample, it will have a tendency to swell. The *swelling index* and *reconsolidation index* can be found from the (negative of the) logarithmic slopes of the rebound and reloading curves, respectively. For practical purposes, these indices are equal to each other and found as the slope of the line that bisects the rebound and reload curves.

Figure 35.11 Consolidation Curves

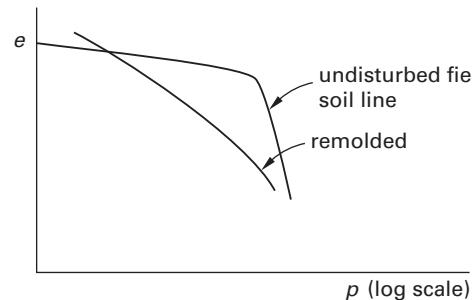

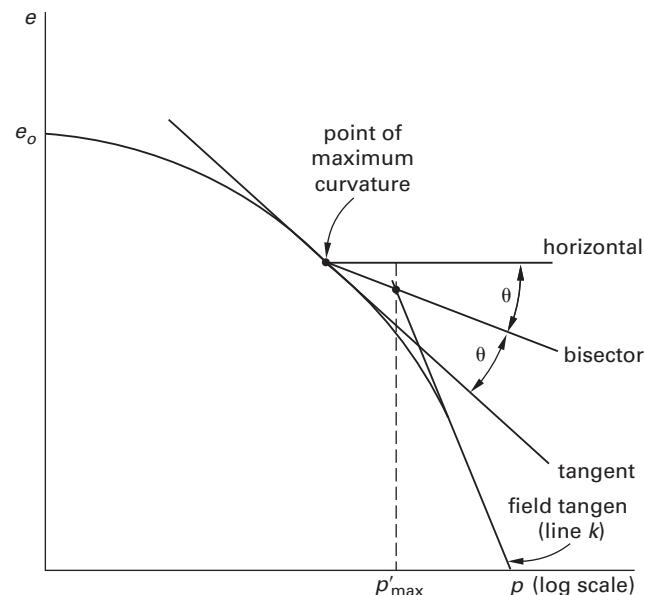

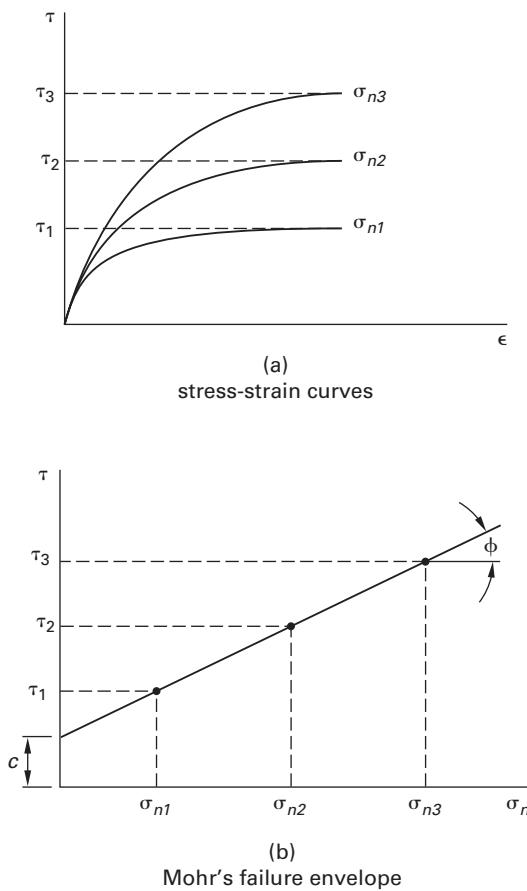

Figure 35.12 Casagrande Method

## 17. DIRECT SHEAR TEST

The *direct shear test* is a relatively simple test used to determine the relationship of shear strength to consolidation stress. In this test, a disc of soil is inserted into the direct shear box. The box has a top half and a bottom half that can slide laterally with respect to each other. A normal stress,  $\sigma_n$ , is applied vertically, and then one half of the box is moved laterally relative to the other at a constant rate. Measurements of vertical and horizontal displacement,  $\delta$ , and horizontal shear load,  $P_h$ , are taken. The test is usually repeated at three different vertical normal stresses. (See Fig. 35.13.)

**Figure 35.13** Graphing Direct Shear Test Results

Because of the box configuration, failure is forced to occur on a horizontal plane. Results from each test are plotted as horizontal displacement versus horizontal stress,  $\tau_h$  (horizontal force divided by the nominal area). Failure is determined as the maximum value of horizontal stress achieved. The vertical normal stress and failure stress from each test are then plotted in Mohr's circle space of normal stress versus shear stress.

A line drawn through all of the test values is called the *failure envelope* (*failure line* or *rupture line*). The equation for the failure envelope is given by *Coulomb's equation*, which relates the strength of the soil,  $S$ , to the normal stress on the failure plane.<sup>11,12,13</sup>

$$S = \tau = c + \sigma \tan \phi \quad 35.37$$

$\phi$  is known as the *angle of internal friction*.<sup>14</sup>  $c$  is the *cohesion intercept*, a characteristic of cohesive soils.

<sup>11</sup>Equation 35.37 is also known as the *Mohr-Coulomb equation*.

<sup>12</sup>The ultimate shear strength may be given the symbol  $S$  in some soils books.

<sup>13</sup> $\tau$  and  $\sigma$  in Coulomb's equation are the shear stress and normal stress, respectively, on the failure plane at failure.

<sup>14</sup>In a physical sense, the angle of internal friction for cohesionless soils is the angle from the horizontal naturally formed by a pile. For example, a uniform fine sand makes a pile with a slope of approximately 30°. For most soils, the natural angle of repose will not be the same as the angle of internal friction, due to the effects of cohesion.

Representative values of typical strength characteristics  $\phi$  and  $c$  are given in Table 35.12.

**Table 35.12** Typical Strength Characteristics (above the water table)

group symbol	cohesion (as compacted), $c$ (lbf/ft <sup>2</sup> (kPa))	cohesion (saturated), $c_{sat}$ (lbf/ft <sup>2</sup> (kPa))	effective stress friction angle, $\phi$
GW	0	0	>38°
GP	0	0	>37°
GM	—	—	>34°
GC	—	—	>31°
SW	0	0	38°
SP	0	0	37°

OH	—	—	—

(Multiply lbf/ft<sup>2</sup> by 0.04788 to obtain kPa.)

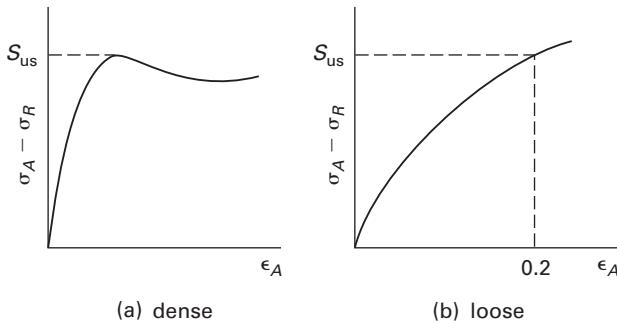

## 18. TRIAXIAL STRESS TEST

The *triaxial test* is a more sophisticated method than the direct shear test for determining the strength of soils. In the triaxial test apparatus, a cylindrical sample is stressed completely around its peripheral surface by pressurizing the sample chamber. This pressure is referred to as the *confining stress*. Then, the soil is loaded vertically to failure through a top piston. The confining stress is kept constant while the axial stress is varied. The radial component of the confining stress is called the *radial stress*,  $\sigma_R$ , and represents the minor principal stress,  $\sigma_3$ . The combined stresses at the ends of the sample (confining stress plus applied vertical stress) are called the *axial stress*,  $\sigma_A$ , and represent the major principal stress,  $\sigma_1$ .<sup>15</sup>

Results of a triaxial test at a given chamber pressure are plotted as a stress-strain curve. Two such examples are illustrated in Fig. 35.14. The axial component of strain is measured and recorded. The stress is the difference between the axial and radial stresses, also called the *deviator stress*,  $\sigma_D$ . The point of failure is usually chosen as the maximum deviator stress in the test. (See Fig. 35.14(a).) It can alternatively be chosen as the stress difference for which the strain is 20%, if the test does not reach a maximum before then. (See Fig. 35.14(b).)

<sup>15</sup>In reality, the triaxial test apparatus is a "biaxial" device because it controls stresses in only two directions: radial and axial.

**Figure 35.14** Triaxial Test Stress-Strain Curves

The normal and shear stresses on any plane can be found from the combined stress equations. The angle  $\alpha$  is measured counterclockwise from the horizontal (i.e., counterclockwise from the plane that  $\sigma_1$  acts on). Compression is considered positive.

$$\sigma_\alpha = \frac{1}{2}(\sigma_A + \sigma_R) + \frac{1}{2}(\sigma_A - \sigma_R)\cos 2\alpha \quad 35.38$$

$$\tau_\alpha = \frac{1}{2}(\sigma_A - \sigma_R) \sin 2\alpha \quad 35.39$$

These equations generate points on Mohr's circle, which can easily be constructed once  $\sigma_A$  and  $\sigma_R$  are known. Representative test results are shown in Fig. 35.15 for two different samples of the same soil that were both tested to failure. The failure envelope is the line that is tangent to all of the Mohr's circles at failure.<sup>16</sup> The ultimate shear strength,  $S_u$ , can be read directly from the  $y$ -axis or can be calculated from Eq. 35.37.

For drained sands and gravels and for normally consolidated clays, the cohesion,  $c$ , is zero. Therefore, it is theoretically possible to draw the rupture line with only one test. (See Fig. 35.16.)

The angle of internal friction for cohesionless soils can be calculated from Eq. 35.40.

$$\frac{\sigma_1}{\sigma_3} = \frac{1 + \sin \phi}{1 - \sin \phi} \quad [c = 0] \quad 35.40$$

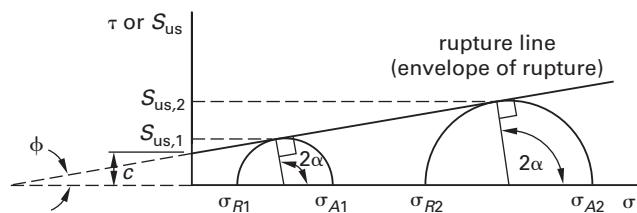

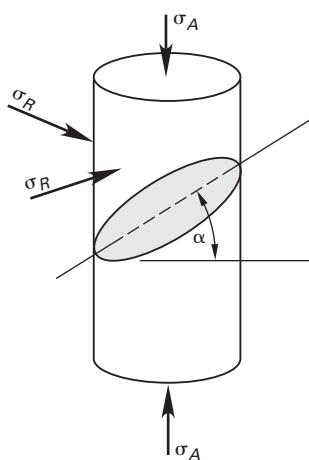

The plane of failure is inclined at the following angle.

$$\alpha = 45^\circ + \frac{1}{2}\phi \quad 35.41$$

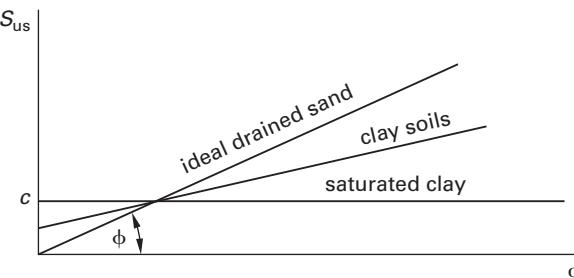

For saturated clays in quick (undrained) shear, it is commonly assumed that  $\phi = 0^\circ$ . This would be represented as a horizontal rupture line. For this condition only, the undrained strength,  $S_{us}$ , is

$$S_{\text{us}} = c = \frac{\sigma_D}{2} \quad 35.42$$

**Figure 35.15** Mohr's Circle of Stress

**Figure 35.16** Rupture Lines

If a soil is saturated, an increase in load may be supported by either the soil grains at their contact points or by an increase in the pore water pressure. How much each mode contributes to the support depends on the rate of loading and the permeability of the soil. Since water cannot carry a shear stress, the effective stress provides the shear strength of soils. The effective stress is the stress that is carried by the soil grains. The strength can be calculated from Eq. 35.43, where  $c'$  and  $\phi'$  are the *effective stress parameters*.

$$s = c' + \sigma' \tan \phi' \quad 35.43$$

The various categories of triaxial tests are shown in Table 35.13. Triaxial tests can be performed on consolidated or unconsolidated specimens, and they can be performed drained or undrained.

<sup>16</sup>In the direct shear test, the stresses on the failure plane are measured directly, because the horizontal plane is forced to be the failure plane. In the triaxial test, the measured stresses are principal stresses, and therefore, a Mohr's construction must be made to determine the stresses on the failure plane.

**Table 35.13** Categories of Triaxial Test

	drained	undrained
consolidated	S-test CD test	R-test CU test
unconsolidated	(not performed)	Q-test UU test

The term “consolidated” refers to the state of the sample just prior to the shearing phase (when the axial stress,  $\sigma_A$ , is varied). In most triaxial tests, the soil is consolidated, which means that a stress simulating the in situ overburden stress is applied and the soil is allowed to drain freely until it is at equilibrium with this stress. The consolidation stress is applied as the pressure in the surrounding chamber.

The terms “drained” and “undrained” refer to conditions during the shearing phase. The distinction is only important for specimens that are fully saturated; for dry or partially saturated specimens, the behavior in an undrained test is similar to that in a drained test. In an undrained test, no pore water is allowed to move in or out of the sample, and the test is usually performed rapidly. In these tests, the shearing phase results in pore water pressure development. In a drained test, water is allowed to move in or out freely, and the test is performed slowly enough that the water drains before pore water pressure develops. The speed of testing is determined by the soil permeability. Clay soils must be tested quite slowly, and a drained test may take several weeks.

A slow, drained test following consolidation is known as an *S-test (slow test)* or a *consolidated-drained test (CD test)*. A rapid, undrained test following consolidation is known as an *R-test* or *consolidated-undrained test (CU test)*. The *Q-test (quick test)* is also known as an *unconsolidated-undrained test (UU test)*.<sup>17</sup> In the Q-test, a chamber pressure is applied to the soil prior to the shearing phase, but the soil is not allowed to drain or consolidate. Such a test is justified only with high-permeability (e.g.,  $10^{-3}$  cm/s or more) soils.<sup>18</sup>

R-tests are used to determine the effective stress parameters,  $c'$  and  $\phi'$ . In the absence of pore pressure measurements, though, R-tests can only determine the total stress parameters  $c$  and  $\phi$ .

### Example 35.8

A sample of dry sand was taken and a triaxial test was performed. The added axial stress causing failure was 5.43 tons/ $\text{ft}^2$  (520 kPa) when the radial stress was 1.5 tons/ $\text{ft}^2$  (145 kPa). (a) What is the angle of internal friction? (b) What is the angle of the failure plane?

<sup>17</sup>The S-test, R-test, and Q-test designations are by the U.S. Army Corps of Engineers. The letter “R” for the R-test was chosen because R is between Q and S in the alphabet. The “R” does not have a meaning.

<sup>18</sup>There is no category for unconsolidated, drained testing. The theoretical justifications for performing Q-tests do not apply to drained testing of unconsolidated specimens.

### SI Solution

Draw a Mohr's circle to plot the stresses in two dimensions. The axial stress at failure is the combination of axial and radial loads.

$$\begin{aligned}\sigma_{A,f} &= p_R + p_A \\ &= 145 \text{ kPa} + 520 \text{ kPa} \\ &= 665 \text{ kPa}\end{aligned}$$

The center of the Mohr's circle is

$$\frac{\sigma_R + \sigma_{A,f}}{2} = \frac{145 \text{ kPa} + 665 \text{ kPa}}{2} = 405 \text{ kPa}$$

The radius of the circle is the distance from the center of the circle to the radial stress.

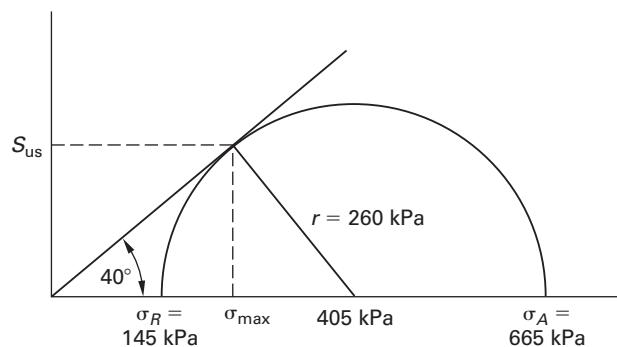

$$405 \text{ kPa} - 145 \text{ kPa} = 260 \text{ kPa}$$

(a) The failure envelope is tangent to the Mohr's circle. (It is assumed that  $c = 0$  for dry sand.) Therefore, from trigonometry,

$$\phi = \arcsin \frac{260 \text{ kPa}}{405 \text{ kPa}} = 40^\circ$$

(b) The angle of the failure plane is given by Eq. 35.41.

$$\begin{aligned}\alpha &= 45^\circ + \frac{1}{2}\phi = 45^\circ + \left(\frac{1}{2}\right)(40^\circ) \\ &= 65^\circ\end{aligned}$$

### Customary U.S. Solution

Draw a Mohr's circle to plot the stresses in two dimensions. The axial stress at failure is the combination of axial and radial loads.

$$\begin{aligned}\sigma_{A,f} &= p_R + p_A \\ &= 1.5 \frac{\text{tons}}{\text{ft}^2} + 5.43 \frac{\text{tons}}{\text{ft}^2} \\ &= 6.93 \frac{\text{tons}}{\text{ft}^2}\end{aligned}$$

The center of the Mohr's circle is

$$\frac{\sigma_R + \sigma_{A,f}}{2} = \frac{1.5 \frac{\text{tons}}{\text{ft}^2} + 6.93 \frac{\text{tons}}{\text{ft}^2}}{2} = 4.215 \frac{\text{tons}}{\text{ft}^2}$$

The radius of the circle is the distance from the center of the circle to the radial stress.

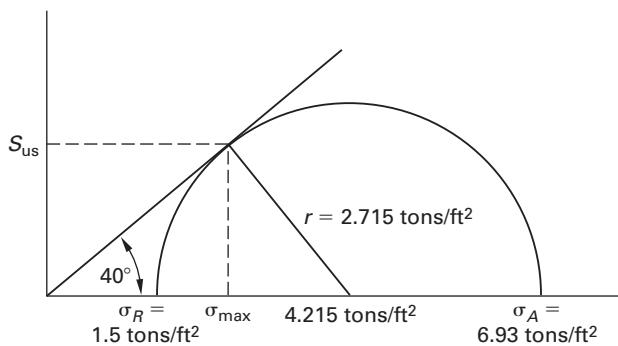

$$4.215 \frac{\text{tons}}{\text{ft}^2} - 1.5 \frac{\text{tons}}{\text{ft}^2} = 2.715 \frac{\text{tons}}{\text{ft}^2}$$

(a) The failure envelope is tangent to the Mohr's circle. (It is assumed that  $c = 0$  for dry sand.) Therefore, from trigonometry,

$$\phi = \arcsin \frac{2.715 \frac{\text{tons}}{\text{ft}^2}}{4.215 \frac{\text{tons}}{\text{ft}^2}} = 40^\circ$$

(b) The angle of the failure plane is given by Eq. 35.41.

$$\alpha = 45^\circ + \frac{1}{2}\phi = 45^\circ + \left(\frac{1}{2}\right)(40^\circ) = 65^\circ$$

## 19. VANE-SHEAR TEST

The shear strength of a low-strength, homogeneous cohesive soil (e.g., clay) can be measured in situ by use of a *vane-shear apparatus*, consisting of a four-bladed vane on a vertical shaft. The blades are pushed into the soil and a torque is applied to the shaft until the apparatus rotates. When the soil is stressed to its shear strength, the vanes will rotate in the soil. Since the soil fails along a cylindrical surface, the shearing resistance can be calculated from the vane dimensions and the applied torque.

The sensitivity of the soil can be determined if the test is repeated after turning the sample several times and allowing the soil to remold.

## 20. UNCONFINED COMPRESSIVE STRENGTH TEST

In an *unconfined compressive strength test*, a cylinder of cohesive soil is loaded axially to compressive failure. Unlike in the triaxial test, there is no radial stress applied before the shearing phase of testing. This test can only be performed on soils that can stand without confinement, usually clays. The unconfined compressive strength test is equivalent to a UU test (Q-test) in which the chamber pressure is zero.

The unconfined compressive strength is calculated using Eq. 35.44. The undrained shear strength is calculated as one half of the unconfined compressive strength.

$$S_{uc} = \frac{P}{A} \quad 35.44$$

$$s_u = \frac{S_{uc}}{2} \quad 35.45$$

## 21. SENSITIVITY

Clay will become softer as it is worked, and clay soils can turn into viscous liquids during construction. This tendency, known as *sensitivity*, is determined by measuring the ultimate strength of two samples, one that is undisturbed before testing and the other that has been fully disturbed, usually by mechanically remolding the soil. Although sensitivity is normally determined as the ratio of unconfined compression strengths, the two strength values compared could be from any two identical tests. Table 35.14 gives the four classes of sensitivity.

$$S_t = \frac{S_{\text{undisturbed}}}{S_{\text{remolded}}} \quad 35.46$$

**Table 35.14** Sensitivity Classifications

sensitivity	class
1–4	insensitive clays
4–8	sensitive
8–16	extra sensitive
> 16	quick

## 22. CALIFORNIA BEARING RATIO TEST

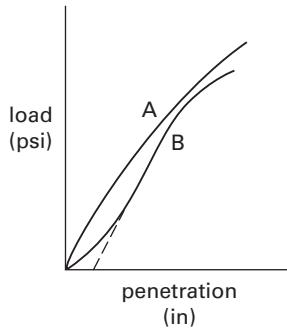

The *California bearing ratio* (CBR) test is used to determine the suitability of a soil for use as a subbase in pavement sections.<sup>19</sup> It is most reliable when used to

<sup>19</sup>California's Department of Transportation (CALTRANS) was the first to make use of the CBR test. However, other states and the Army Corps of Engineers have adopted CBR testing techniques. These states have, generally, retained the California bearing ratio test name for the test.

test cohesive soils. The test measures the relative load required to cause a standard 3 in<sup>2</sup> (19.3 cm<sup>2</sup>) plunger to penetrate a water-saturated soil specimen at a specific rate to a specific depth. The word "relative" is used because the actual load is compared to a standard load derived from a sample of crushed stone. The ratio is multiplied by 100, and the result is reported without a percentage symbol.

The resulting data will be in the form of inches of penetration versus load. This data can be plotted as shown in Fig. 35.17. If the plot is concave upward (curve B), the steepest slope is extended downward to the *x*-axis. This point is taken as the zero penetration point, and all penetration values are adjusted accordingly.

**Figure 35.17** Plotting CBR Test Data

Standard CBR loads for crushed stone are given in Table 35.15. For a plunger of 3 in<sup>2</sup> (19.3 cm<sup>2</sup>), the CBR is the ratio of the load for a 0.1 in (2.54 mm) penetration divided by 1000 lbf/in<sup>2</sup> (6900 kPa). The CBR for 0.2 in (5.08 mm) should also be calculated. The test should be repeated if  $CBR_{0.2} > CBR_{0.1}$ . If the results are similar,  $CBR_{0.2}$  should be used. Table 35.16 gives typical CBR values.

$$CBR = \frac{\text{actual load}}{\text{standard load}} \times 100 \quad 35.47$$

**Table 35.15** Standard CBR Loads

depth of penetration (in)	standard load (lbf/in <sup>2</sup> (MPa))
0.1	1000 (7)
0.2	1500 (10)
0.3	1900 (13)
0.4	2300 (16)
0.5	2600 (18)

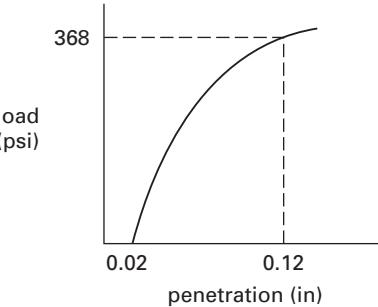

(Multiply in by 25.4 to obtain mm.)  
(Multiply lbf/in<sup>2</sup> by 0.00689 to obtain MPa.)

**Table 35.16** Typical CBR Values

group symbol	range of CBR values

### Example 35.9

The following load data are collected for a 3 in<sup>2</sup> plunger test. What is the California bearing ratio?

penetration (in)	load (lbf/in <sup>2</sup> )
0.020	0
0.025	20
0.050	130
0.075	230
0.100	320
0.125	380
0.150	470
0.175	530
0.200	600
0.250	700
0.300	830

**Solution**

After graphing the data, it is apparent that a 0.02 in correction is required. Therefore, the 0.1 in load is read from the graph as a 0.12 in load.

(Since a 0.02 deflection was recorded for a zero load, the first 0.02 of soil must consist of uncompacted fluff, which would not occur in a roadbed.)

From Eq. 35.47, the California bearing ratio is

$$\text{CBR} = \frac{\text{actual load}}{\text{standard load}} \times 100$$

Therefore,

$$\begin{aligned}\text{CBR}_{0.1} &= \frac{368 \frac{\text{lbf}}{\text{in}^2}}{1000 \frac{\text{lbf}}{\text{in}^2}} \times 100 \\ &= 36.8 \\ \text{CBR}_{0.2} &= \frac{645 \frac{\text{lbf}}{\text{in}^2}}{1500 \frac{\text{lbf}}{\text{in}^2}} \times 100 \\ &= 43.0\end{aligned}$$

Since  $\text{CBR}_{0.2}$  is greater than  $\text{CBR}_{0.1}$ , the test should be repeated.

**23. PLATE BEARING VALUE TEST**

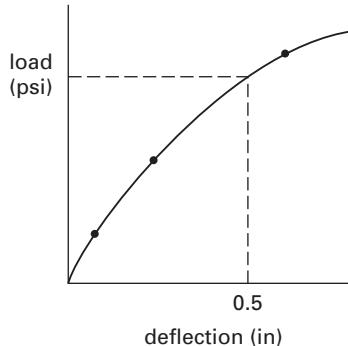

The *plate bearing value test* is performed on compacted soil in the field and provides an indication of the shear strength of pavement components. A standard diameter round steel plate is set over the soil on a bedding of fine sand or plaster of Paris. Smaller diameter plates are placed on top of the bottom plate to ensure rigidity. After the plate is seated by a quick but temporary load, it is loaded to a deflection of about 0.04 in (1 mm). This load is maintained until the deflection rate decreases to 0.001 in/min (0.03 mm/min). The load is then released. The deflection prior to loading, the final deflection, and the deflection at each minute are recorded.

The test is repeated 10 times. For each repetition of each load, the endpoint deflection is found for which the deflection rate is exactly 0.001 in/min (0.03 mm/min). The loads are then corrected for dead weights of jacks, plates, and so on.

The corrected load versus the corrected deflection is graphed for the 10th repetition. (See Fig. 35.18.) The bearing value is the interpolated load that would produce

a deflection of 0.5 in (12 mm). The *subgrade modulus* (*modulus of subgrade reaction*),  $k$ , is the slope of the line (in psi per inch) in the loading range encountered by the soil. Typical values are given in Table 35.17.

**Figure 35.18** 10th Repetition Bearing Load

**Table 35.17** Typical Values of the Subgrade Modulus

group symbol	range of subgrade modulus, $k$ (psi/in (kPa/mm))
GW	300–500 (80–140)

MH	50–100 (14–27)
CH	50–150 (14–41)
OH	25–100 (6.8–27)

(Multiply psi/in by 0.2714 to obtain kPa/mm.)

**24. HVEEM'S RESISTANCE VALUE TEST**

*Hveem's resistance value test* is performed to evaluate the suitability of a soil for use in pavement sections. The term "resistance" refers to the ability of a soil to resist lateral deformation when a vertical load acts upon it. When displacement does occur, the soil moves out and away from the applied load.

The *R-value* (*resistance value*) of a soil is measured in a *stabilometer test*. The *R-value* will range from zero (the resistance of water) to 100 (the approximate resistance of steel). Typical values are clay, 5–15; sandy clay, 10–20; clayey silts, 20–35; sandy silts, 20–55; silty sands, 25–70; sand, 40–75; gravel, 20–80; and good crushed rock, 75–90.

The *R-value* is determined using soil samples that are compacted as they would be during normal construction. They are tested as near to saturation as possible to give the lowest expected *R-value*. Thus, the *R-value* represents the worst possible state the soil might attain during use.

When a compacted soil expands due to the absorption of water, damage such as pavement distortion may result. A determination of expansion pressures is usually performed along with the *R-value* test.

## 25. CLASSIFICATION OF ROCKS

Geologists classify rocks into three groups, according to the major Earth processes that formed them. The three rock groups are igneous, sedimentary, and metamorphic rocks.

*Igneous rock* is formed from melted rock that has cooled and solidified. When rock is buried deep within the Earth, it melts due to the high pressure and temperature. When magma cools slowly, usually at depths of thousands of feet, crystals grow from the molten liquid, forming a coarse-grained rock. When magma cools rapidly, usually at or near the Earth's surface, the crystals are extremely small, and a fine-grained rock results. Rocks formed from cooling magma are known as *intrusive igneous rocks*; rocks formed from cooling lava are known as *extrusive igneous rocks*. A wide variety of rocks are formed by different cooling rates and different chemical compositions of the original magma. Obsidian (volcanic glass), granite, basalt, and andesite porphyry are four of the many types of igneous rock. *Granite* is composed of three main minerals: quartz, mica, and feldspar.

*Sedimentary rocks* such as chalk, sandstone, and clay are formed at the surface of the Earth. They are layered accumulations of sediments—fragments of rocks, minerals, or animal or plant material. Temperatures and pressures are low at the Earth's surface, and sedimentary rocks are easily identified by their appearance and by the diversity of minerals they contain. Most sedimentary rocks become cemented together by minerals and chemicals or are held together by electrical attraction. Some, however, remain loose and virtually unconsolidated. The layers are originally parallel to the Earth's surface. Sand and gravel on beaches or in river bars consolidate into *sandstone*. Compacted and

dried mud flats harden into *shale*. Sediments of mud and shells settling on the floors of lagoons form sedimentary *chalk*.

There are several ways to classify sedimentary rocks, but a common one is according to the process which led to their deposition. Rocks formed from particles of older eroded rocks are known as *clastic sedimentary rocks*. These include sandstones and clays. Rocks formed from plant and animal remains are known as *organic sedimentary rocks*. Examples include limestone, chalk, and coal. Rocks formed from chemical action are known as *chemical sedimentary rocks*. These include sedimentary iron ores, evaporites such as rock salt (halite), and to some extent, flint, limestone, and chert.

Sometimes sedimentary and igneous rocks buried in the Earth's crust are subjected to pressures so intense or heat so high that the rocks are completely changed. They then become *metamorphic rocks*. Common metamorphic rocks include slate, schist, gneiss, and marble. The process of metamorphism does not melt the rocks, but it does transform them into denser, more compact rocks. New minerals are created, either by rearrangement of mineral components or by reactions with fluids that enter the rocks. Pressure or temperature can even change previously metamorphosed rocks into new types. In this way, limestone can become marble and shale can be converted into slate.

## 26. CHARACTERIZING ROCK MASS QUALITY

The suitability of rock for certain exposures (e.g., water scour, tunneling, and foundation compression) has been characterized by its *rock quality designation* (RQD) using a method proposed by D.U. Deere in 1967. RQD is a rough measure of the degree of fracturing (jointing) in a rock mass, measured as a percentage of drill core lengths that are unfragmented. Rock cores are taken using ASTM D6032 procedures. Then, the lengths of naturally-occurring individual core segments longer than 4 in (10.2 cm) and that are hard and sound are summed. The RQD is the percentage of the core run that consists of pieces longer than 4 in (10.2 cm).

$$\text{RQD} = \frac{\sum L_i}{L_{\text{core}}} \times 100\% \quad 35.48$$

If pieces are broken by the recovery or handling process, the broken segments are assembled and counted as single lengths. Judgment is required in some cases. To minimize core recovery damage, cores should have diameters larger than 2<sup>1/8</sup> in (corresponding to the NX core size) and be obtained from double-tube core barrels, although decades of experience has shown that use of smaller diameter NQ cores provides reliable samples.

Rock quality is characterized as very good ( $RQD > 90\%$ ), good ( $90\text{--}75\%$ ), fair ( $75\text{--}50\%$ ), poor ( $50\text{--}25\%$ ), or very poor ( $RQD < 25\%$ ). Soil is assumed to be soil-like with regard to scour potential when  $RQD < 50\%$ . Table 35.18 contains recommendations for allowable bearing pressure for RQD categories.

$RQD$  is not the only method of characterizing rock mass quality. Other characteristics include unconfined compressive strength (ASTM D2938), slake durability (useful on metamorphic and sedimentary rocks such as slate and shale), soundness (AASHTO T104), and abrasion (AASHTO T96, the “Los Angeles Abrasion Test”).  $RQD$  has also been incorporated (as one of multiple quantified parameters) into two *rock mass rating systems*: the *Rock Mass Rating (RMR) System* (ca. 1972) and the *Q-system* (ca. 1974).

## 27. GEOTECHNICAL SAFETY AND RISK MITIGATION

Geotechnical designs, sequencing, and construction methods can have significant unintended impacts on personnel—particularly those involved in construction. In addition to being needed for structural design, soil characteristics are used to evaluate soil stability and the risks of soil collapse during excavation and construction. Access points and depths of cuts, shoring and shields, slopes and benches, piles and storage, temporary stabilization, supervision and monitoring, access, and personal protective equipment are some of the subjects affected by soil characteristics. In the United States, in addition to state and local agencies, safety in the workplace is under the purview of the Occupational Safety and Health Administration (OSHA).<sup>20</sup>

## 1. SHALLOW FOUNDATIONS

A *foundation* is the part of an engineered structure that transmits the structure's forces into the soil or rock that supports it. The shape, depth, and materials of the foundation design depend on many factors including the structural loads, the existing ground conditions, and local material availability.

The term *shallow foundation* refers to a foundation system in which the depth of the foundation is shallow relative to its width, usually  $D_f/B \leq 1$ . This category of foundations includes spread footings, continuous (or wall) footings, and mats.

The main considerations in designing shallow foundations are ensuring against bearing capacity failures and excessive settlements. *Bearing capacity* is the ability of the soil to support the foundation loads without shear failure. *Settlement* is the tendency of soils to deform (densify) under applied loads. Since structures can tolerate only a limited amount of settlement, foundation design will often be controlled by settlement criteria, because soil usually deforms significantly before it fails in shear. Methods of calculating foundation settlements are reviewed in Chap. 40. The most damaging settlements are *differential settlements*—those that are not uniform across the supported area. Excessive settlements may only lead to minor damage such as cracked floors and walls, windows and doors that do not operate correctly, and so on. However, bearing capacity failures have the potential to cause major damage or collapse.

## 2. SAND VERSUS CLAY

Ordinarily, sand makes a good foundation material. Sand is usually strong, and it drains quickly. It may have an initial, “immediate” settlement upon first loading, but this usually is small and is complete before most architectural elements (drywall, brick, glass), which are brittle and more susceptible to settlement damage, are constructed. However, it behaves poorly in excavations because it lacks cohesion. When sand is loose and saturated, it can become “quick” (i.e., liquefy), and a major loss in supporting strength occurs.

Clay is generally good in excavations but poor in foundations. Clay strength is usually lower than that of sand. Clays retain water, are relatively impermeable, and do not drain freely. Settlement in clays continues beyond the end of construction, and significant settlement can continue for years or even indefinitely. Large volume changes result from *consolidation*, which is the squeezing out of water from the pores as the soil comes to equilibrium with the applied loads.

A slightly different approach to calculating bearing capacity is used for sands and clays. Clays are not free-draining, so an undrained approach is used as the critical condition. But soils do not always fall into a pure category of “sand” or “clay.” Silt, for example, is an intermediate soil type that will behave like a sand or a clay depending on the fraction of clay minerals it possesses. Many soils are a mixture of sand, silt, and clay. It is necessary to use engineering judgment when applying the bearing capacity equations to intermediate soils.

## 3. GENERAL CONSIDERATIONS FOR FOOTINGS

A *footing* is an enlargement at the base of a load-supporting column that is designed to transmit forces to the soil. The area of the footing will depend on the load and the soil characteristics. Several types of footings are used, including spread and continuous footings, which are shown in Fig. 36.1. A *spread footing* is a footing used to support a single column. This is also known as an *individual column footing* or an *isolated footing*. A *continuous footing*, also known as a *wall footing* or *strip footing*, is a long footing supporting a continuous wall. A *combined footing* is a footing carrying more than one column. A *cantilever footing* is a combined footing that supports a column and an exterior wall or column.

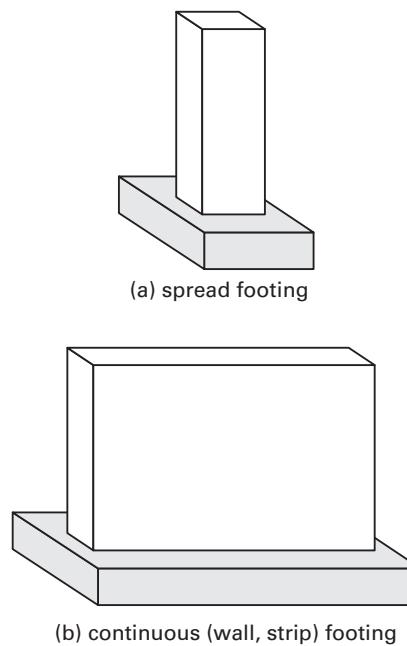

Footings should be designed according to the following general considerations.

- The footing should be located below the frost line and below the level affected by seasonal moisture content changes.
- Footings do not need to be any lower than the bottom of the highest inadequate stratum (layer).

Inadequate strata include disturbed or compressible soils, uncompacted fills, and soils that are susceptible to erosion or scour.

- The foundation should be safe against overturning, sliding, and uplift. The resultant of the applied load should coincide with the middle third of the footing.
- The allowable soil pressure should not be exceeded.
- Loose sand should be densified prior to putting footings on it. “Loose” is roughly defined as  $D_r < 50\%$  for natural sands and the relative compaction (RC) < 90% (modified Proctor) for compacted sands or fill.
- Footings should be sized to the nearest 3 in (0.075 m) greater than or equal to the theoretical size.

**Figure 36.1** Types of Footings

## 4. ALLOWABLE BEARING CAPACITY

The *allowable bearing capacity* (also known as the *net allowable bearing pressure* or *safe bearing pressure*) is the net pressure in excess of the overburden stress that will not cause shear failure or excessive settlements. This is the soil pressure that is used to design the foundation. (The term “allowable” means that a factor of safety has already been applied.) When data from soil tests are unavailable, Table 36.1 can be used for preliminary calculations.

## 5. GENERAL BEARING CAPACITY EQUATION

With *general shear failures*, the soil resists an increased load until a sudden failure occurs. *Local shear failure* occurs in looser, more compressible soils and at high

**Table 36.1** Typical Allowable Soil Bearing Capacities\*

type of soil	allowable pressure	
	(tons/ft <sup>2</sup> )	(kPa)
massive crystalline bedrock	2	200
sedimentary and foliated rock	1	100
sandy gravel and/or gravel (GW and GP)	1	100
sand, silty sand, clayey sand, silty gravel, and clayey gravel (SW, SP, SM, SC, GM, and GC)	0.75	75
clay, sandy clay, silty clay, and clayey silt (CL, ML, MH, and CH)	0.5	50

(Multiply tons/ft<sup>2</sup> by 95.8 to obtain kPa.)

\*inclusive of a factor of safety

bearing pressures. The boundaries between these types of behavior are not distinct, and the methods of calculating general shear failure are commonly used for most soil conditions.

The *ultimate (or gross) bearing capacity* for a shallow continuous footing is given by Eq. 36.1, which is known as the *Terzaghi-Meyerhof equation*. The equation is valid for both sandy and clayey soils.  $p_q$  is an additional surface surcharge, if any.

$$q_{ult} = \frac{1}{2}\rho g B N_\gamma + c N_c + (p_q + \rho g D_f) N_q \quad [\text{SI}] \quad 36.1(a)$$

$$q_{ult} = \frac{1}{2}\gamma B N_\gamma + c N_c + (p_q + \gamma D_f) N_q \quad [\text{U.S.}] \quad 36.1(b)$$

Various researchers have made improvements on the theory supporting this equation, leading to somewhat different terms and sophistication in evaluating  $N_\gamma$ ,  $N_c$ , and  $N_q$ . The approaches differ in the assumptions made of the shape of the failure zone beneath the footing. However, the general form of the equation is the same in most cases.

Figure 36.2 and Table 36.2 can be used to evaluate the *capacity factors*  $N_\gamma$ ,  $N_c$ , and  $N_q$  in Eq. 36.1. Alternatively, Table 36.3 can be used. The bearing capacity factors in Table 36.2 are based on Terzaghi's 1943 studies. The values in Table 36.3 are based on Meyerhof's 1955 studies and others, and have been widely used. Other values are also in use.

Equation 36.1 is appropriate for a foundation in a continuous wall footing. Corrections, called *shape factors*, for various footing geometries are presented in Table 36.4 and Table 36.5 using the parameters identified in Fig. 36.3. The bearing capacity factors  $N_c$  and  $N_\gamma$  are multiplied by the appropriate shape factors when they are used in Eq. 36.1.

Several researchers have recommended corrections to  $N_c$  to account for footing depth. (Corrections to  $N_q$  for footing depth have also been suggested. No corrections to  $N_\gamma$  for footing depth have been suggested.) There is considerable variation in the method of calculating this

correction, if it is used at all. A multiplicative correction factor,  $d_c$ , which is used most often, has the form

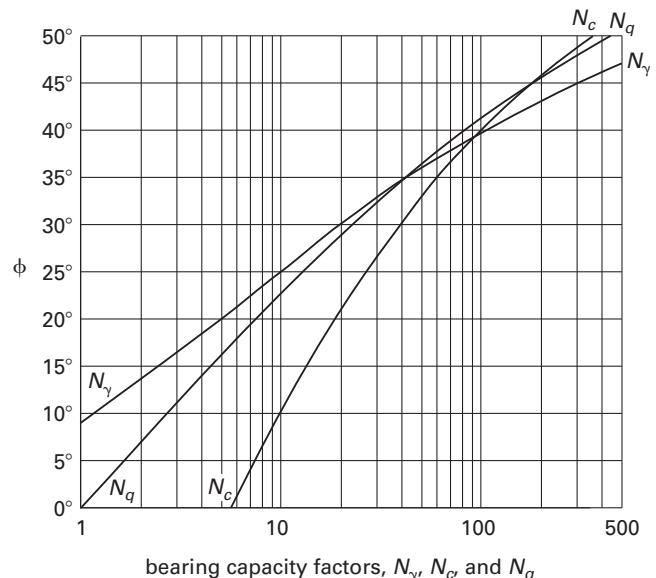

$$d_c = 1 + \frac{KD_f}{B} \quad 36.2$$

$K$  is a constant for which values of 0.2 and 0.4 have been proposed. The depth factor correction is applied to  $N_c$  along with the shape factor correction in Eq. 36.1.

Once the ultimate bearing capacity is determined, it is corrected by the *overburden*, giving the *net bearing capacity*. This is the net pressure the soil can support beyond the pressure applied by the existing overburden.

$$q_{net} = q_{ult} - \rho g D_f \quad [\text{SI}] \quad 36.3(a)$$

$$q_{net} = q_{ult} - \gamma D_f \quad [\text{U.S.}] \quad 36.3(b)$$

The *allowable bearing capacity*,  $q_a$ , is determined by dividing the net capacity by a factor of safety,  $F$ . The safety factor accounts for the uncertainties in evaluating soil properties and anticipated loads, and also on the amount of risk involved in building the structure. A safety factor between 2 and 3 (based on  $q_{net}$ ) is common for average conditions. Smaller safety factors are sometimes used for transient load conditions such as from wind and seismic forces.

$$q_a = \frac{q_{net}}{F} \quad 36.4$$

## 6. SELECTING A BEARING CAPACITY THEORY

Terzaghi's 1943 shallow foundation bearing capacity theory predicts shear failure along known planes. The theory is derived from level strip footings placed on or near the surface and with footing depths less than the smallest footing width (i.e.,  $D_f < B$ ). The footing is assumed to be in plastic equilibrium with defined failure surfaces that follow the theoretical Boussinesq distribution pattern.

The 1951 Meyerhof model includes correction factors for footing shape, eccentricity, load inclination, and foundation depth. This model varies from the basic Terzaghi model in that the influence of shear strength of soil above the base of the foundation is considered, so the beneficial effect of surcharge is included. The footing is still in plastic equilibrium (as with the Terzaghi theory), but the failure plane has a log spiral surface that includes shear above the base of the foundation.

The 1957 Hansen model considers footing depth and shape and load inclination. The 1975 Vesic model closely follows the Meyerhof and Hansen models but addresses the concern that local shear failure leads to lower bound estimates of ultimate bearing capacity. Unlike the Hansen model, the Vesic shape factors are not generally reevaluated based on subsequent steps.

These models generally specify the same basic bearing capacity equation, but they differ in their values of bearing capacity and shape factors, particularly the inclination shape factors. The choice of these factors (Terzaghi, Meyerhof, Vesic, or Hansen) will affect the final bearing capacity significantly, particularly for low values of  $\phi$ . In practice, a particular model may be specified by statute or code, employer convention, or other requirement. In some cases, taking an average of the bearing capacities calculated from the individual theories may be appropriate. It may be possible to logically exclude one or more theories as being unnecessary or inappropriate, according to the theory's basic assumptions. For example, Terzaghi and Meyerhof equations were developed for shallow, horizontal, strip foundations that were vertically loaded, so the theory would be inappropriate in other configurations, including very large or deep footings, complex site conditions,

and non-vertical loadings. In the absence of those conditions, the Terzaghi model produces reasonably accurate bearing capacities. Meyerhof's values tend to be conservative—often quite conservative. In the absence of a significant surcharge or inclined loadings, the Meyerhof model may be unnecessary. Hansen's model accommodates inclined loads and is essentially the same as the Meyerhof model. Even when a theory is known to be appropriate, the bearing capacity it predicts is still an estimate, hence the frequent use of liberal factors of safety. Rule of thumb methods have been used by engineers for years, so the desire to use the perfect bearing capacity factors may be unnecessary.

## 7. BEARING CAPACITY OF CLAY

Clay is often soft and fairly impermeable. When loads are first applied to saturated clay, the pore pressure increases. For a short time, this pore pressure does not dissipate, and the angle of internal friction should be taken as  $\phi = 0^\circ$ . This is known as the  $\phi = 0^\circ$  case or the *undrained case*, which is the critical condition for clays. As discussed in Chap. 35, the undrained shear strength of clays is equal to the cohesion, which is one-half of the unconfined compressive strength.

$$S_u = c = \frac{S_{uc}}{2} \quad 36.5$$

If  $\phi = 0^\circ$ , then  $N_\gamma = 0$  and  $N_q = 1$ . If there is no surface surcharge (i.e.,  $p_q = 0$ ), the ultimate bearing capacity is given by Eq. 36.6.

$$q_{ult} = cN_c + \rho g D_f \quad [\text{SI}] \quad 36.6(a)$$

$$q_{ult} = cN_c + \gamma D_f \quad [\text{U.S.}] \quad 36.6(b)$$

$$q_{net} = q_{ult} - \rho g D_f = cN_c \quad [\text{SI}] \quad 36.7(a)$$

$$q_{net} = q_{ult} - \gamma D_f = cN_c \quad [\text{U.S.}] \quad 36.7(b)$$

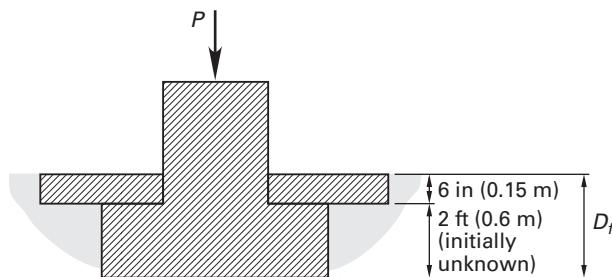

The allowable clay loading is based on a factor of safety, which is typically taken as 3 for clay.

$$q_a = \frac{q_{net}}{F} \quad 36.8$$

From Eq. 36.6 and Eq. 36.7, it is evident that the cohesion term dominates the bearing capacity in cohesive soil.

### Example 36.1

An individual square column footing has an 83,800 lbf (370 kN) dead load and a 75,400 lbf (335 kN) live load. The unconfined compressive strength of the supporting clay at all footing depths is 0.84 tons/ft<sup>2</sup> (80 kPa). Its specific weight is  $\gamma = 115 \text{ lbf/ft}^3$  ( $\rho = 1840 \text{ kg/m}^3$ ).  $\phi = 0^\circ$ . The footing is covered by a 6.0 in (0.15 m) thick basement slab whose upper surface is flush with the original grade. The footing thickness is initially unknown. Neglect depth correction factors. Do not design the structural steel. Specify the footing size and thickness.

*SI Solution*

The strategy for determining the depth and width of the footing is to calculate the allowable bearing pressure, assume a width and depth that will support the dead load and live load, and then compare the actual pressures on the footing with the allowable pressures, considering the effect of soil displacement by the concrete footing and slab.

From Eq. 36.7 and Eq. 36.8, the allowable bearing capacity at all footing depths is

$$q_a = \frac{q_{net}}{F} = \frac{cN_c}{F}$$

From Table 36.2, the bearing capacity factor is  $N_c = 5.7$ . From Table 36.4, for square footings, the shape factor is 1.25. The cohesion is estimated from the unconfined compressive strength and Eq. 36.5.

$$c = \frac{S_{uc}}{2} = \frac{80 \text{ kPa}}{2} = 40 \text{ kPa}$$

Using a factor of safety of 3, the allowable pressure at all footing depths is

$$q_a = \frac{cN_c}{F} = \frac{(40 \text{ kPa})(5.7)(1.25)}{3} \\ = 95 \text{ kPa}$$

The total load on the column is

$$P = \text{DL} + \text{LL} = 370 \text{ kN} + 335 \text{ kN} \\ = 705 \text{ kN}$$

The approximate area required is

$$A = \frac{705 \text{ kN}}{95 \text{ kPa}} \\ = 7.42 \text{ m}^2$$

Try a 3 m square footing (area = 9 m<sup>2</sup>).

The actual pressure under the footing due to the applied column load is

$$p_{actual} = \frac{705 \text{ kN}}{9 \text{ m}^2} = 78.3 \text{ kPa} < q_a \quad [\text{OK}]$$

This first iteration did not consider the concrete weight. The concrete density is approximately 2400 kg/m<sup>3</sup>.

Therefore, the pressure surcharge due to 1 m<sup>2</sup> of concrete floor slab is

$$p_{\text{floor slab}} = \frac{(1 \text{ m})(1 \text{ m})(0.15 \text{ m}) \left( 2400 \frac{\text{kg}}{\text{m}^3} \right) \left( 9.81 \frac{\text{m}}{\text{s}^2} \right)}{1000 \frac{\text{Pa}}{\text{kPa}}} = 3.53 \text{ kPa}$$

Similarly, the footing itself has weight. At this point, a footing thickness would be determined based on concrete design considerations, and it is reasonable to assume a 0.6 m footing thickness.

$$p_{\text{footing}} = \frac{(1 \text{ m})(1 \text{ m})(0.6 \text{ m}) \left( 2400 \frac{\text{kg}}{\text{m}^3} \right) \left( 9.81 \frac{\text{m}}{\text{s}^2} \right)}{1000 \frac{\text{Pa}}{\text{kPa}}} = 14.13 \text{ kPa}$$

The net actual pressure under the footing is

$$p_{\text{net,actual}} = 78.3 \text{ kPa} + 3.53 \text{ kPa} + 14.13 \text{ kPa} = 95.96 \text{ kPa}$$

This is the net actual pressure to be compared to the allowable pressure.

This is essentially the same as  $q_a$  (95 kPa).

#### *Customary U.S. Solution*

The strategy for determining the depth and width of the footing is to calculate the allowable bearing pressure, assume a width and depth that will support the dead load and live load, and then compare the actual pressures on the footing with the allowable pressures, considering the effect of soil displacement by the concrete footing and slab.

From Eq. 36.7 and Eq. 36.8, the allowable bearing capacity at all footing depths is

$$q_a = \frac{q_{\text{net}}}{F} = \frac{cN_c}{F}$$

From Table 36.2, the bearing capacity factor is  $N_c = 5.7$ . From Table 36.4, for square footings, the shape factor is

1.25. The cohesion is estimated from the unconfined compressive strength and Eq. 36.5.

$$c = \frac{S_{uc}}{2} = \frac{0.84 \frac{\text{tons}}{\text{ft}^2}}{2} = 0.42 \text{ tons}/\text{ft}^2$$

Using a factor of safety of 3, the allowable pressure at all footing depths is

$$q_a = \frac{cN_c}{F} = \frac{\left( 0.42 \frac{\text{tons}}{\text{ft}^2} \right)(5.7)(1.25)}{3} = 0.99 \text{ tons}/\text{ft}^2 \quad [\text{round down}]$$

The total load on the column is

$$P = \text{DL} + \text{LL} = \frac{83,800 \text{ lbf} + 75,400 \text{ lbf}}{2000 \frac{\text{lbf}}{\text{ton}}} = 79.6 \text{ tons}$$

The approximate area required is

$$A = \frac{79.6 \text{ tons}}{0.99 \frac{\text{tons}}{\text{ft}^2}} = 80.4 \text{ ft}^2$$

Try a 10 ft square footing (area = 100 ft<sup>2</sup>).

The actual pressure under the footing due to the applied column load is

$$p_{\text{actual}} = \frac{79.6 \text{ tons}}{100 \text{ ft}^2} = 0.796 \text{ tons}/\text{ft}^2 < q_a \quad [\text{OK}]$$

This first iteration did not consider the concrete weight. The concrete specific weight is approximately 150 lbf/ft<sup>3</sup>. Therefore, the pressure surcharge due to 1 ft<sup>2</sup> of concrete floor slab is

$$p_{\text{floor slab}} = \frac{(1 \text{ ft})(1 \text{ ft})(6 \text{ in}) \left( 150 \frac{\text{lbf}}{\text{ft}^3} \right)}{\left( 2000 \frac{\text{lbf}}{\text{ton}} \right) \left( 12 \frac{\text{in}}{\text{ft}} \right)} = 0.04 \text{ tons}/\text{ft}^2$$

Similarly, the footing itself has weight. At this point, a footing thickness would be determined based on

concrete design considerations, and it is reasonable to assume a 2 ft footing thickness.

$$p_{\text{footing}} = \frac{(1 \text{ ft})(1 \text{ ft})(2 \text{ ft}) \left( 150 \frac{\text{lbf}}{\text{ft}^3} \right)}{2000 \frac{\text{lbf}}{\text{ton}}} = 0.15 \text{ tons}/\text{ft}^2$$

The net actual pressure under the footing is

$$p_{\text{net,actual}} = 0.796 \frac{\text{tons}}{\text{ft}^2} + 0.04 \frac{\text{tons}}{\text{ft}^2} + 0.15 \frac{\text{tons}}{\text{ft}^2} = 0.986 \text{ tons}/\text{ft}^2$$

This is the net actual pressure to be compared to the allowable pressure.

This is essentially the same as  $q_a$  (0.99 tons/ $\text{ft}^2$ ).

## 8. BEARING CAPACITY OF SAND

The cohesion,  $c$ , of ideal sand is zero. The ultimate bearing capacity can be derived from Eq. 36.1 by setting  $c=0$ .

$$q_{\text{ult}} = \frac{1}{2}B\rho gN_\gamma + (p_q + \rho gD_f)N_q \quad [\text{SI}] \quad 36.9(a)$$

$$q_{\text{ult}} = \frac{1}{2}B\gamma N_\gamma + (p_q + \gamma D_f)N_q \quad [\text{U.S.}] \quad 36.9(b)$$

The net bearing capacity when there is no surface surcharge (i.e.,  $p_q = 0$ ) is

$$\begin{aligned} q_{\text{net}} &= q_{\text{ult}} - \rho gD_f \\ &= \frac{1}{2}B\rho gN_\gamma + \rho gD_f(N_q - 1) \end{aligned} \quad [\text{SI}] \quad 36.10(a)$$

$$\begin{aligned} q_{\text{net}} &= q_{\text{ult}} - \gamma D_f \\ &= \frac{1}{2}B\gamma N_\gamma + \gamma D_f(N_q - 1) \end{aligned} \quad [\text{U.S.}] \quad 36.10(b)$$

From Eq. 36.9 and Eq. 36.10, it is evident that the depth term  $\rho gD_f N_q$  dominates the bearing capacity in cohesionless soil. A small increase in depth increases the bearing capacity substantially.

The allowable bearing capacity is based on a factor of safety, which is typically taken as 2 for sand.

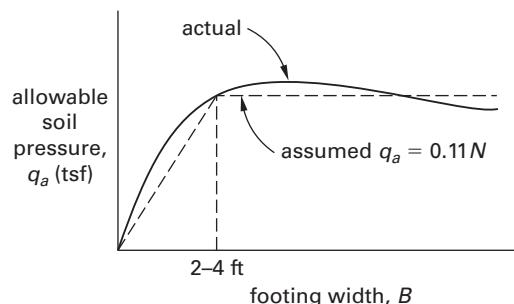

$$\begin{aligned} q_a &= \frac{q_{\text{net}}}{F} \\ &= \frac{B}{F} \left( \frac{1}{2}\rho gN_\gamma + \rho g(N_q - 1) \left( \frac{D_f}{B} \right) \right) \end{aligned} \quad [\text{SI}] \quad 36.11(a)$$

$$\begin{aligned} q_a &= \frac{q_{\text{net}}}{F} \\ &= \frac{B}{F} \left( \frac{1}{2}\gamma N_\gamma + \gamma(N_q - 1) \left( \frac{D_f}{B} \right) \right) \end{aligned} \quad [\text{U.S.}] \quad 36.11(b)$$

For common applications, (cohesionless soil, settlement governing, footing width greater than 2–4 ft, and no groundwater within  $B$  of bottom of footing), Eq. 36.11 can be simplified. The quantity in brackets in Eq. 36.12 is constant for specific  $D_f/B$  ratios, and the bearing capacity factors depend on  $\phi$ , which can be correlated to the *standard penetration test* (SPT)  $N$ -value in blows per foot. Assuming  $F=2$ ,  $\gamma=100 \text{ lbf}/\text{ft}^3$ , and  $D_f < B$ , Eq. 36.12 can be derived for use with spread footings. Equation 36.12 is illustrated by the rightmost part of Fig. 36.4.

$$q_a = 0.11 C_n N \quad [\text{in tons}/\text{ft}^2, B > 2-4 \text{ ft}, N \leq 50] \quad 36.12$$

**Figure 36.4** Soil Pressure on Sand (constant settlement)

Corrections are required for shallow water tables. (See Sec. 36.9.) No correction is usually made to Eq. 36.12 if the density is different from  $100 \text{ lbf}/\text{ft}^3$ . However, the equation assumes that the overburden load,  $\gamma D_f$ , is approximately 1 ton/ $\text{ft}^2$ . This means that the  $N$ -values will correspond to data from a depth of 10–15 ft below the original surface, not the basement surface. If the footing is to be installed close to the original surface, then a correction factor is required (as given in Table 36.6). (The correction is actually a correction for  $N$ . If corrected  $N$ -values are known,  $C_n$  may be neglected.) The potential failure zone extends into the soil below the footing, and it is common practice to evaluate  $N$  from the bottom of the footing to a depth  $B$  below the footing. The lowest average value of  $N$  from this zone is used to calculate the bearing capacity.

For a given sand settlement, the soil pressure will be greatest in intermediate-width ( $B = 2-4 \text{ ft}$ ) footings. This is illustrated in Fig. 36.4. Equation 36.12 should not be used for small-width footings, since bearing pressure governs. For wide footings (i.e.,  $B > 2-4 \text{ ft}$ ), settlement governs. Equation 36.12 was derived to ensure total settlement on sand would be 1 in or less.

## 9. SHALLOW WATER TABLE CORRECTION

If the simplified analysis in Eq. 36.12 (as proposed by Peck, Hanson, and Thornburn) is used, a multiplicative

**Table 36.6** Overburden Corrections

overburden (tons/ft <sup>2</sup> (kPa))	$C_n$
0 (0)	2
0.25 (24)	1.45
0.5 (48)	1.21
1.0 (96)	1.00
1.5 (144)	0.87
2.0 (192)	0.77
2.5 (240)	0.70
3.0 (287)	0.63
3.5 (335)	0.58
4.0 (383)	0.54
4.5 (431)	0.50
5.0 (479)	0.46

(Multiply tons/ft<sup>2</sup> by 95.8 to obtain kPa.)

correction is required when the water table is at the surface or below, down to a distance  $B$  below the footing depth,  $D_f$ . The allowable bearing pressure from Eq. 36.12 is multiplied by  $C_w$  from Eq. 36.13.

$$C_w = 0.5 + 0.5 \left( \frac{D_w}{D_f + B} \right) \quad 36.13$$

## 10. BEARING CAPACITY OF ROCK

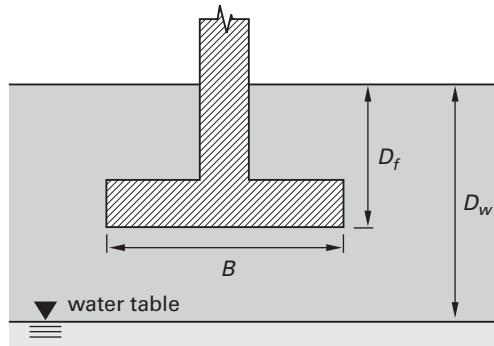

If bedrock can be reached by excavation, the allowable pressure is likely to be determined by local codes. A minimum safety factor of 3 based on the unconfined compressive strength is typical. For most rock beds, the design will be based on settlement characteristics, not strength.

## 11. EFFECTS OF WATER TABLE ON FOOTING DESIGN

The presence of a water table within the soil support zone, as shown in Fig. 36.5, may or may not affect bearing capacity, according to the following principles. (Also, see Sec. 36.9.)

*General Principle 1:* For cohesive soils (e.g., clay), the location of the water table does not affect the bearing capacity, and the effect of the water table is disregarded. (Strictly speaking, the water table has some effect, but the theory predicts none. If  $\phi = 0^\circ$ , then  $N_\gamma = 0$ . Also,  $N_q = 1$ , which is essentially zero. These two terms “zero out” the density terms in Eq. 36.1.)

*General Principle 2:* For sand, use the *submerged density*  $\gamma_b = \gamma_s - 62.4 \text{ lbf/ft}^3$  ( $\rho_b = \rho_s - 1000 \text{ kg/m}^3$ ) in the equation for bearing capacity, Eq. 36.1. Since the submerged density is approximately half of the dry

**Figure 36.5** Water Table Beneath a Footing

(drained) density, it is commonly stated that the bearing capacity of a footing with the water table at the ground surface is half of the dry bearing capacity, varying linearly to full strength at a distance  $B$  below the footing base. However, a more accurate estimate can be obtained from the following cases.

(a) When the water table is at the base of the footing, use the submerged density in the first term of Eq. 36.1. Since  $c = 0$  for sand, the bearing capacity is

$$q_{ult} = \frac{1}{2} \rho_b g B N_\gamma + \rho_b g D_f N_q \quad [\text{SI}] \quad 36.14(a)$$

$$q_{ult} = \frac{1}{2} \gamma_b B N_\gamma + \gamma_b D_f N_q \quad [\text{U.S.}] \quad 36.14(b)$$

(b) When the water table is at the surface, use the submerged density in both the first and third terms of Eq. 36.1.

$$q_{ult} = \frac{1}{2} \rho_b g B N_\gamma + \rho_b g D_f N_q \quad [\text{SI}] \quad 36.15(a)$$

$$q_{ult} = \frac{1}{2} \gamma_b B N_\gamma + \gamma_b D_f N_q \quad [\text{U.S.}] \quad 36.15(b)$$

(c) When the water table is between the base of the footing and the surface, linear interpolation is used between cases (a) and (b). This is equivalent to using the submerged density in the first term as in (a) above, and calculating the third term in Eq. 36.1 as

$$\begin{aligned} & \left( \rho_b g D_w + \left( \rho_b - 1000 \frac{\text{kg}}{\text{m}^3} \right) g (D_f - D_w) \right) N_q \\ &= \left( \rho_b g D_f + \left( 1000 \frac{\text{kg}}{\text{m}^3} \right) g (D_w - D_f) \right) N_q \end{aligned} \quad [\text{SI}] \quad 36.16(a)$$

$$\begin{aligned} & \left( \gamma D_w + \left( \gamma - 62.4 \frac{\text{lbf}}{\text{ft}^3} \right) (D_f - D_w) \right) N_q \\ & = \left( \gamma D_f + \left( 62.4 \frac{\text{lbf}}{\text{ft}^3} \right) (D_w - D_f) \right) N_q \\ & \quad [\text{U.S.}] \quad 36.16(b) \end{aligned}$$

*General Principle 3:* For sand, if the water table depth,  $D_w$ , is greater than  $D_f + B$  (i.e., more than a distance  $B$  below the base of the footing), the bearing capacity is not affected. Calculate the bearing capacity from Eq. 36.1 as if there was no water table.

$$q_{ult} = \frac{1}{2} \rho g B N_\gamma + \rho g D_f N_q \quad [\text{SI}] \quad 36.17(a)$$

$$q_{ult} = \frac{1}{2} \gamma B N_\gamma + \gamma D_f N_q \quad [\text{U.S.}] \quad 36.17(b)$$

*General Principle 4:* For sand, if the water table depth,  $D_w$ , is between  $D_f$  and  $D_f + B$ , the bearing capacity is calculated using the drained density in the  $D_f N_q$  term, and a weighted average of the drained and submerged densities in the  $B N_\gamma$  term.

## 12. ECCENTRIC LOADS ON RECTANGULAR FOOTINGS

If a rectangular footing carries a moment in addition to its vertical load, an eccentric loading situation is created. (See Fig. 36.6.) Under these conditions, the footing bearing capacity should be analyzed assuming an area in which the size is reduced by twice the eccentricity.

$$\epsilon_B = \frac{M_B}{P}; \quad \epsilon_L = \frac{M_L}{P} \quad 36.18$$

$$L' = L - 2\epsilon_L; \quad B' = B - 2\epsilon_B \quad 36.19$$

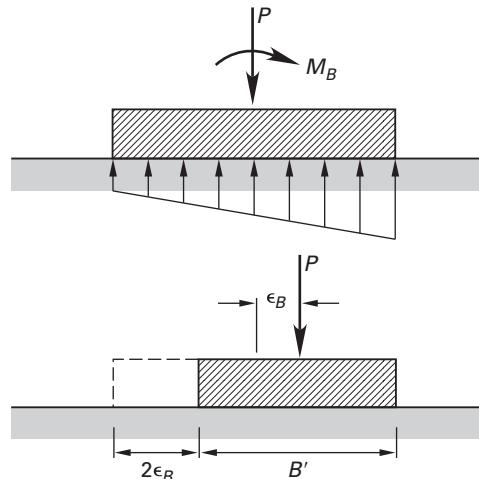

$$A' = L' B' \quad 36.20$$

This area reduction places the equivalent force at the centroid of the reduced area. The equivalent width  $B'$  should be used in Eq. 36.1, and both  $B'$  and  $L'$  should be used in the ratio  $B'/L'$  used to determine shape factors. The footing bearing capacity is reduced in two ways. First, a smaller  $B$  in Eq. 36.1 results in a smaller  $q_{ult}$  and  $q_a$ . Second, a smaller  $q_a$  results in a smaller allowable load (i.e.,  $P = q_a B' L'$ ).

Although the eccentricity is independent of the footing dimensions, a trial-and-error solution may be necessary when designing footings. Trial and error is not required when analyzing a rectangular footing of known dimensions.

Assuming  $M_L = 0$  and  $\epsilon_B = \epsilon$  and disregarding the concrete and overburden weights, the actual soil pressure distribution is given by Eq. 36.21.  $B'$  and  $L'$  should not be used in Eq. 36.21 because these variables place

**Figure 36.6** Footing with Overturning Moment

the load at the centroid of the reduced area, assuming a uniform pressure distribution.

$$p_{max}, p_{min} = \frac{P}{BL} \left( 1 \pm \frac{6\epsilon}{B} \right) \quad 36.21$$

If the eccentricity,  $\epsilon$ , is sufficiently large, a negative soil pressure will result. Since soil cannot carry a tensile stress, such stresses are neglected. This results in a reduced area to carry the load.

If the resultant force is within the middle third of the footing, the contact pressures will be distributed over the entire footing. That is, the maximum eccentricity without incurring a reduction in footing contact area will be  $B/6$ .

## 13. GENERAL CONSIDERATIONS FOR RAFTS

A *raft* or *mat* foundation is a combined footing slab that usually covers the entire area beneath a building and supports all walls and columns. (The term *pad* is also used.) A raft foundation should be used (at least for economic reasons) any time the individual footings would constitute half or more of the area beneath a building. Rafts are also used to combine foundations with basement floor slabs, to minimize differential settlements over compressible soils, or to provide resistance to uplift.

## 14. RAFTS ON CLAY

The net and ultimate bearing capacities for rafts on clay is found in the same manner as for shallow footings. Since the size of the raft is usually fixed by the building size (within a few feet), the only method available to increase the allowable loading is to lower the elevation (i.e., increase  $D_f$ ) of the raft.

The factor of safety available with raft construction is given by Eq. 36.22, which can also be solved to give the required values of  $D_f$  if the factor of safety is known. The factor of safety should be at least 3 for normal loadings, but it may be reduced to 2 during temporary loading.

$$F = \frac{cN_c}{\frac{P_{\text{total}}}{A_{\text{raft}}} - \rho g D_f} \quad [\text{SI}] \quad 36.22(a)$$

$$F = \frac{cN_c}{\frac{P_{\text{total}}}{A_{\text{raft}}} - \gamma D_f} \quad [\text{U.S.}] \quad 36.22(b)$$

If the denominator in Eq. 36.22 is small, the factor of safety is very large. If the denominator is zero, the raft is said to be a *fully compensated foundation*. In a fully compensated foundation, the loads imposed on the foundation by the structure are exactly equal to the weight of the soil that is excavated. For  $D_f$  less than the fully compensated depth, the raft is said to be a *partially compensated foundation*.

### Example 36.2

A raft foundation is to be designed for a 120 ft  $\times$  200 ft (36 m  $\times$  60 m) building that has a total loading of  $5.66 \times 10^7$  lbf ( $2.5 \times 10^5$  kN). The clay specific weight is  $\gamma = 115$  lbf/ft<sup>3</sup> ( $\rho = 1840$  kg/m<sup>3</sup>), and the clay has an average unconfined compressive strength of 0.3 tons/ft<sup>2</sup> (28.7 kPa). Neglect depth correction factors. (a) What should be the raft depth,  $D_f$ , for full compensation? (b) What should be the raft depth for a factor of safety of 3?

#### SI Solution

(a) Use Eq. 36.22 for full compensation.

$$D_f = \frac{\frac{P_{\text{total}}}{A_{\text{raft}}} - \rho g D_f}{\frac{P_{\text{total}}}{A_{\text{raft}}} - \frac{(2.5 \times 10^5 \text{ kN}) (1000 \frac{\text{N}}{\text{kN}})}{(36 \text{ m})(60 \text{ m})}} = \frac{5.66 \times 10^7 \text{ lbf}}{115 \frac{\text{lbf}}{\text{ft}^3}} = 6.4 \text{ m}$$

(b) From Eq. 36.22,

$$F = \frac{cN_c}{\frac{P_{\text{total}}}{A_{\text{raft}}} - \rho g D_f}$$

From Table 36.2,  $N_c = 5.7$ . Since  $B/L = 36 \text{ m}/60 \text{ m} = 0.6$ , use an  $N_c$  multiplier of 1.15 from Table 36.4. The cohesion is calculated from Eq. 36.5.

$$\begin{aligned} c &= \frac{S_{uc}}{2} = \frac{28.7 \text{ kPa}}{2} = 14.35 \text{ kPa} \\ D_f &= \frac{\frac{P_{\text{total}}}{A_{\text{raft}}} - \frac{cN_c}{F}}{\rho g} \\ &= \frac{\frac{(2.5 \times 10^5 \text{ kN}) (1000 \frac{\text{N}}{\text{kN}})}{(36 \text{ m})(60 \text{ m})} - \frac{(14.35 \text{ kPa}) (1000 \frac{\text{N}}{\text{kN}}) (5.7)(1.15)}{3}}{\left(1840 \frac{\text{kg}}{\text{m}^3}\right) \left(9.81 \frac{\text{m}}{\text{s}^2}\right)} \\ &= 4.67 \text{ m} \end{aligned}$$

#### Customary U.S. Solution

(a) Use Eq. 36.22 for full compensation.

$$\frac{P_{\text{total}}}{A_{\text{raft}}} - \gamma D_f = 0$$

$$D_f = \frac{\frac{P_{\text{total}}}{A_{\text{raft}}}}{\gamma} = \frac{5.66 \times 10^7 \text{ lbf}}{(120 \text{ ft})(200 \text{ ft})} = 20.5 \text{ ft}$$

(b) From Eq. 36.22,

$$F = \frac{cN_c}{\frac{P_{\text{total}}}{A_{\text{raft}}} - \gamma D_f}$$

From Table 36.2,  $N_c = 5.7$ . Since  $B/L = 120 \text{ ft}/200 \text{ ft} = 0.6$ , use an  $N_c$  multiplier of 1.15 from Table 36.4. The cohesion is calculated from Eq. 36.5.

$$\begin{aligned} c &= \frac{S_{uc}}{2} = \frac{\left(0.3 \frac{\text{ton}}{\text{ft}^2}\right)\left(2000 \frac{\text{lbf}}{\text{ton}}\right)}{2} \\ &= 300 \frac{\text{lbf}}{\text{ft}^2} \\ D_f &= \frac{\frac{P_{\text{total}}}{A_{\text{raft}}} - \frac{cN_c}{F}}{\gamma} \\ &= \frac{\frac{5.66 \times 10^7 \text{ lbf}}{(120 \text{ ft})(200 \text{ ft})} - \frac{\left(300 \frac{\text{lbf}}{\text{ft}^2}\right)(5.7)(1.15)}{3}}{115 \frac{\text{lbf}}{\text{ft}^3}} \\ &= 14.8 \text{ ft} \end{aligned}$$

## 15. RAFTS ON SAND

Rafts on sand are well protected against bearing capacity failure. (The depth of the potential failure zone,  $D_f + B$ , is very large for a raft foundation.) Therefore, settlement will govern the design. Since differential settlement will be much smaller for various locations on the raft (due to the raft's rigidity), differential settling is not a factor, and the allowable soil pressure may be doubled (compared to Eq. 36.12).  $C_w$  was previously defined in Eq. 36.13.

$$q_a = 0.22 C_w C_n N \quad [\text{in tons}/\text{ft}^2] \quad 36.23$$

$N$  should always be at least 5 after correcting for overburden. Otherwise, the sand should be compacted, or a pier or pile foundation should be used.

To calculate the factor of safety in bearing, the net bearing capacity from Eq. 36.3 should be compared with the actual (net) bearing pressure. The actual (net) bearing pressure is

$$p = \frac{P_{\text{total}}}{A_{\text{raft}}} - \rho g D_f \quad [\text{SI}] \quad 36.24(a)$$

$$p = \frac{P_{\text{total}}}{A_{\text{raft}}} - \gamma D_f \quad [\text{U.S.}] \quad 36.24(b)$$

### 1. TYPES OF RETAINING WALL STRUCTURES

A *gravity wall* is a high-bulk structure that relies on self-weight and the weight of the earth over the heel to resist overturning. *Semi-gravity walls* are similar though less massive. A *buttress wall* depends on compression ribs (*buttresses*) between the stem and the toe to resist flexure and overturning. *Counterfort walls* depend on tension ribs between the stem and the heel to resist flexure and overturning. A *cantilever wall* resists overturning through a combination of the soil weight over the heel and the resisting pressure under the base. Figure 37.1 illustrates types of retaining walls.

A *cantilever retaining wall* consists of a base, a stem, and an optional key.<sup>1</sup> The stem may have a constant thickness, or it may be tapered. The taper is known as *batter*. The *batter decrement* is the change in stem thickness per unit of vertical distance. Batter is used to “disguise” bending (deflection) that would otherwise make it appear as if the wall were failing. It also reduces the quantity of

<sup>1</sup>The use of a key may increase the cost of installing the retaining wall by more than just the cost of extending the thickness of the base by the depth of the key. To install a key, the contractor will have to hand-shovel the keyway or change buckets on the backhoe. Arranging any vertical key steel is also time consuming.

**Figure 37.1** Types of Retaining Walls

## Geotechnical

material needed at the top of the wall where less strength is needed.

Cantilever retaining walls are generally intended to be permanent and are made of cast-in-place poured concrete. However, retaining walls may also be constructed from reinforced masonry block, stacked elements of various types, closely spaced driven members, railroad ties, and heavy lumber.

*Gabion walls*, consisting of stacked layers of rock-filled wire cages (baskets), may be economical if adequate rock is available nearby. Gabions are applicable to waterway lining, embankment control, spillways, and stilling basins, as well as retaining walls. Other stacked-wall structures use interlocking concrete blocks, with and

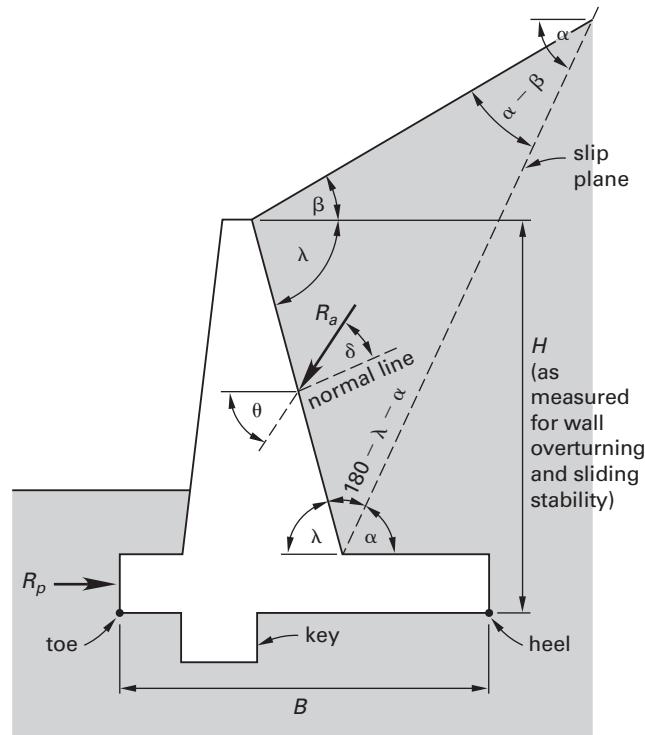

without tension cabling. Geosynthetic fabrics may be needed with gabion and stacked-block walls to prevent the migration of fines.

## 2. COHESIVE AND GRANULAR SOILS

The nature of the backfilled or retained soil greatly affects the design of retaining walls. The two main soil classifications are granular and cohesive soils. *Cohesive soils* are clay-type soils with angles of internal friction,  $\phi$ , of close to zero. *Granular soils* (also referred to as *noncohesive soils* and *cohesionless soils*) are sand- and gravel-type soils with values of cohesion,  $c$ , of close to zero. Granular soils also encompass “moist sands” and “drained sands.”

## 3. EARTH PRESSURE

*Earth pressure* is the force per unit area exerted by soil on the retaining wall. Generally, the term is understood to mean “horizontal earth pressure.” *Active earth pressure* (also known as *tensioned soil pressure* and *forward soil pressure*) is present behind a retaining wall that moves away from and tensions the remaining soil. *Passive earth pressure* (also known as *backward soil pressure* and *compressed soil pressure*) is present in front of a retaining wall that moves toward and compresses the soil. Figure 37.2 illustrates both active and passive earth pressure.

**Figure 37.2** Active and Passive Earth Pressure

There are three common earth pressure theories. The *Rankine earth pressure theory* assumes that failure occurs along a flat plane behind the wall inclined at an angle  $\alpha$  from the horizontal (counterclockwise being positive). The area above the failure plane is referred to as the *active zone*. The Rankine theory disregards friction between the wall and the soil.

$$\alpha = 45^\circ + \frac{\phi}{2} \quad [\text{Rankine}] \quad 37.1$$

The *Coulomb earth pressure theory* also assumes a flat failure plane, but the effect of wall friction is included. Where friction is significant, the Coulomb theory can predict a lower active pressure than the Rankine theory. The angle of the failure plane depends on both  $\phi$  and  $\delta$ , but not on  $H$  or  $\gamma$ .  $\alpha$  is measured from the horizontal, with counterclockwise being positive.

$$\alpha = \phi + \arctan \left( \frac{-\tan \phi + \sqrt{\tan \phi (\tan \phi + \cot \phi) \times (1 + \tan \delta \cot \phi)}}{1 + \tan \delta (\tan \phi + \cot \phi)} \right) \quad [\text{Coulomb}] \quad 37.2$$

The *log-spiral theory* assumes that the failure surface will be curved. The sophistication of a log-spiral solution is probably warranted only for the passive case, and even then, only when  $\delta$  is large (i.e., larger than approximately  $15^\circ$ ).

#### 4. VERTICAL SOIL PRESSURE

*Vertical soil pressure*,  $p_v$ , is caused by the soil's own weight and is calculated in the same manner as for a fluid column.  $H$  is measured from the bottom of the base.

$$p_v = \rho g H \quad [\text{SI}] \quad 37.3(a)$$

$$p_v = \gamma H \quad [\text{U.S.}] \quad 37.3(b)$$

#### 5. ACTIVE EARTH PRESSURE

Equation 37.4 is the equation for horizontal active earth pressure with level backfill for all soil types (i.e., sandy soils and clayey soils).  $k_a$  is the *coefficient of active earth pressure* (*active earth pressure coefficient*). Depending on the value of the cohesion,  $c$ ,  $p_a$  can become negative (i.e., develop tension cracks) above the wall base.

$$p_a = p_v k_a - 2c\sqrt{k_a} \quad 37.4$$

The method of calculating  $k_a$  depends on the assumptions made. Equation 37.5 is the most general form of the active Coulomb equation. This form allows for sloping backfill (angle  $\beta$ ), inclined active-side wall face

(angle  $\lambda$ ), and *external friction angle* between the soil and wall face (angle  $\delta$ ). Table 37.1 gives external friction angles for a variety of interface materials.

$$k_a = \frac{\sin^2(\lambda + \phi)}{\sin^2 \lambda \sin(\lambda - \delta) \left( 1 + \sqrt{\frac{\sin(\phi + \delta) \sin(\phi - \beta)}{\sin(\lambda - \delta) \sin(\lambda + \beta)}} \right)^2} \quad [\text{Coulomb}] \quad 37.5$$

The Rankine theory disregards wall friction. The most general Rankine equation is derived by setting  $\delta = 0^\circ$  in Eq. 37.5.

$$k_a = \cos \beta \left( \frac{\cos \beta - \sqrt{\cos^2 \beta - \cos^2 \phi}}{\cos \beta + \sqrt{\cos^2 \beta - \cos^2 \phi}} \right) \quad [\text{Rankine}] \quad 37.6$$

If the backfill is horizontal ( $\beta = 0^\circ$ ) and the wall face is vertical ( $\lambda = 90^\circ$ ), then

$$k_a = \frac{1}{k_p} = \tan^2 \left( 45^\circ - \frac{\phi}{2} \right) = \frac{1 - \sin \phi}{1 + \sin \phi} \quad \begin{matrix} \text{Rankine: horizontal} \\ \text{backfill; vertical face} \end{matrix} \quad 37.7$$

For saturated clays, the angle of internal friction,  $\phi$ , is zero. As long as tension cracks do not develop near the top of the retaining wall,  $k_a = 1$ , and Eq. 37.4 resolves to

$$p_a = p_v - 2c \quad [\phi = 0^\circ] \quad 37.8$$

For granular soils,  $c = 0$ . In that case, Eq. 37.4 resolves to

$$p_a = k_a p_v \quad [c = 0] \quad 37.9$$

Since Eq. 37.9 describes a triangular pressure distribution, the *total active resultant* acts  $H/3$  above the base for both the Rankine and Coulomb cases and is, per unit width of wall,

$$R_a = \frac{1}{2} p_a H = \frac{1}{2} k_a \rho g H^2 \quad [\text{SI}] \quad 37.10(a)$$

$$R_a = \frac{1}{2} p_a H = \frac{1}{2} k_a \gamma H^2 \quad [\text{U.S.}] \quad 37.10(b)$$

Since wall friction is disregarded with the Rankine case, the earth pressure resultant is normal to the wall. For the Coulomb case, there is a downward force component, and the earth pressure resultant is directed at the angle  $\delta$  above the normal, or  $90^\circ - \delta$  from the wall.

$$\theta_R = 90^\circ \text{ from the wall} \quad [\text{Rankine}] \quad 37.11$$

$$\theta_R = 90^\circ - \delta \text{ from the wall} \quad [\text{Coulomb}] \quad 37.12$$

<sup>a</sup>For material not listed, use  $\delta = \frac{2}{3}\phi$ .<sup>b</sup>Angles given are ultimate values that require significant movement before failure occurs.Source: *Foundations and Earth Structures*, NAVFAC DM-7.2, 1986, Table 1, p. 7.2-63

## 6. PASSIVE EARTH PRESSURE

Equation 37.13 is the equation for horizontal passive earth pressure with level backfill for all soil types (i.e., sandy soils and clayey soils).  $k_p$  is the coefficient of passive earth pressure (passive earth pressure coefficient).

$$p_p = p_v k_p + 2c\sqrt{k_p} \quad 37.13$$

The method of calculating  $k_p$  depends on the assumptions made. Equation 37.14 is the most general form of the passive Coulomb equation. This form allows for sloping backfill (angle  $\beta$ ), inclined active-side wall face (angle  $\lambda$ ), and friction between the soil and wall face (angle  $\delta$ ).

$$k_p = \frac{\sin^2(\lambda - \phi)}{\sin^2 \lambda \sin(\lambda + \delta) \left(1 - \sqrt{\frac{\sin(\phi + \delta)\sin(\phi + \beta)}{\sin(\lambda + \delta)\sin(\lambda + \beta)}}\right)^2} \quad [Coulomb] \quad 37.14$$

The Rankine theory disregards wall friction. The most general Rankine equation is derived by setting  $\delta = 0^\circ$  in Eq. 37.14.

$$k_p = \cos \beta \left( \frac{\cos \beta + \sqrt{\cos^2 \beta - \cos^2 \phi}}{\cos \beta - \sqrt{\cos^2 \beta - \cos^2 \phi}} \right) \quad [\text{Rankine}]$$

37.15

If the backfill is horizontal ( $\beta = 0^\circ$ ) and the wall face is vertical ( $\lambda = 90^\circ$ ), then

$$\begin{aligned} k_p &= \frac{1}{k_a} = \tan^2 \left( 45^\circ + \frac{\phi}{2} \right) \\ &= \frac{1 + \sin \phi}{1 - \sin \phi} \quad \left[ \begin{array}{l} \text{Rankine: horizontal} \\ \text{backfill; vertical face} \end{array} \right] \end{aligned} \quad 37.16$$

For saturated clays, the angle of internal friction,  $\phi$ , is zero, and  $k_p = 1$ . Equation 37.13 resolves to

$$p_p = p_v + 2c \quad [\phi = 0^\circ] \quad 37.17$$

For granular soils,  $c = 0$ . In that case, Eq. 37.13 resolves to

$$p_p = k_p p_v \quad [c = 0] \quad 37.18$$

$$R_p = \frac{1}{2}p_p H = \frac{1}{2}k_p \rho g H^2 \quad [\text{SI}] \quad 37.19(a)$$

$$R_p = \frac{1}{2}p_p H = \frac{1}{2}k_p \gamma H^2 \quad [\text{U.S.}] \quad 37.19(b)$$

Passive earth pressure may not always be present during the life of the wall. When a retaining wall is first backfilled, or when the toe of the wall is excavated for repair or other work, the passive pressure may be absent. Because of this, the restraint from passive pressure is usually disregarded in factor-of-safety calculations.

## 7. AT-REST SOIL PRESSURE

The active and passive pressures predicted by the Rankine and Coulomb theories assume the wall moves slightly. Lateral movement as little as  $H/200$  is sufficient for the active/passive distributions to develop. In some situations, however, the soil is completely confined and cannot move. This “at rest” case is appropriate for soil next to bridge abutments, basement walls restrained at their tops, walls bearing on rock, and walls with soft-clay backfill, as well as for sand deposits of infinite depth and extent.

The horizontal pressure at rest depends on the *coefficient of earth pressure at rest*,  $k_o$ , which varies from 0.4 to 0.5 for untamped sand, from 0.5 to 0.7 for normally consolidated clays, and from 1.0 and up for overconsolidated clays. (See Table 37.2.)

$$p_o = k_o p_v \quad 37.20$$

$$k_o \approx 1 - \sin \phi \quad 37.21$$

$$R_o = \frac{1}{2}k_o \rho g H^2 \quad [\text{SI}] \quad 37.22(a)$$

$$R_o = \frac{1}{2}k_o \gamma H^2 \quad [\text{U.S.}] \quad 37.22(b)$$

**Table 37.2** Typical Range of Earth Pressure Coefficients

condition	granular soil	cohesive soil
active	0.20–0.33	0.25–0.5
passive	3–5	2–4
at rest	0.4–0.6	0.4–0.8

## 8. DETERMINING EARTH PRESSURE COEFFICIENTS

Methods of calculating exact values of Coulomb's active and passive earth pressure constants,  $k_a$  and  $k_p$  (Eq. 37.5 and Eq. 37.14), are widely available, but short-cut, trial-and-error (i.e., “trial wedge”), tabular, and graphical methods may still be used to evaluate them.

All of the evaluation methods require knowing the angle of external friction (angle of wall friction),  $\delta$ , which can be estimated as  $\frac{1}{3}\phi$  for smooth retaining walls (e.g., sheet piles or concrete surfaces cast against timber formwork), or as  $\frac{1}{2}\phi - \frac{2}{3}\phi$  for rough surfaces (e.g., cast-in-place retaining walls and drilled piers).<sup>2</sup> In the absence of other information, the assumption of  $\frac{2}{3}\phi$  is commonly made.

Limited tabulated values (calculated from the original equations) are available for a few specific configurations and assumptions. Table 37.3 and Table 37.4 are typical. Linear interpolation is routinely used and justified on the basis of practicality and illusory precision.

Graphical methods are available, although no single graph can present all configurations. A curve that permits non-vertical face rake angles, for example, may not be able to permit inclined backfill. Similarly, a curve for granular backfill may not be applicable to cohesive soil. The first graphical methods to be widely used were the Terzaghi curves (shown in App. 37.C and App. 37.D) based on a log-spiral failure surface. They were developed for continuous vertical walls, and, therefore, are considered to yield conservative results.

If a soil can be categorized according to the Unified Soil Classification System and the wall is limited to 20 ft (6 m), App. 37.A predicts horizontal and vertical active forces (per foot of wall), even for cohesive soils. Appendix 37.A incorporates assumed soil densities into the  $K$  values, so  $k$  (as used in this chapter) and  $K$  (as used in App. 37.A and App. 37.B) are not the same variable:  $K_h$  and  $K_v$  have units of lbf/ft<sup>3</sup> (lbf/ft<sup>2</sup> per linear foot of wall). Distance  $H$  is specifically defined as extending from the base of the heel to the soil surface; it is not the retaining wall height. Inasmuch as App. 37.A uses average densities and lateral earth pressure coefficients, its use is understood to be limited to rough estimates.

$$R_{a,h} = \frac{1}{2}K_h H^2 \quad 37.23$$

$$R_{a,v} = \frac{1}{2}K_v H^2 \quad 37.24$$

$$R_a = \sqrt{R_{a,h}^2 + R_{a,v}^2} \quad 37.25$$

$$\theta = \arctan \frac{R_v}{R_h} \quad 37.26$$

<sup>2</sup>If a vertical course of granular (gravel) backfill separates the retaining wall stem from the backfill, the values of  $\phi$  should be averaged.

More complex situations involving irregular and stratified backfill, reinforced soil layers, irregular surcharges, sloping water tables, and dynamic (e.g., seismic) response require different analyses. However, App. 37.B provides a convenient way of initially evaluating retaining walls with *broken slope backfill*.

## 9. EFFECTS OF INCLINED BACKFILL

Since the Rankine theory is based on vertical wall faces and frictionless wall-soil contact, for the most general case, inclined planar backfills are better accommodated

by the Coulomb theory. Both theories propose wedge-shaped (triangular) failure masses that shear on planar surfaces. Accordingly, to use the Coulomb theory, the backfill must be planar, homogeneous, and cohesionless throughout the failure plane.<sup>3</sup>

Retaining walls supporting inclined backfills will experience inclined resultant soil pressure forces. The active resultant,  $R_a$ , is calculated from Eq. 37.10, as in the case of horizontal backfills. The point of application is  $H/3$

<sup>3</sup>Cohesive soils are handled by using Eq. 37.4 and Eq. 37.13.

above the base of the heel, as with a horizontal backfill, although the active resultant force will have both horizontal and vertical components.

Unlike the Rankine theory, which predicts the active resultant will be inclined (from the horizontal) at an angle  $\beta$ , the Coulomb theory predicts the angle of the active resultant to be  $\lambda + \delta$ .

In Eq. 37.10, the distance  $H$  is affected by the type of retaining wall and soil geometries.  $H$  is measured vertically upward to the top of the soil from the bottom of the heel point. For cantilever retaining walls with base extensions and sloping backfill, the distance  $H$  will be different from the physical wall height due to the sloping backfill. In this configuration, the active resultant is assumed to act on the soil plane that extends vertically upwards from the heel, not on the face of the retaining wall itself.

Once the active force has been determined, trigonometry can be used to determine the horizontal and vertical components. The horizontal component will contribute to overturning and sliding, while the vertical component increases the vertical forces on the retaining wall, which contributes to sliding and overturning moment resistance and affects the soil pressure distribution under the base. Since the active vertical component is assumed to act on the heel soil face, the moment arm for the vertical resultant's contribution to overturning resistance includes all of the heel.

$$R_{a,h} = |R_a \cos(90^\circ + \delta - \lambda)| \quad 37.27$$

$$R_{a,v} = |R_a \sin(90^\circ + \delta - \lambda)| \quad 37.28$$

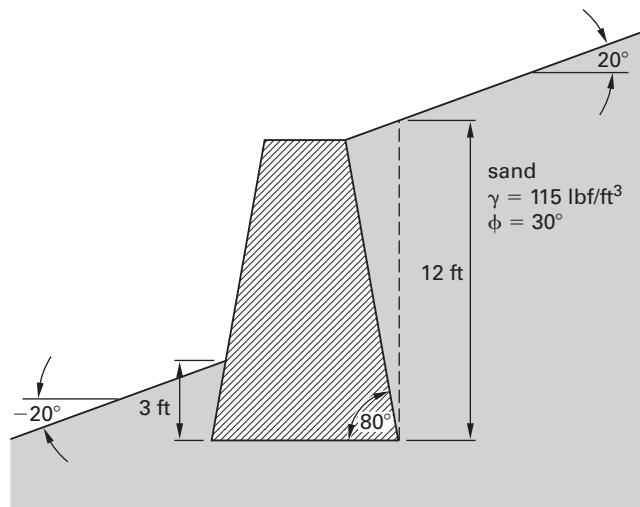

The components of  $R_a$  that are normal (perpendicular) and parallel to the wall face are

$$R_{a,N} = R_a \cos \delta \quad 37.29$$

$$R_{a,P} = R_a \sin \delta \quad 37.30$$

### Example 37.1

Cohesionless sand has a unit weight of  $115 \text{ lbf/ft}^3$  and an internal friction angle of  $30^\circ$ . The sand is supported by a rough-faced gravity retaining wall with a vertical face angle of  $80^\circ$  measured clockwise from the horizontal, and a height of 12 ft, measured from the bottom of the heel to the soil surface. The backfill slopes away from the active side of the retaining wall at an angle of  $20^\circ$ . The passive side is backfilled to a depth of 3 ft above the bottom of the toe, and the backfill slopes away from the passive side at an angle of  $-20^\circ$ . The angle of friction between the soil and the retaining wall is  $20^\circ$ . The active earth pressure coefficient is 0.540. Determine the horizontal and vertical components of the total active and passive resultants per foot of wall.

*Solution*

The total active force is given by Eq. 37.10.

$$\begin{aligned} R_a &= \frac{1}{2} k_a \gamma H^2 = \left(\frac{1}{2}\right)(0.540) \left(115 \frac{\text{lbf}}{\text{ft}^3}\right) (12 \text{ ft})^2 \\ &= 4471 \text{ lbf/ft} \end{aligned}$$

From Eq. 37.27 and Eq. 37.28, the horizontal and vertical components are

$$\begin{aligned} R_{a,h} &= |R_a \cos(90^\circ + \delta - \lambda)| \\ &= \left| \left(4471 \frac{\text{lbf}}{\text{ft}}\right) \cos(90^\circ + 20^\circ - 80^\circ) \right| \\ &= 3872 \text{ lbf/ft} \end{aligned}$$

$$\begin{aligned} R_{a,v} &= |R_a \sin(90^\circ + \delta - \lambda)| \\ &= \left| \left(4471 \frac{\text{lbf}}{\text{ft}}\right) \sin(90^\circ + 20^\circ - 80^\circ) \right| \\ &= 2236 \text{ lbf/ft} \end{aligned}$$

Since  $\delta$  is given, use Eq. 37.14.

$$\begin{aligned} k_p &= \frac{\sin^2(\lambda - \phi)}{\sin^2 \lambda \sin(\lambda + \delta)} \\ &\times \left(1 - \sqrt{\frac{\sin(\phi + \delta)\sin(\phi + \beta)}{\sin(\lambda + \delta)\sin(\lambda + \beta)}}\right)^2 \\ &= \frac{\sin^2(80^\circ - 30^\circ)}{\sin^2 80^\circ \sin(80^\circ + 20^\circ)} \\ &\times \left(1 - \sqrt{\frac{\sin(30^\circ + 20^\circ)\sin(30^\circ + (-20^\circ))}{\sin(80^\circ + 20^\circ)\sin(80^\circ + (-20^\circ))}}\right)^2 \\ &= 1.678 \end{aligned}$$

The total passive force is

$$R_p = \frac{1}{2}k_p\gamma H^2 = \left(\frac{1}{2}\right)(1.678)\left(115 \frac{\text{lbf}}{\text{ft}^3}\right)(3 \text{ ft})^2 \\ = 868 \text{ lbf/ft}$$

The horizontal and vertical components are

$$R_{p,h} = |R_p \cos(90^\circ + \delta - \lambda)| \\ = \left| \left(868 \frac{\text{lbf}}{\text{ft}}\right) \cos(90^\circ + 20^\circ - 80^\circ) \right| \\ = 752 \text{ lbf/ft}$$

$$R_{p,v} = |R_p \sin(90^\circ + \delta - \lambda)| \\ = \left| \left(868 \frac{\text{lbf}}{\text{ft}}\right) \sin(90^\circ + 20^\circ - 80^\circ) \right| \\ = 434 \text{ lbf/ft}$$

$$m = \frac{x}{H} \quad 37.38$$

$$n = \frac{y}{H} \quad 37.39$$

## 10. SURCHARGE LOADING

A *surcharge* is an additional force applied at the exposed upper surface of the restrained soil, as shown in Fig. 37.3. A surcharge can result from a uniform load, point load, line load, or strip load. (Line and strip loads are parallel to the wall.)

With a *uniform load surcharge* of  $q$  (in  $\text{lbf}/\text{ft}^2$  ( $\text{Pa}$ )) at the surface, there will be an additional active force,  $R_q$ .  $R_q$  acts horizontally at  $H/2$  above the base. This surcharge resultant is in addition to the backfill active force that acts at  $H/3$  above the base.

$$p_q = k_a q \quad 37.31$$

$$R_q = k_a q H w \quad 37.32$$

If a vertical *point load surcharge* (e.g., a truck wheel),  $V_q$ , in pounds (newtons) is applied a distance  $x$  back from the wall face, the approximate distribution of pressure behind the wall can be found from Eq. 37.33 or Eq. 37.34. These equations assume elastic soil performance and a Poisson's ratio of 0.5. The coefficients have been adjusted to bring the theoretical results into agreement with observed values.

$$p_q = \frac{1.77 V_q m^2 n^2}{H^2(m^2 + n^2)^3} \quad [m > 0.4] \quad 37.33$$

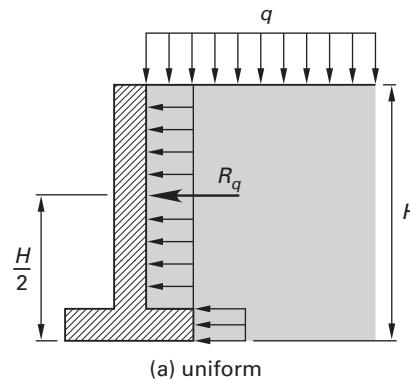

$$p_q = \frac{0.28 V_q n^2}{H^2(0.16 + n^2)^3} \quad [m \leq 0.4] \quad 37.34$$

$$R_q \approx \frac{0.78 V_q}{H} \quad [m = 0.4] \quad 37.35$$

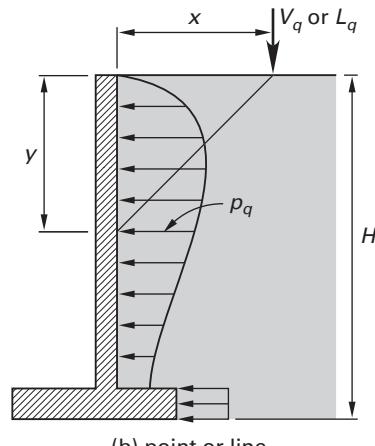

$$R_q \approx \frac{0.60 V_q}{H} \quad [m = 0.5] \quad 37.36$$

$$R_q \approx \frac{0.46 V_q}{H} \quad [m = 0.6] \quad 37.37$$

**Figure 37.3** Surcharges

(a) uniform

(b) point or line

For a *line load surcharge*,  $L_q$  (in  $\text{lbf}/\text{ft}$  ( $\text{N/m}$ )), the distribution of pressure behind the wall is given by Eq. 37.40 and Eq. 37.42.  $m$  and  $n$  are as defined in Eq. 37.38 and Eq. 37.39.

$$p_q = \frac{4L_q m^2 n}{\pi H(m^2 + n^2)^2} \quad [m > 0.4] \quad 37.40$$

$$R_q = \frac{0.64 L_q}{m^2 + 1} \quad 37.41$$

$$p_q = \frac{0.203 L_q n}{H(0.16 + n^2)^2} \quad [m \leq 0.4] \quad 37.42$$

$$R_q = 0.55 L_q \quad 37.43$$

Sidewalks, railways, and roadways parallel to the retaining wall are examples of *strip surcharges*. The effect of a strip surcharge,  $S_q$  (in  $\text{lbf}/\text{ft}^2$  ( $\text{Pa}$ )), is covered in most soils textbooks.

## 11. EFFECTIVE STRESS

Rarely in a properly designed retaining wall is the *groundwater table* (GWT) above the base. However, with submerged construction or when drains become plugged, a significant water table can exist behind the wall. The *pore pressure* (i.e., the *hydrostatic pressure*),  $\mu$ , behind the wall at a point  $h$  below the water table is

$$\mu = \rho_w gh \quad [\text{SI}] \quad 37.44(a)$$

$$\mu = \gamma_w h \quad [\text{U.S.}] \quad 37.44(b)$$

The soil pressure behind the wall depends on its saturated density. The saturated soil density can be calculated from the porosity,  $n$ , or void ratio,  $e$ .

$$\begin{aligned} \rho_{\text{sat}} &= \rho_{\text{dry}} + n\rho_w \\ &= \rho_{\text{dry}} + \left( \frac{e}{1+e} \right) \rho_w \end{aligned} \quad [\text{SI}] \quad 37.45(a)$$

$$\begin{aligned} \gamma_{\text{sat}} &= \gamma_{\text{dry}} + n\gamma_w \\ &= \gamma_{\text{dry}} + \left( \frac{e}{1+e} \right) \gamma_w \end{aligned} \quad [\text{U.S.}] \quad 37.45(b)$$

The water provides a buoyant effect, since each sand particle is submerged. The *effective pressure* (generally referred to as the *effective stress*) is the difference between the *total pressure* and the pore pressure.

$$p_v = g(\rho_{\text{sat}} H - \rho_w h) \quad [\text{SI}] \quad 37.46(a)$$

$$p_v = \gamma_{\text{sat}} H - \gamma_w h \quad [\text{U.S.}] \quad 37.46(b)$$

The total horizontal pressure from the submerged sand is the sum of the hydrostatic pressure and the lateral earth pressure considering the buoyant effect.

$$\begin{aligned} p_h &= g(\rho_w h + k_a(\rho_{\text{sat}} H - \rho_w h)) \\ &= g(k_a \rho_{\text{sat}} H + (1 - k_a) \rho_w h) \end{aligned} \quad [\text{SI}] \quad 37.47(a)$$

$$\begin{aligned} p_h &= \gamma_w h + k_a(\gamma_{\text{sat}} H - \gamma_w h) \\ &= k_a \gamma_{\text{sat}} H + (1 - k_a) \gamma_w h \end{aligned} \quad [\text{U.S.}] \quad 37.47(b)$$

The increase in horizontal pressure above the saturated condition is the *equivalent hydrostatic pressure* (*equivalent fluid pressure*) caused by the *equivalent fluid weight* (*equivalent fluid density*, *equivalent fluid specific weight*, etc.),  $\gamma_{\text{eq}}$ . Considering typical values of  $k_a$ , the

equivalent specific weight of water behind a retaining wall is typically taken as 45 lbf/ft<sup>3</sup> (720 kg/m<sup>3</sup>).

$$\rho_{\text{eq}} = (1 - k_a) \rho_w \quad [\text{SI}] \quad 37.48(a)$$

$$\gamma_{\text{eq}} = (1 - k_a) \gamma_w \quad [\text{U.S.}] \quad 37.48(b)$$

The effective pressure can be quite low due to submergence and tension cracking in cohesive clays. However, all retaining walls should be designed for a minimum equivalent fluid weight of 30 lbf/ft<sup>3</sup> (480 kg/m<sup>3</sup>).

## 12. CANTILEVER RETAINING WALLS: ANALYSIS

Retaining walls must have sufficient resistance against overturning and sliding, and they must possess adequate structural strength against bending outward. The maximum soil pressure under the base must be less than the allowable soil pressure. The following procedure can be used to analyze a retaining wall whose dimensions are known.

*step 1:* Determine the horizontal and vertical active earth pressure resultants from the backfill and all surcharges,  $R_{a,h,i}$  and  $R_{a,v,i}$ . Determine the points of application and moment arms,  $y_{a,h,i}$ , above the base.

*step 2:* Unless it is reasonable to assume that they will always be present, restraint from passive distributions is disregarded. If it is to be considered, however, determine the passive earth pressure.

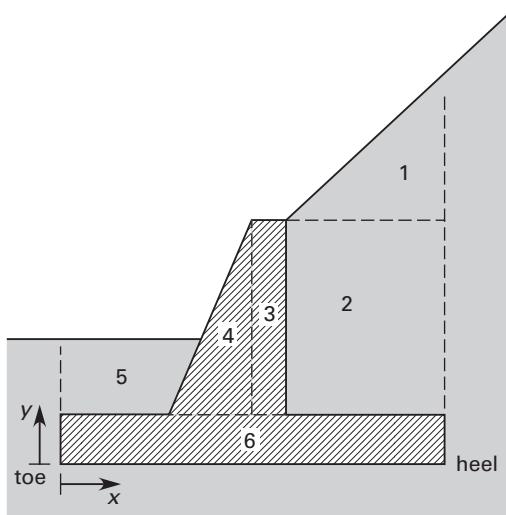

*step 3:* Find all of the vertical forces acting at the base. These include the weights of the retaining wall itself, the soil directly above the heel, and the soil directly above the toe. Each of these weights can be evaluated individually by dividing the concrete and soil into areas with simple geometric shapes. The specific weight of steel-reinforced concrete is almost always taken as 150 lbf/ft<sup>3</sup> (2400 kg/m<sup>3</sup>). Find the location of the centroid of each shape and the moment arm,  $x_i$ , measured as a distance from the toe. (See Fig. 37.4.)

$$W_i = g\rho_i A_i \quad [\text{SI}] \quad 37.49(a)$$

$$W_i = \gamma_i A_i \quad [\text{U.S.}] \quad 37.49(b)$$

*step 4:* Find the net moment about the toe from the forces found in steps 1 through 3.

$$M_{\text{toe}} = \sum W_i x_i - R_{a,h} y_{a,h} + R_{a,v} x_{a,v} \quad 37.50$$

**Figure 37.4** Elements Contributing to Vertical Force\* (step 3)

\*Some retaining walls may not have all elements.

**step 5:** Determine the location,  $x_R$ , and eccentricity,  $\epsilon$ , of the vertical force component. The eccentricity is the distance from the center of the base to the vertical force resultant. Eccentricity should be less than  $B/6$  for the entire base to be in compression.

$$x_R = \frac{M_{\text{toe}}}{R_{a,v} + \sum W_i} \quad 37.51$$

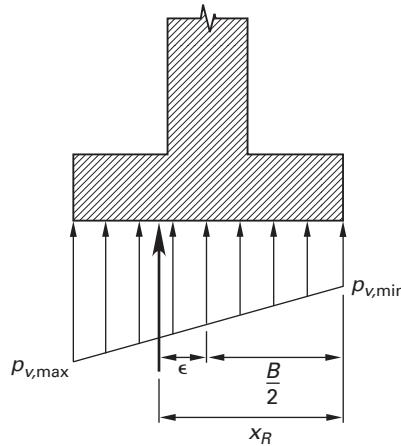

$$\epsilon = \left| \frac{B}{2} - x_R \right| \quad 37.52$$

**step 6:** Check the factor of safety,  $F$ , against overturning. The factor of safety generally should be greater than 1.5 for granular soils and 2.0 for cohesive soils.

$$\begin{aligned} F_{\text{OT}} &= \frac{M_{\text{resisting}}}{M_{\text{overturning}}} \\ &= \frac{\sum W_i x_i + R_{a,v} x_{a,v}}{R_{a,h} y_{a,h}} \end{aligned} \quad 37.53$$

**step 7:** Find the maximum pressure (at the toe) and the minimum pressure (at the heel) on the base. The maximum pressure should not exceed the allowable pressure. (See Fig. 37.5.)

$$\begin{aligned} p_{v,\max}, p_{v,\min} &= \left( \frac{\sum W_i + R_{a,v}}{B} \right) \\ &\times \left( 1 \pm \frac{6\epsilon}{B} \right) \end{aligned} \quad 37.54$$

**Figure 37.5** Resultant Distribution on the Base (step 7)

**step 8:** Calculate the resistance against sliding. The active pressure is resisted by friction and adhesion between the base and the soil, and in the case of a keyed base, also by the shear strength of the soil. Equation 37.55 is for use when the wall has a key, and then only for the compressed soil in front of the key. Equation 37.56 is for use with a keyless base and for tensioned soil behind the key.

$$R_{\text{SL}} = (\sum W_i + R_{a,v}) \tan \phi + c_A B \quad 37.55$$

$$R_{\text{SL}} = (\sum W_i + R_{a,v}) \tan \delta + c_A B \quad 37.56$$

The adhesion,  $c_A$ , is zero for granular soil.  $\tan \delta$  is referred to as a coefficient of friction and is given the symbol  $k$  or  $f$  by some authorities. In the absence of more sophisticated information,  $\tan \delta$  is approximately 0.60 for rock, 0.55 for sand without silt, 0.45 for sand with silt, 0.35 for silt, and 0.30 for clay.

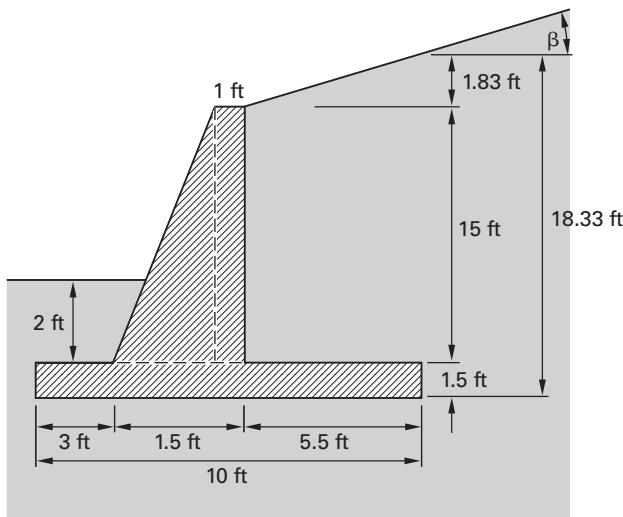

**step 9:** Calculate the factor of safety against sliding. A lower factor of safety (which may be referred to as the "minimum" factor of safety), 1.5, is permitted when the passive resultant is disregarded. If the passive resultant is included, the factor of safety (referred to as the "maximum" factor of safety) should be higher (e.g., 2). If the factor of safety is too low, the base length,  $B$ , can be increased, or a vertical key can be used. In Eq. 37.57,  $R_{a,h}$  includes the horizontal effects of any surcharge.

$$F_{\text{SL}} = \frac{R_{\text{SL}}}{R_{a,h}} \quad 37.57$$

**Example 37.2**

The unkeyed retaining wall shown has been designed for a type-3 backfill of coarse-grained sand with silt having a weight of 125 lbf/ft<sup>3</sup>. The angle of internal friction,  $\phi$ , is 30°, and the angle of external friction,  $\delta$ , is 17°. The backfill is sloped as shown. The maximum allowable soil pressure is 3000 lbf/ft<sup>2</sup>. The adhesion is 950 lbf/ft<sup>2</sup>. Calculate the factor of safety against sliding.

per foot of wall				
area $i$ (ft <sup>2</sup> )	$\gamma$ (lbf/ft <sup>3</sup> )	$W_i$ (lbf)	$x_i$ (ft)	$M_i$ (ft-lbf)
1 (0.5)(5.5)(1.83) = 5.03	125	629	8.17	5139
2 (5.5)(15) = 82.5	125	10,313	7.25	74,769
3 (1)(15) = 15	150	2250	4.0	9000
4 (0.5)(0.5)(15) = 3.75	150	563	3.33	1875
5 (2)(3) = 6	125	750	1.5	1125
6 (1.5)(10) = 15	150	2250	5.0	11,250
totals		16,755		103,158

**Solution**

step 1:  $\beta = \arctan(1.83 \text{ ft}/5.5 \text{ ft}) = \arctan^{1/3} = 18.4^\circ$ . ( $H$  is defined as shown in App. 37.A.) From App. 37.A with a type-3 fill,  $K_v = 17 \text{ lbf/ft}^2$  and  $K_h = 42 \text{ lbf/ft}^2$ . (Equation 37.6 could also be used and  $R$  then broken into components, resulting in somewhat different values, specifically  $R_{a,v} = 1980 \text{ lbf}$  and  $R_{a,h} = 6482 \text{ lbf}$ .)

$$R_{a,v} = \frac{1}{2} K_v H^2 = \left(\frac{1}{2}\right) \left(17 \frac{\text{lbf}}{\text{ft}^2}\right) (18.33 \text{ ft})^2 = 2856 \text{ lbf}$$

$$R_{a,h} = \frac{1}{2} K_h H^2 = \left(\frac{1}{2}\right) \left(42 \frac{\text{lbf}}{\text{ft}^2}\right) (18.33 \text{ ft})^2 = 7056 \text{ lbf}$$

$R_{a,h}$  is located  $18.33 \text{ ft}/3 = 6.11 \text{ ft}$  above the bottom of the base.

step 2: Disregard the passive earth pressure.

step 3: Calculate the weights of soil and concrete. Refer to Fig. 37.4.

step 4: Find the moment about the toe. Notice that  $R_{a,v}$  goes through the heel and has a moment arm equal to the base length. Use Eq. 37.50.

$$\begin{aligned} M_{\text{toe}} &= \sum W_i x_i - R_{a,h} y_{a,h} + R_{a,v} x_{a,v} \\ &= 103,158 \text{ ft-lbf} - (7056 \text{ lbf})(6.11 \text{ ft}) \\ &\quad + (2856 \text{ lbf})(10 \text{ ft}) \\ &= 88,606 \text{ ft-lbf} \end{aligned}$$

step 5: Use Eq. 37.51.

$$\begin{aligned} x_R &= \frac{M_{\text{toe}}}{R_{a,v} + \sum W_i} \\ &= \frac{88,606 \text{ ft-lbf}}{2856 \text{ lbf} + 16,755 \text{ lbf}} \\ &= 4.52 \text{ ft} \end{aligned}$$

Use Eq. 37.52.

$$\epsilon = \frac{B}{2} - x_R = \frac{10 \text{ ft}}{2} - 4.52 \text{ ft} = 0.48 \text{ ft}$$

Since  $0.48 \text{ ft} < 10 \text{ ft}/6$ , the base is in compression everywhere.

step 6: (This step is skipped.)

step 7: Use Eq. 37.54.

$$\begin{aligned} p_{v,\max} &= \left( \frac{\sum W_i + R_{a,v}}{B} \right) \left( 1 + \frac{6\epsilon}{B} \right) \\ &= \left( \frac{16,755 \text{ lbf} + 2856 \text{ lbf}}{10 \text{ ft}} \right) \\ &\quad \times \left( 1 + \frac{(6)(0.48 \text{ ft})}{10 \text{ ft}} \right) \\ &= 2526 \text{ lbf/ft}^2 \quad [< 3000 \text{ lbf/ft}^2, \text{ so OK}] \end{aligned}$$

step 8: Use Eq. 37.56.

$$\begin{aligned} R_{SL} &= \left( \sum W_i + R_{a,v} \right) \tan \delta + c_A B \\ &= (16,755 \text{ lbf} + 2856 \text{ lbf})(\tan 17^\circ) \\ &\quad + \left( 950 \frac{\text{lbf}}{\text{ft}^2} \right) (10 \text{ ft}) \\ &= 15,496 \text{ lbf} \end{aligned}$$

step 9: Use Eq. 37.57.

$$\begin{aligned} F_{SL} &= \frac{R_{SL}}{R_{a,h}} = \frac{15,496 \text{ lbf}}{7056 \text{ lbf}} \\ &= 2.20 \quad [ > 1.5, \text{ so OK}] \end{aligned}$$

### 13. CANTILEVER RETAINING WALLS: DESIGN

A retaining wall is most likely to fail structurally at its base due to the applied moment. In this regard, a retaining wall is similar to a cantilever beam with a nonuniform load. The following characteristics are typical of retaining walls and can be used as starting points for more detailed designs.

- To prevent frost heaving, the top of the base should be below the frost line. This establishes a minimum wall height,  $H$ .
- The heel length,  $L$ , can be determined analytically by setting the active soil moment equal to the “resisting moment” due to the weight of the soil above the heel.

$$R_{a,h} \left( \frac{H}{3} \right) \approx (W_{\text{above heel}}) \left( \frac{L}{2} \right) \quad 37.58$$

- The toe should project approximately  $B/3$  beyond the stem face.

$$B \approx \frac{3}{2}L \quad 37.59$$

- If an analytical method is not used to determine its size, the base should be proportioned such that

$$B = 0.4H \quad [\text{granular backfills and nominal surcharges}]$$

$$B = 0.5H \quad [\text{granular backfills and heavier surcharges}]$$

$$B = 0.6H \quad [\text{cohesive backfills and nominal surcharges}]$$

$$B = 0.7H \quad [\text{cohesive backfills and heavier surcharges}]$$

- The stem thickness,  $t_{\text{stem}}$ , should be proportioned such that

$$8 < \frac{H}{t_{\text{stem}}} < 12 \quad 37.60$$

- The base thickness should be approximately equal to the thickness of the stem at the base, with a minimum of 12 in (300 mm). Alternatively, the base should be proportioned such that

$$10 < \frac{H}{t_{\text{base}}} < 14 \quad 37.61$$

- The *batter decrement* should be approximately  $1/4-1/2$  in per vertical foot.
- The minimum stem thickness at the top should be approximately 12 in (300 mm).

## 1. INTRODUCTION

*Piles* are slender members that are hammered, drilled, or jetted into the ground. They provide strength in soils that would otherwise be too weak to support a foundation. Piles may be constructed of timber, steel, or prestressed reinforced concrete. *Composite piles* include any combination of timber, steel, concrete, and fiberglass (e.g., a concrete-filled steel or concrete-filled fiberglass casing). Other deep foundations include micropiles, auger-cast piles, I-piles, and H-piles (i.e., steel piles with H-shaped cross sections).

*Friction piles* derive the majority of their load-bearing ability from the skin friction between the soil and the pile. *Point-bearing piles* derive their load-bearing ability from the support of the layer at the tip. (Point-bearing piles are used to transfer loads to rock or firm layers below.) Skin friction capacity and point-bearing capacity are simultaneously present to some degree in all piles. However, one mode is usually dominant.

The capacity of a pile to support static loadings is easily calculated. The capacity of a pile exposed to dynamic loads from earthquakes, explosions, and other vibrations is relevant in many cases, but dynamic capacity is more difficult to determine. All calculations in this chapter are for static capacity.

The *ultimate static bearing capacity*,  $Q_{ult}$ , of a single pile is the sum of its point-bearing and skin-friction capacities. For piles supporting a compressive load, the pile weight is balanced by the overburden and is not considered. Other than its effect on the cohesion (undrained shear strength), the position of the groundwater table has no effect on the ultimate bearing capacity.

$$Q_{ult} = Q_p + Q_f$$

38.1

The allowable capacity of a pile depends on the factor of safety, which is typically 2 to 3 for both compression and tension piles, the lower value of 2 being used when the

capacity can be verified by pile loading tests. Even lower values can be specified in unusual and extreme cases.

$$Q_a = \frac{Q_{\text{ult}}}{F} \quad 38.2$$

Pile capacities do not consider settlement, which might actually be the controlling factor.

## 2. PILE CAPACITY FROM DRIVING DATA

The *safe load* (*safe bearing value*) can be calculated empirically from installation data using the *Engineering News Record* (ENR or *Engineering News*) equations. For a pile driven in by a drop hammer of weight  $W$ , falling a distance  $H_{\text{hammer}}$ , driving a weight of  $W_{\text{driven}}$  (including the pile weight), and penetrating an average distance  $S$  per blow during the last five blows, the maximum allowable vertical load per pile,  $Q_a$ , referred to as *design capacity* and *pile resistance*, is calculated as  $1/6$  of the ultimate strength and, incorporating the conversion from feet to inches, is

$$Q_{a,\text{lbf}} = \frac{Q_{\text{ult}}}{FS} = \frac{2W_{\text{hammer,lbf}}H_{\text{fall,ft}}}{S_{\text{in}} + 1} \quad [\text{drop hammer}] \quad 38.3$$

$$Q_{a,\text{lbf}} = \frac{2W_{\text{hammer,lbf}}H_{\text{fall,ft}}}{S_{\text{in}} + 0.1} \quad \begin{cases} \text{single-acting steam hammer;} \\ \text{driven weight} < \text{striking weight} \end{cases} \quad 38.4$$

$$Q_{a,\text{lbf}} = \frac{2W_{\text{hammer,lbf}}H_{\text{fall,ft}}}{S_{\text{in}} + 0.1 \left( \frac{W_{\text{driven}}}{W_{\text{hammer}}} \right)} \quad \begin{cases} \text{single-acting steam hammer;} \\ \text{driven weight} > \text{striking weight} \end{cases} \quad 38.5$$

For double-acting (i.e., powered) hammers, the energy,  $E_{\text{ft-lbf}}$ , transferred to the pile on each stroke replaces the  $WH$  potential energy term. Typical values of energy per blow for timber piles are 7500–14,000 ft-lbf (10–19 kJ) for single-acting hammers and 14,000 ft-lbf (19 kJ) for double-acting hammers. For concrete and steel piles, the typical energy per blow is 15,000–20,000 ft-lbf (20–27 kJ).

$$Q_{a,\text{lbf}} = \frac{2E_{\text{ft-lbf}}}{S_{\text{in}} + 0.1} \quad \begin{cases} \text{double-acting steam hammer;} \\ \text{driven weight} < \text{striking weight} \end{cases} \quad 38.6$$

$$Q_{a,\text{lbf}} = \frac{2E_{\text{ft-lbf}}}{S_{\text{in}} + 0.1 \left( \frac{W_{\text{driven}}}{W_{\text{hammer}}} \right)} \quad \begin{cases} \text{double-acting steam hammer;} \\ \text{driven weight} > \text{striking weight} \end{cases} \quad 38.7$$

Correlations with standard penetration tests (i.e., those that derive the  $N$ -value) have also been established and can be used with adequate testing.

## 3. THEORETICAL POINT-BEARING CAPACITY

The theoretical point-bearing capacity (also known as the *tip resistance* and *point capacity*),  $Q_p$ , of a single pile can be calculated in much the same manner as for a footing. Since the pile size,  $B$ , is small, the  $1/2\gamma BN_\gamma$  term is generally omitted.

$$Q_p = A_p \left( \frac{1}{2}\rho gBN_\gamma + cN_c + \rho gD_f N_q \right) \quad [\text{SI}] \quad 38.8(a)$$

$$Q_p = A_p \left( \frac{1}{2}\gamma BN_\gamma + cN_c + \gamma D_f N_q \right) \quad [\text{U.S.}] \quad 38.8(b)$$

For cohesionless (granular) soil,  $c = 0$ . For sands and silts, the tip point-bearing capacity increases down to a *critical depth*,  $D_c$ , after which it is essentially constant. For loose sands (i.e., with relative densities less than 30%) and loose silts, the critical depth is taken as  $10B$ . For dense sands (relative densities above 70%), and dense silts, the critical depth is  $20B$ . Between relative densities of 30% and 70%, the critical depth can be interpolated between  $10B$  and  $20B$ .

$$Q_p = A_p \rho g DN_q \quad [\text{cohesionless}; D \leq D_c] \quad [\text{SI}] \quad 38.9(a)$$

$$Q_p = A_p \gamma DN_q \quad [\text{cohesionless}; D \leq D_c] \quad [\text{U.S.}] \quad 38.9(b)$$

For cohesive soils with  $\phi = 0^\circ$ ,  $N_q = 1$  and the  $\gamma D_f$  term is approximately cancelled by the pile weight.  $N_c = 9$  for driven piles of virtually all conventional dimensions. (See Table 38.1 and Table 38.2.)

$$Q_p = A_p c N_c \approx 9A_p c \quad [\text{cohesive}] \quad 38.10$$

**Table 38.1** Meyerhof Values of  $N_q$  for Piles\*

$\phi$	20°	25°	28°	30°	32°	34°	36°	38°	40°	42°	45°
driven	8	12	20	25	35	45	60	80	120	160	230
drilled	4	5	8	12	17	22	30	40	60	80	115

\*Significant variation in  $N_q$  has been reported by various researchers. The actual value is highly dependent on  $\phi$  and the installation method.

**Table 38.2** Values of  $N_c$  for Driven Piles\*  
(square and cylindrical perimeters)

$\frac{D_f}{B}$	$N_c$
0	6.3
1	7.8
2	8.5
$\geq 4$	9

\*Not for use with drilled piles.

Derived from *Foundations and Earth Structures Design Manual*, NAVFAC DM-7.2, 1986, Fig. 2, p. 7.2-196.

#### 4. THEORETICAL SKIN-FRICTION CAPACITY

The skin-friction capacity,  $Q_f$  (also known as *side resistance*, *skin resistance*, and *shaft capacity*), is given by Eq. 38.11.  $L_e$  is the *effective pile length*, which can be estimated as the pile length less the depth of the *seasonal variation*, if any.

$$Q_f = A_s f_s = p f_s L_e = p f_s (L - \text{seasonal variation}) \quad 38.11$$

For piles passing through two or more layers, the skin friction capacity of each layer is calculated separately, considering only the thickness,  $L_i$ , of one layer at a time. Individual layer capacities are summed. Alternatively, a weighted average value of the skin friction coefficient can be calculated by weighting the individual coefficients by the layer thicknesses.

$$Q_f = p \sum f_{s,i} L_{e,i} \quad 38.12$$

The *skin friction coefficient* (*unit shaft friction* or *side friction factor*),  $f_s$ , includes both cohesive and adhesive components. The external friction angle,  $\delta$ , is zero (as is  $\phi$ ) for saturated clay, and is generally taken as  $2/3\phi$  in the absence of specific information. The *adhesion*,  $c_A$ , should be obtained from testing, or it can be estimated from the undrained shear strength (cohesion),  $c$ . Table 38.3 gives recommended values of adhesion for piles used in clay. For rough concrete, rusty steel, and corrugated metal,  $c_A = c$ . For smooth concrete,  $0.8c \leq c_A \leq c$ . For clean steel,  $0.5c \leq c_A \leq 0.9c$ .

$$f_s = c_A + \sigma_h \tan \delta \quad 38.13$$

The  $\alpha$ -method determines the *adhesion factor*,  $\alpha$ , as the ratio of the skin friction factor,  $f_s$ , to the undrained shear strength (cohesion),  $c$ . As in Table 38.4, the values of  $\alpha$  are correlated with  $c$ .

$$f_s = \alpha c \quad 38.14$$

**Table 38.3** Recommended Values of Adhesion (piles in clay)

pile type	consistency of clay	cohesion, $c$ (lbf/ft <sup>2</sup> (kPa))	adhesion, $c_A$ (lbf/ft <sup>2</sup> (kPa))
timber or concrete	very soft	0–250 (0–12)	0–250 (0–12)
	soft	250–500 (12–24)	250–480 (12–23)

	very stiff	2000–4000 (96–192)	720–750 (34.5–36)

(Multiply lbf/ft<sup>2</sup> by 0.04788 to obtain kPa.)

Source: *Foundations and Earth Structures Design Manual*, NAVFAC DM-7.2, 1986, Fig. 2, p. 7.2-196.

**Table 38.4** Typical Values\* of the Adhesion Factor,  $\alpha$  (for use with Eq. 38.14)

cohesion, $c$ (lbf/ft <sup>2</sup> (kPa))	$\alpha$ range of values	average
500 (24)	—	1.0
1000 (48)	0.56–0.96	0.83
2000 (96)	0.34–0.83	0.56
3000 (144)	0.26–0.78	0.43

(Multiply lbf/ft<sup>2</sup> by 0.04788 to obtain kPa.)

\*Reported values vary widely.

For sand, the lateral earth pressure,  $\sigma_h$ , depends on the depth, down to a critical depth,  $D_c$ , after which it is essentially constant. (See Fig. 38.1.) Below a depth of  $D_c$ , skin friction is directly proportional to the length. For loose sands (i.e., relative densities less than 30%), the critical depth is taken as  $10B$ . For dense sands (relative densities above 70%), the critical depth is  $20B$ . Between relative densities of 30% and 70%, the critical depth can be interpolated between  $10B$  and  $20B$ .

$$\sigma_h = k_s \sigma'_v = k_s (\rho g D - \mu) \quad [\text{SI}] \quad 38.15(a)$$

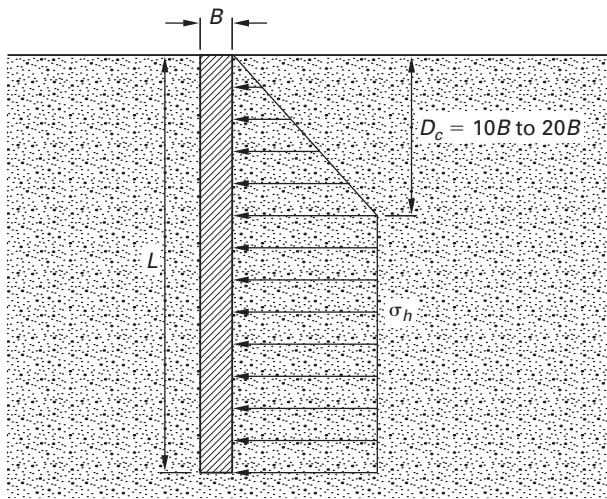

$$\sigma_h = k_s \sigma'_v = k_s (\gamma D - \mu) \quad [\text{U.S.}] \quad 38.15(b)$$

For compression piles driven in clay and silt, the *coefficient of lateral earth pressure*,  $k_s$ , is 1.0. For piles driven in sand, the coefficient varies from 1.0 to 2.0, with the higher value applicable to the most dense sands. For drilled piles, the coefficients of lateral earth pressure are approximately half of the values for driven piles. For jetted piles, the coefficients are approximately 25% of the driven values.

The *pore pressure*,  $\mu$ , a distance  $h$  below the water table is the hydrostatic pressure at that depth.

$$\mu = \rho_w g h \quad [\text{SI}] \quad 38.16(a)$$

$$\mu = \gamma_w h \quad [\text{U.S.}] \quad 38.16(b)$$

**Figure 38.1** Lateral Earth Pressure Distribution on a Pile in Sand

For piles through layers of cohesionless sand,  $c = c_A = 0$ .

$$Q_f = p k_s \tan \delta \sum L_i \sigma' \quad [\text{cohesionless}] \quad 38.17$$

For piles in clay,  $\tan \delta = 0$ ,  $f_s = c_A$ , and  $k_s = 1$ .

$$Q_f = p \sum c_A L_i \quad [\text{cohesive}] \quad 38.18$$

With the  $\beta$ -method for cohesive clay, the friction capacity is estimated as a fraction of the average effective vertical stress (as evaluated halfway down the pile). Values of  $\beta$  are correlated with pile length. (See Table 38.5.) For a pile passing through one layer, the friction capacity is

$$Q_f = p \beta \sigma' L \quad [\text{cohesive}] \quad 38.19$$

**Table 38.5** Typical Values of  $\beta^*$  (for use with Eq. 38.19)

pile length, $L$ (ft (m))	skin friction factor, $\beta$
0 (0)	0.3
25 (7.5)	0.3
50 (15)	0.3
75 (23)	0.27
100 (30)	0.23
125 (38)	0.20
150 (45)	0.18
175 (53)	0.17
200 (60)	0.16

(Multiply ft by 0.3048 to obtain m.)

\* For driven piles in soft and medium clays with  $c < 2000 \text{ lbf/ft}^2$  (96 kPa). After Meyerhof.

## 5. H-PILES

Analysis of steel H-pile capacity is similar to that of other piles except for the perimeter calculation and friction angle. The area between the flanges is assumed to

fill with soil that moves with the pile. In calculating the skin area,  $A_s$ , the perimeter should be taken as the block perimeter of the pile. The friction angle should be the average of the soil-on-steel and soil-on-soil cases.

Similarly, the tip capacity should be calculated using the area enclosed by the block perimeter.

### Example 38.1

A round, smooth concrete pile with a diameter of 11 in is driven 60 ft into wetlands clay. The clay's undrained shear strength and specific weight are  $1400 \text{ lbf/ft}^2$  and  $120 \text{ lbf/ft}^3$ , respectively. At high tide, the water table extends to the ground surface. Using a factor of safety of 3, what is the allowable bearing capacity of the pile?

*Solution*

$$B = \frac{11 \text{ in}}{12 \frac{\text{in}}{\text{ft}}} = 0.917 \text{ ft}$$

The pile's end and surface areas are

$$A_p = \frac{\pi}{4} B^2 = \left(\frac{\pi}{4}\right)(0.917 \text{ ft})^2 = 0.66 \text{ ft}^2$$

$$A_s = \pi B L = \pi(0.917 \text{ ft})(60 \text{ ft}) = 172.9 \text{ ft}^2$$

The tip capacity is given by Eq. 38.10.

$$Q_p = A_p c N_c = 9 A_p c$$

$$= \frac{(9)(0.66 \text{ ft}^2) \left(1400 \frac{\text{lbf}}{\text{ft}^2}\right)}{1000 \frac{\text{lbf}}{\text{kip}}}$$

$$= 8.3 \text{ kips}$$

Estimate  $c_A = 0.8c$  for smooth concrete. The friction capacity is given by Eq. 38.11.

$$Q_f = A_s f_s = A_s c_A$$

$$= \frac{(172.9 \text{ ft}^2)(0.8) \left(1400 \frac{\text{lbf}}{\text{ft}^2}\right)}{1000 \frac{\text{lbf}}{\text{kip}}}$$

$$= 193.6 \text{ kips}$$

The total capacity is

$$Q_{\text{ult}} = Q_p + Q_f = 8.3 \text{ kips} + 193.6 \text{ kips} = 201.9 \text{ kips}$$

With a factor of safety of 3, the allowable load is

$$Q_a = \frac{Q_{\text{ult}}}{F} = \frac{201.9 \text{ kips}}{3} = 67.3 \text{ kips}$$

## 6. TENSILE CAPACITY

*Tension piles* are intended to resist upward forces. Basements and buried tanks below the water level may require tension piles to prevent “floating away.” However, tall buildings subjected to overturning moments also need to resist pile pull-out.

Unlike piles loaded in compression, the *pull-out capacity* of piles does not include the tip capacity. The pullout capacity includes the weight of the pile and the shaft resistance (skin friction). Tensile shaft resistance is calculated similarly to, but not necessarily the same as, compressive shaft resistance. For example, the lateral earth pressure coefficient,  $k_s$ , in tension is approximately 50–75% of the equivalent values in compression.

## 7. CAPACITY OF PILE GROUPS

Some piles are installed in groups, spaced approximately 3 to 3.5 times the pile diameter apart. The piles function as a group due to the use of a concrete load-transfer cap encasing all of the pile heads. The weight of the cap subtracts from the gross group capacity. The capacity due to the pile cap resting on the ground (as a spread footing) is disregarded.

For cohesionless (granular) soils, the capacity of a pile group is taken as the sum of the individual capacities, although the actual capacity will be greater. In-situ tests should be used to justify any increases.

For cohesive soils, the group capacity is taken as the smaller of (a) the sum of the individual capacities and (b) the capacity assuming block action. The block action capacity is calculated assuming that the piles form a large pier whose dimensions are the group's perimeter. The block depth,  $L$ , is the distance from the surface to the depth of the pile points. The width,  $w$ , and length,  $b$ , of the pier are the length and width of the pile group as measured from the outsides (not centers) of the outermost piles. (See Fig. 38.2.)

The average cohesion (undrained shear strength),  $c_1$ , along the depth of the piles is used to calculate the skin friction capacity. The cohesion (undrained shear strength) at the pile tips,  $c_2$ , is used to calculate the end-bearing capacity. A factor of safety of 3 is used to determine the allowable capacity. Any increase in friction capacity due to lateral soil pressure is disregarded.

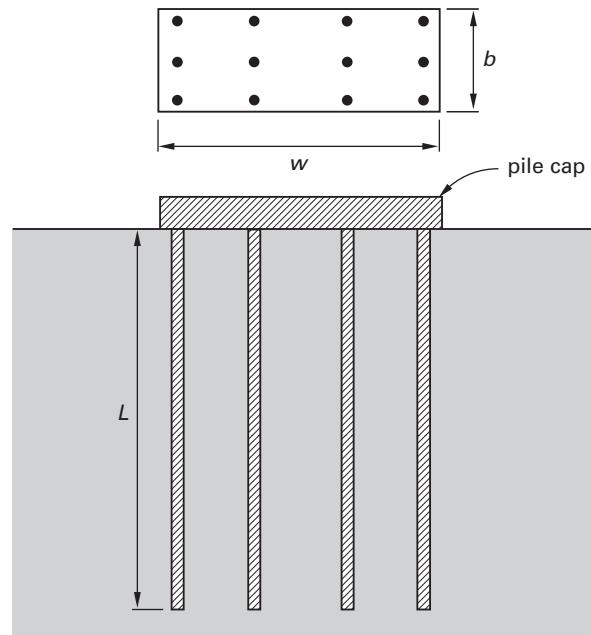

$$Q_s = 2(b + w)L_e c_1 \quad 38.20$$

$$Q_p = 9c_2 bw \quad 38.21$$

$$Q_{ult} = Q_s + Q_p \quad 38.22$$

$$Q_a = \frac{Q_{ult}}{F} \quad 38.23$$

Figure 38.2 Pile Group

The group capacity can be more or less than the sum of the individual pile capacities. The *pile group efficiency*,  $\eta_G$ , is

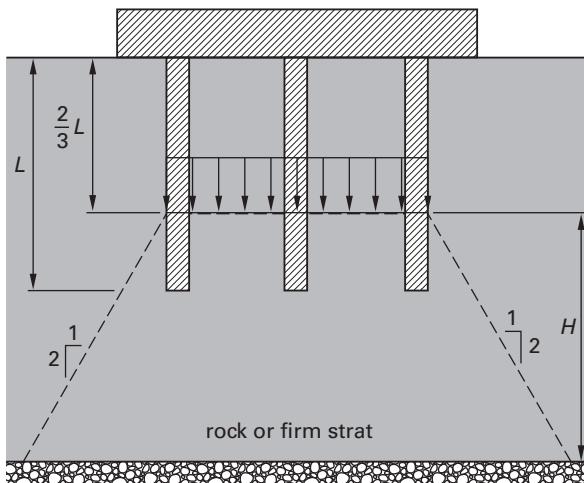

$$\eta_G = \frac{Q_G}{\sum Q_i} \quad 38.24$$

For pile groups in clay, the efficiency is typically less than 100% for spacings up to approximately  $8B$ , above which an efficiency of 100% is maintained for all reasonable pile spacings. For pile groups in sand, efficiencies are similar, although some researchers report efficiencies higher than 100% at very close (e.g.,  $2B$ ) spacings. Efficiencies higher than 100% are rarely considered in designs.

## 8. SETTLEMENT OF PILES AND PILE GROUPS

Piles bearing on rock essentially do not settle. Piles in sand experience minimal settlement. There are few theoretical or empirical methods of evaluating settlement of piles in sand.

Piles in clay may experience significant settling. (See Fig. 38.3.) The settlement of a pile group can be estimated by assuming that the support block (used to calculate the group capacity) extends to a depth of only two thirds of the pile length. Settlement above  $\frac{2}{3}L$  is assumed to be negligible. Below the  $\frac{2}{3}L$  depth, the pressure distribution spreads out at a vertical:horizontal rate of 2:1 (i.e., at an angle of approximately  $60^\circ$  from the horizontal). The consolidation of the layers encountering the pressure distribution is the pile group settlement. The presence of the lower  $L/3$  pile length is disregarded.

**Figure 38.3** Settlement of Pile Groups

## 9. DOWNDRAg AND AdFREEZE FORCES

*Downdrag* occurs when the skin friction force is in the same direction as the axial load. *Negative skin friction* occurs when the settlement of the surrounding soil exceeds the downward movement of the pile shaft. This can occur when a pile passes through an under-consolidated layer of fill that is consolidating under its own weight, but can also be due to a lowering of the water table or placement of surcharges.

Pile support is also affected by the freeze-thaw process. *Frost jacking* occurs when the frozen ground moves upward (*frost heave*) and takes a pile with it. The forces

from this process are known as *adfreeze forces*. When the soil subsequently thaws in the summer, a downdrag force will be experienced. Thus, a pile may experience upward adfreeze forces each winter and downdrag forces each summer. The effects of such forces are particularly pronounced in piles penetrating permafrost.

## 10. MICROPILES

Machine-drilled micropiles (small-diameter grouted piles, minipiles, pin piles, root piles, and needle piles) are piles that are 4–10 in (100–250 mm) in diameter and 65–100 ft (20–30 m) long. Significant column strength is obtained from thick wall sections, usually occupying 50% of the cross-sectional area.

Micropiles are installed using rotary drilling techniques. (The micropile can serve as its own drill bit.) After installation, grout is used to fill the interior of the pile, as well as the tip and any annular voiding. Micropiles are used when traditional pile driving is prevented by restricted access. (This is usually the case in urban areas and in seismic retrofits.)

## 11. PIERS

A *pier* is a deep foundation with a significant cross-sectional area. A pier differs from a pile in its diameter (larger), load-carrying capacity (much larger), and installation method (usually cased within an excavation). In other respects, the analysis of pier foundations is similar to that of piles.

### 1. EXCAVATION

*Excavation*<sup>1</sup> is the removal of soil to allow construction of foundations and other permanent features below the finished level of the grade. It is usually done with machinery, although small areas may be excavated by hand. When a relatively narrow, long excavation is done for piping or for narrow footings and foundation walls, it is called *trenching*.

For large excavations, excess soil has to be removed from the site. However, to minimize cost, it is best to use the soil elsewhere on the site for backfill or in contour modification.

Because excavations can pose a hazard to workers, unshored sides of soil should be no steeper than their natural angle of repose or not greater than a slope of 1½ horizontal to 1 vertical.

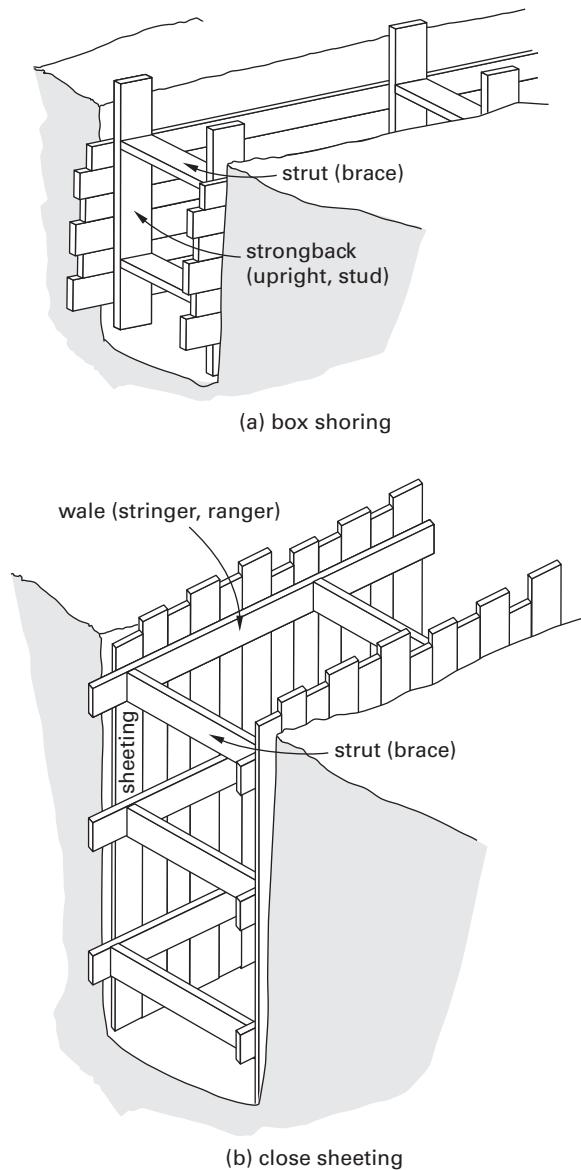

For shallow excavations in open areas, the sides of the excavation can be sloped without the need for some supporting structure. However, if the depth increases or the excavation walls need to be vertical in confined locations, temporary support is required. Shoring and bracing are used to temporarily support adjacent buildings and other construction with posts, timbers, and beams when excavation is proceeding, and to temporarily support the sides of an excavation.

### 2. BRACED CUTS

Bracing is used when temporary trenches for water, sanitary, and other lines are opened in soil. A *braced cut* is an excavation in which the active earth pressure from one bulkhead is used to support the facing bulkhead. The bulkhead members in contact with the soil are known as sheeting, sheathing, sheet piling, lagging, and, rarely, poling. The *box-shoring* and *close-sheeting* methods of support are shown in Fig. 39.1. In box shoring, each of the upright-strut units is known as a *set*. (A partial support system known as *skeleton shoring* is not shown.) Deeper braced cuts may be constructed with vertical *soldier piles* (typically steel H-sections) with horizontal timber sheeting members between the soldiers.

The load is transferred to the struts at various points, so the triangular active pressure distribution does not develop. Since struts are installed as the excavation goes

<sup>1</sup>Chapter 39 Sec. 1 and Sec. 14 are reprinted with permission from *Standard Handbook for Civil Engineers*, 4th edition, by Frederick Merritt, © 1996 by The McGraw-Hill Companies.

**Figure 39.1** Shoring of Braced Cuts

Geotechnical

down, the upper part of the wall deflects very little due to the strut restraint. The pressure on the upper part of the wall is considerably higher than is predicted by the active earth pressure equations. Failure in soils above the water table generally occurs by wale (stringer) crippling followed by strut buckling.

The soil removed from the excavation is known as the *spoils*. Spoils should be placed far enough from the edge of the cut so that they do not produce a surcharge lateral loading.

The bottom of the excavation is referred to as the *base of the cut, mud line* (or *mudline*), *dredge line*, and *toe of the excavation*.

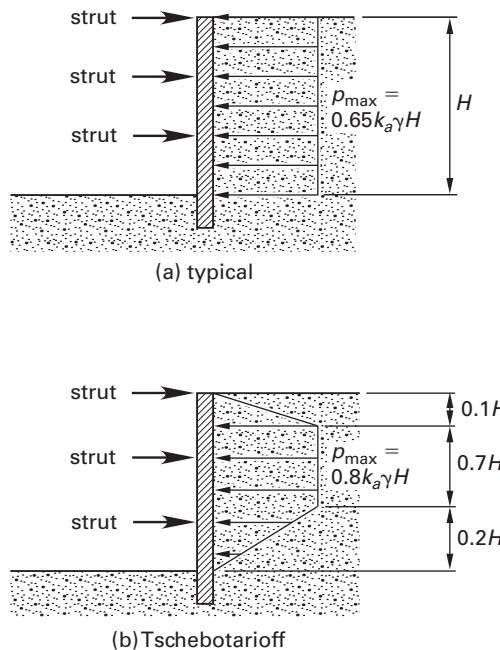

Excavations below the water table should be dewatered prior to cutting.

### 3. BRACED CUTS IN SAND

The analysis of braced cuts is approximate due to the extensive bending of the sheeting. For drained sand, the pressure distribution is approximately uniform with depth. The maximum lateral pressure is given by Eq. 39.1. (The *Tschebotarioff trapezoidal pressure distribution*, Fig. 39.2(b), has also been proposed for sand.)

$$p_{\max} = 0.65k_a\rho gH \quad [\text{SI}] \quad 39.1(a)$$

$$p_{\max} = 0.65k_a\gamma H \quad [\text{U.S.}] \quad 39.1(b)$$

**Figure 39.2** Cuts in Sand

### 4. BRACED CUTS IN STIFF CLAY

For undrained clay (typical of cuts made rapidly in comparison to drainage times),  $\phi = 0^\circ$ . In this case, the lateral pressure distribution depends on the average undrained shear strength (cohesion) of the clay. If  $\gamma H/c \leq 4$ , the clay is stiff, and the pressure distribution is as given in Fig. 39.3. (The quantity  $\gamma H/c$  is known as the *stability number* and is sometimes given the symbol  $N_o$ . More information on this is available in Sec. 40.10) The value of  $p_{\max}$  is affected by many variables. Use the lower range of values of  $p_{\max}$  in Eq. 39.2 when movement is minimal or when the construction period is short.

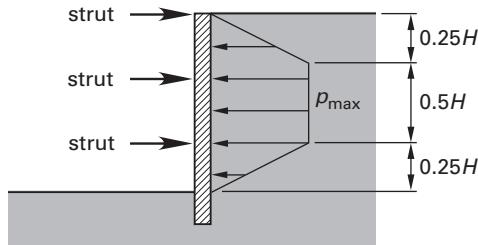

$$0.2\rho gH \leq p_{\max} \leq 0.4\rho gH \quad [\text{SI}] \quad 39.2(a)$$

$$0.2\gamma H \leq p_{\max} \leq 0.4\gamma H \quad [\text{U.S.}] \quad 39.2(b)$$

Except when the cut is underlain by deep, soft, normally consolidated clay, the maximum pressure can be estimated using Eq. 39.3 and Eq. 39.4.

$$\begin{aligned} p_{\max} &= k_a \rho g H & [\text{SI}] & 39.3(a) \\ p_{\max} &= k_a \gamma H & [\text{U.S.}] & 39.3(b) \\ k_a &= 1 - \frac{4c}{\rho g H} & [\text{SI}] & 39.4(a) \\ k_a &= 1 - \frac{4c}{\gamma H} & [\text{U.S.}] & 39.4(b) \end{aligned}$$

**Figure 39.3** Cuts in Stiff Clay

## 5. BRACED CUTS IN SOFT CLAY

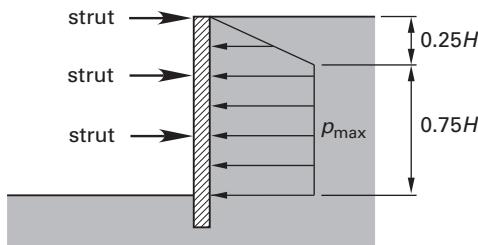

If  $\gamma H / c \geq 6$ , the clay is soft, and the lateral pressure distribution will be as shown in Fig. 39.4. Except for cuts underlain by deep, soft, normally consolidated clays, the maximum pressure is

$$p_{\max} = \rho g H - 4c \quad [\text{SI}] \quad 39.5(a)$$

$$p_{\max} = \gamma H - 4c \quad [\text{U.S.}] \quad 39.5(b)$$

If  $6 \leq \gamma H / c \leq 8$ , the bearing capacity of the soil is probably sufficient to prevent shearing and upward heave. Simple braced cuts should not be attempted if  $\gamma H / c > 8$ .

**Figure 39.4** Cuts in Soft Clay

## 6. BRACED CUTS IN MEDIUM CLAY

If  $4 < \gamma H / c < 6$ , the soft and stiff clay cases should both be evaluated. The case that results in the greater pressure should be used when designing the bracing.

## 7. STABILITY OF BRACED EXCAVATIONS IN CLAY

*Heave* may occur at the bottom of cuts in soft clay. The depth of excavation at which a heaving failure can be expected to occur is referred to as the *critical height of excavation*,  $H_c$ .  $B$  is the width of the excavation. In Eq. 39.6 and Eq. 39.7, it is assumed that there is sufficient distance between the base of the cut and any hard stratum below to allow the heave failure surface to fully form. Friction and adhesion on the back of the sheeting are disregarded.

$$H_c = \frac{5.7c}{\rho g - \sqrt{2}\left(\frac{c}{B}\right)} \quad [H < B] \quad [\text{SI}] \quad 39.6(a)$$

$$H_c = \frac{5.7c}{\gamma - \sqrt{2}\left(\frac{c}{B}\right)} \quad [H < B] \quad [\text{U.S.}] \quad 39.6(b)$$

$$H_c = \frac{N_c c}{\rho g} \quad [H > B] \quad [\text{SI}] \quad 39.7(a)$$

$$H_c = \frac{N_c c}{\gamma} \quad [H > B] \quad [\text{U.S.}] \quad 39.7(b)$$

Approximate values (originally compiled by Alec Westley Skempton) of the bearing capacity factor  $N_c$  for infinitely long trenches in clay are given in Table 39.1. Different values are necessary for circular, square, and rectangular cofferdam-like excavations that are sheeted on all sides.

**Table 39.1** Approximate Skempton Values of  $N_c$  for Infinitely Long Trenches in Clay (for use in Eq. 39.7 and Eq. 39.8)

$H/B$	$N_c$
0	5.1
1	6.3
2	7.0
3	7.3
$\geq 4$	7.5

Equation 39.6(a) and Eq. 39.6(b) are for analysis. (For design, it is common to apply a factor of safety of 1.5 to the undrained shear strength (cohesion),  $c$ .) If the factor of safety is less than 1.25–1.5, the sheeting must be carried down approximately  $B/2$  below the base of the cut until a factor of safety of 1.25–1.5 is achieved. For the common case where  $H > B$ , where sheeting terminates at the base of the cut, and where there may be a surface surcharge loading,  $q$ , the factor of safety is

$$F = \frac{N_c c}{\rho g H + q} \quad [\text{SI}] \quad 39.8(a)$$

$$F = \frac{N_c c}{\gamma H + q} \quad [\text{U.S.}] \quad 39.8(b)$$

## 8. STABILITY OF BRACED EXCAVATIONS IN SAND

For braced excavations in sand, the stability is independent of  $H$  and  $B$ . However, stability does depend on density, friction angle, and seepage conditions. When the water table is at least a distance of  $B$  below the base of the cut and the drained (dry, moist, etc.) sand density below the cut is the same as behind the cut, the factor of safety is

$$F = 2N_\gamma k_a \tan \phi \quad 39.9$$

If the water table is stationary (i.e., not rising or falling) at the base of the cut,

$$F = 2N_\gamma \left( \frac{\rho_{\text{submerged}}}{\rho_{\text{drained}}} \right) k_a \tan \phi \quad [\text{SI}] \quad 39.10(a)$$

$$F = 2N_\gamma \left( \frac{\gamma_{\text{submerged}}}{\gamma_{\text{drained}}} \right) k_a \tan \phi \quad [\text{U.S.}] \quad 39.10(b)$$

If there is continual upward seepage through the base of the cut, the uplift pressure must also be evaluated.

## 9. SHEET PILING

Steel *sheet piles* (also known as *trenchsheets*) are blade-like rolled steel sections that are driven into the ground to provide lateral support. Sheet piles are placed side by side and generally have interlocking edges ("clutches") that enable the individual sheet piles to act as a continuous wall. Sheet piles are driven into the unexcavated ground ahead of the trenching operation.

Sheet piling is selected according to its geometry (i.e., flat, waffle, Z-, etc.) and the required section modulus. ASTM A572 is a typical steel, with the grade indicating the minimum yield point in ksi. The allowable design (bending) stress,  $F_b$ , is usually taken as 65% of the minimum yield stress, with some increases for temporary overstresses typically being allowed. Values of  $F_b$  for common steel grades are given in Table 39.2.

**Table 39.2** Suggested Allowable Design Stress in Sheet Piling

steel grade	minimum yield point		allowable design bending stress, $F_b^*$	
	ksi	MPa	ksi	MPa
A572 grade 55 (Ex-Ten 55)	55	380	35	240
A572 grade 50 (Ex-Ten 50)	50	345	32	220
A572 grade 45 (Ex-Ten 45)	45	310	29	200
A328 regular carbon	38.5	265	25	170

(Multiply ksi by 6.9 to obtain MPa.)

\*65% of the minimum yield stress

## 10. ANALYSIS/DESIGN OF BRACED EXCAVATIONS

Since braced excavations with more than one strut are statically indeterminate, strut forces and sheet piling moments may be evaluated by assuming continuous beam action or hinged beam action (i.e., with hinges at the strut points). In the absence of a true indeterminate analysis, the axial strut compression can be determined by making several strategic assumptions.

A hinge (point of zero moment) is assumed to exist at the second (from the top) strut support point. If moments above that point are taken, a force in the first strut will be derived. Next, a hinge is assumed at the third (from the top) strut support point, and moments are taken about that point (including moments from the top strut, now known), giving the force in the second strut. The process is repeated for all lower struts, finishing by assuming the existence of a fictitious support at the base of the cut in order to determine the force in the last real strut. The pressure distribution on any embedment below the base of the cut is disregarded.

The required section modulus of the sheet piling is given by Eq. 39.11. Typical values of  $F_b$  are given in Table 39.2.

$$S = \frac{M_{\max, \text{sheet piling}}}{F_b} \quad 39.11$$

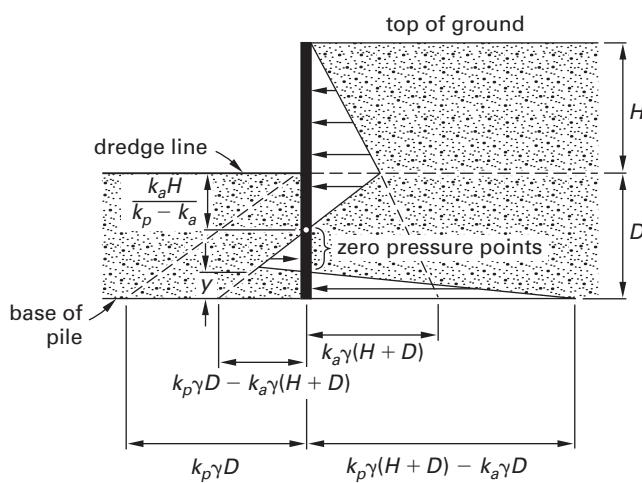

Struts are selected as column members in order to support the axial loads with acceptable slenderness ratios. Wales are selected as uniform-loaded beams, although cofferdam wales are simultaneously loaded in compression and are designed as beam-columns.

## 11. ANALYSIS/DESIGN OF FLEXIBLE BULKHEADS

There are two types of flexible bulkheads: untied and tied (i.e., anchored). If the bulkhead is untied, it is designed as a cantilever beam. This is known as a *cantilever wall* or *cantilever bulkhead*.

The first step in the design of flexible bulkheads is determining the lateral pressure distribution due to the restrained soil and surcharges. Below the base of the cut, the passive pressure distribution opposes the active pressure distribution. Figure 39.5 illustrates simplified pressure distributions on a flexible bulkhead due to cohesionless granular soil (e.g., sand). As shown, there are two points where the net pressure is zero. The upper zero pressure point may be referred to as a *point of rotation* or *pivot point*, reflecting a rigid bulkhead's instantaneous center during soil failure. Locations of the zero pressure points are not needed but can be found from the active and passive pressure distribution equations. The point of maximum bending moment on a bulkhead occurs a distance,  $y$ , above the base of the pile

**Figure 39.5** Net Horizontal Pressure Distribution on a Bulkhead in Uniform Granular Soil (simplified analysis)

at a *point of inflection (point of counterflexure)* where the sum of horizontal forces (i.e., the shear) is zero.

The depth of embedment,  $D$ , must simultaneously satisfy both the zero shear and zero moment equilibrium conditions. After the distance,  $y$ , has been calculated from Eq. 39.12, the pressure distributions are completely defined. The depth of embedment,  $D$ , is determined by trial and error such that the sum of moments (taken about the base of the pile) is zero. A factor of safety is incorporated by increasing  $D$  by 20% to 40%, or alternatively, by dividing  $k_p$  by 1.5 to 2.0.

Analysis and design of bulkheads with different pressure distributions, water tables, and tie-backs are similar to, although more complex than, those with triangular pressure distributions. The procedure for cohesive soils (e.g., clays) is complicated by pressure distributions that depend on the backfill material and time.

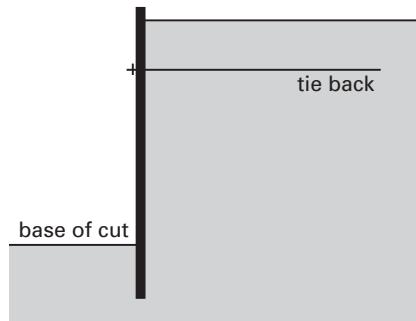

$$y = \frac{k_p D^2 - k_a (H + D)^2}{(k_p - k_a)(H + 2D)} \quad [\text{cohesionless}] \quad 39.12$$

## 12. ANCHORED BULKHEADS

An *anchored bulkhead (tied bulkhead)*, as shown in Fig. 39.6, is supported at its base by its embedment. The bulkhead is anchored near the top by *tie rods (tendons, ties, tiebacks, etc.)* projecting back into the soil. These rods can terminate at deadmen, vertical piles, walls, beams, or various other types of anchors. To be effective, the anchors must be located outside of the failure zone (i.e., behind the slip plane).

Anchored bulkheads can fail in several ways. (a) The soil's base layer can heave (i.e., fail due to inadequate bearing capacity). The soil will shear along a circular arc passing under the bulkhead. (b) The anchorage can fail. (c) The toe embedment at the base of the cut can fail. This is often referred to as *toe kick-out* and *toe wash-out*. (d) Rarely, the sheeting can fail.

**Figure 39.6** Anchored Bulkhead

## 13. ANALYSIS/DESIGN OF ANCHORED BULKHEADS

The *anchor pull* (tension in the tie) is found by setting to zero the sum of all horizontal loads on the bulkhead, including the passive loads on the embedded portion.

If the dimensions are known, the factor of safety against toe failure is found by taking moments about the anchor point on the bulkhead. (Alternatively, if the dimensions are not known, the depth of embedment can be found by taking moments about the anchor point.)

The maximum bending moment in the bulkhead sheeting is found by taking moments about the hinge point, where the shear is zero. If the dimensions are not known, the location of this point must be initially assumed. For firm and dense embedment soils, the hinge point is assumed to be at the base of the cut. For loose and weak soils, it is 1–2 ft below the base of the cut. For a soft layer over a hard layer, it is at the depth of the hard layer. The stress in the bulkhead is

$$f = \frac{M}{S} \quad 39.13$$

The required section modulus is

$$S = \frac{M}{F_b} \quad 39.14$$

With multiple ties, the strut forces are statically indeterminate. Although exact methods (e.g., moment distribution) could be used, it is more expedient to assign portions of the active distribution to the struts based on the tributary areas. The area tributary to a strut is bounded by imaginary lines running midway between it and an adjacent strut, in all four directions.

## 14. COFFERDAMS

Temporary walls or enclosures for protecting an excavation are called *cofferdams*. Generally, one of the most important functions of a cofferdam is to permit work to be carried out on a nearly dry site.

Cofferdams should be planned so that they can be easily dismantled for reuse. Since they are temporary, safety

factors can be small, 1.25–1.5, when all probable loads are accounted for in the design. But design stresses should be kept low when stresses, unit pressure, and bracing reactions are uncertain. Design should allow for construction loads and the possibility of damage from construction equipment. For cofferdams in water, the design should provide for dynamic effect of flowing water and impact of waves. The height of the cofferdam should be adequate to keep out floods that occur frequently.

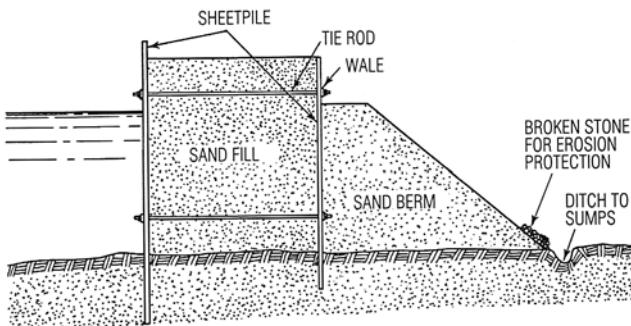

### Double-Wall Cofferdams

Double-wall cofferdams, shown in Fig. 39.7, consist of two lines of sheet piles tied to each other; the space between is filled with sand. These may be erected in water to enclose large areas. For sheet piles driven into irregular rock or gravel, or onto boulders, the bottom of the space between walls may be plugged with a thick layer of tremie concrete to seal gaps below the tips of the sheeting. Double-wall cofferdams are likely to be more watertight than single-wall ones and can be used to greater depths.

A berm may be placed against the outside face of a cofferdam for stability. If so, it should be protected against erosion. For this purpose, riprap, woven mattresses, streamline fins or jetties, or groins may be used. If the cofferdam rests on rock, a berm needs to be placed on the inside only if required to resist sliding, overturning, or shearing.

On sand, a substantial berm must be provided so that water has a long path to travel to enter the cofferdam. (See Fig. 39.7.) (The amount of percolation (seepage) is inversely proportional to the length of path and proportional to the head.) Otherwise, the inside face of the cofferdam may settle, and the cofferdam may overturn as water percolates under the cofferdam and causes a quick, or boiling, excavation bottom. An alternative to the wide berm is wider spacing of the cofferdam walls. This is more expensive, but has the added advantage that the top of the fill can be used by construction equipment.

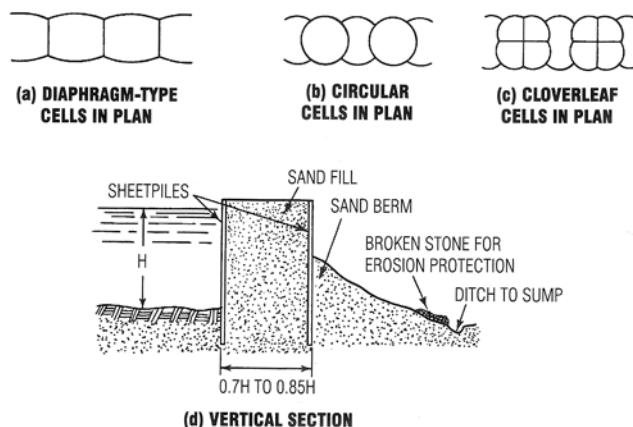

**Figure 39.7** Double-Wall Cofferdam

### Cellular Cofferdams

Used in construction of dams, locks, wharves, and bridge piers, cellular cofferdams are suitable for enclosing large areas in deepwater. These enclosures are composed of relatively wide units. The average width of a cellular cofferdam on rock should be 0.70 to 0.85 times the head of water against the outside. When constructed on sand, a cellular cofferdam should have an ample berm on the inside to prevent the excavation bottom from becoming quick. (See Fig. 39.8(d).)

**Figure 39.8** Cellular Sheet Pile Cofferdam

Steel sheet piles interlocked form the cells. One type of cell consists of circular arcs connected by straight diaphragms. (See Fig. 39.8(a).) Another type comprises circular cells connected by circular arcs. (See Fig. 39.8(b).) Still another type is the coverleaf, composed of large circular cells subdivided by straight diaphragms. (See Fig. 39.8(c).) The cells are filled with sand. The internal shearing resistance of the sand contributes substantially to the strength of the cofferdam. For this reason, it is unwise to fill a cofferdam with clay or silt. Weepholes on the inside sheet piles drain the fill, thus relieving the hydrostatic pressure on those sheets and increasing the shear strength of the fill.

In circular cells, lateral pressure of the fill causes only ring tension in the sheet piles. The maximum stress in the pile interlocks usually is limited to 8000 lbf/in (1400 kN/m). This in turn limits the maximum diameter of the circular cells. Because of numerous uncertainties, this maximum generally is set at 60 ft (18 m). When larger cells are needed, the cloverleaf type may be used.

Circular cells are preferred to the diaphragm type because each circular cell is a self-supporting unit. It may be filled completely to the top before construction of the next cell starts. (Unbalanced fills in a cell may distort straight diaphragms.) When a circular cell has been filled, the top may be used as a platform for construction of the next cell. Also, circular cells require less steel per linear foot of cofferdam. The diaphragm type, however, may be made as wide as desired.

When the sheet piles are being driven, care must be taken to avoid breaking the interlocks. The sheetpiles should be accurately set and plumbed against a structurally sound template. They should be driven in short increments, so that when uneven bedrock or boulders are encountered, driving can be stopped before the cells or interlocks are damaged. Also, all the piles in a cell should be started until the cell is ringed. This can reduce jamming troubles with the last piles to be installed for the cell.

### Single-Wall Cofferdams

Single-wall cofferdams form an enclosure with only one line of sheeting. If there will be no water pressure on the sheeting, they may be built with *soldier beams* (piles extended to the top of the enclosure) and horizontal wood lagging. (See Fig. 39.9.) If there will be water pressure, the cofferdam may be constructed of sheet piles. Although they require less wall material than double-wall or cellular cofferdams, single-wall cofferdams generally require bracing on the inside. Also, unless the bottom is driven into a thick, impervious layer, they may leak excessively at the bottom. There may also be leakage at interlocks. Furthermore, there is danger of flooding and collapse due to hydrostatic forces when these cofferdams are unwatered.

**Figure 39.9** Soldier Beams and Wood Lagging Retaining the Sides of an Excavation

For marine applications, therefore, it is advantageous to excavate, drive piles, and place a seal of tremie concrete without unwatering single-wall sheet pile cofferdams. Often, it is advisable to predredge the area before the cofferdam is constructed, to facilitate placing of bracing and to remove obstructions to pile driving. Also, if blasting is necessary, it would severely stress the sheeting and bracing if done after they were installed.

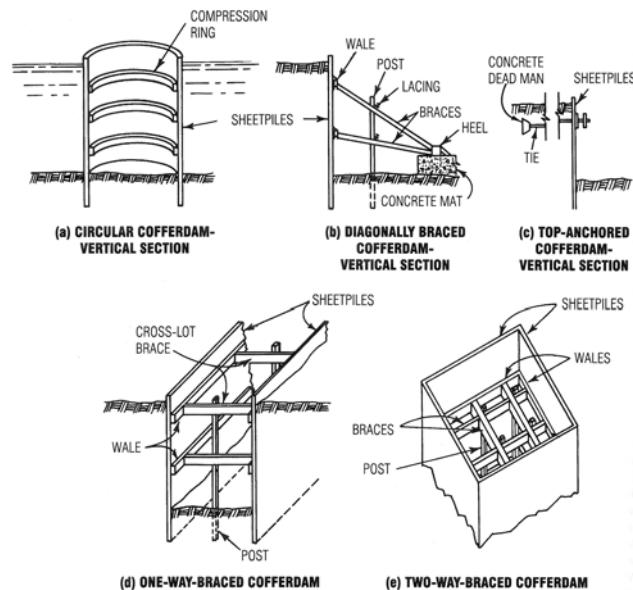

For buildings, single-wall cofferdams must be carefully installed. Small movements and consequent loss of ground usually must be prevented to avoid damaging neighboring structures, streets, and utilities. Therefore, the cofferdams must be amply braced. Sheetng close to an existing structure should not be a substitute for underpinning.

### Bracing

Cantilevered sheet piles may be used for shallow single-wall cofferdams in water or on land where small lateral movement will not be troublesome. Embedment of the piles in the bottom must be deep enough to ensure stability. Design usually is based on the assumptions that lateral passive resistance varies linearly with depth and the point of inflection is about two-thirds of the embedded length below the surface. In general, however, cofferdams require bracing.

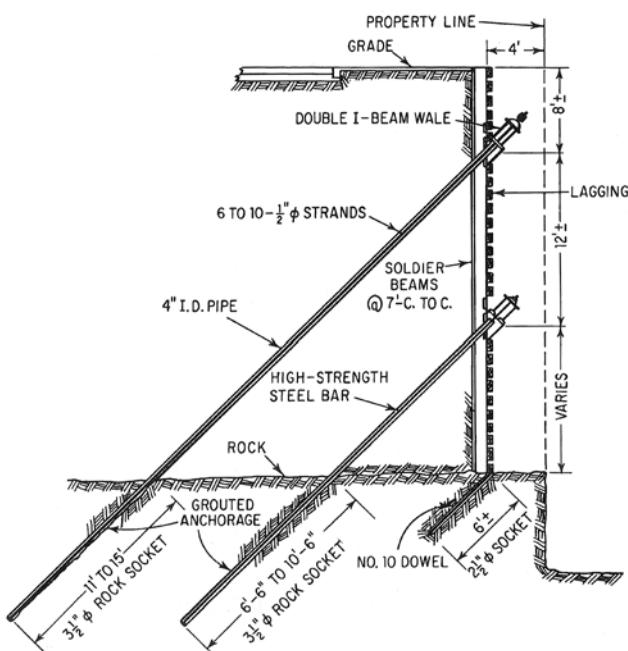

Cofferdams may be braced in many ways. Figure 39.10 shows some commonly used methods. Circular cofferdams may be braced with horizontal rings, as shown in Fig. 39.10(a). For small rectangular cofferdams, horizontal braces, or wales, along sidewalls and end walls may be connected to serve only as struts. For larger cofferdams, diagonal bracing (as in Fig. 39.10(b)) or cross-lot bracing (as in Fig. 39.10(d) and Fig. 39.10(e)) is necessary. When space is available at the top of an excavation, pile tops can be anchored with concrete dead men anchored in grouted sockets in the rock, as shown in Fig. 39.11.

**Figure 39.10** Types of Cofferdam Bracing Including Compression Ring, Diagonal (Rakers) and Cross-Lot Bracing, Wales, and Tiebacks

Horizontal cross braces should be spaced to minimize interference with excavation, form construction, concreting, and pile driving. Spacing of 12 ft and 18 ft (3.6 m and 5.4 m) is common. Piles and wales selected should be strong enough as beams to permit such spacing. In marine applications, divers often have to install the wales and braces underwater. To reduce the amount of such work, tiers of bracing may be prefabricated and lowered into the cofferdam from falsework or from the top set of wales and braces, which is installed above the water surface. In some cases, it may be advantageous to prefabricate and

**Figure 39.11** Vertical Section Showing Prestressed Tiebacks for Soldier Beams

## Geotechnical

erect the whole cage of bracing before the sheet piles are driven. Then, the cage, supported on piles, can serve also as a template for driving the sheet piles.

All wales and braces should be forced into bearing with the sheeting by wedges and jacks.

When pumping cannot control leakage into a cofferdam, excavation may have to be carried out in compressed air. This requires a sealed working chamber, access shafts, and air locks, as for pneumatic caissons. Other techniques, such as use of a tremie concrete seal or chemical solidification or freezing of the soil, if practicable, however, will be more economical.

Braced sheet piles may be designed as continuous beams subjected to uniform loading for earth and to loading varying linearly with depth for water. (Actually, earth pressure depends on the flexibility of the sheeting and relative stiffness of supports.) Wale may be designed for uniform loading. Allowable unit stresses in the wales, struts, and ties may be taken at half the elastic limit for the materials because the construction is temporary and the members are exposed to view. Distress in a member can easily be detected and remedial steps taken quickly.

*Soldier beams* and horizontal wood sheeting are a variation of single-wall cofferdams often used where impermeability is not required. The soldier beams, or piles, are driven vertically into the ground to below the bottom of the proposed excavation. Spacing usually ranges from 5–10 ft (1.5–3 m), as shown in Table 39.3. (The wood

**Table 39.3** Usual Maximum Spans of Horizontal Sheetings with Soldier Piles

nominal thickness of sheeting (in mm)	in well-drained soils (ft (m))	in cohesive soils with low shear resistance (ft (m))
2 (50)	5 (1.5)	4.5 (1.4)
3 (76)	8.5 (2.6)	6 (1.8)
4 (102)	10 (3)	8 (2.4)

(Multiply in by 25.4 to obtain mm.)  
(Multiply ft by 0.3048 to obtain m.)

lagging can be used in the thicknesses shown in Table 39.3 because of arching of the earth between successive soldier beams.)

As excavation proceeds, the wood boards are placed horizontally between the soldiers, as shown in Fig. 39.9. Louvers or packing spaces, 1–2 in (2.5–5 cm) high, are left between the boards so that earth can be tamped behind them to hold them in place. Hay, geotechnical fabric, or plastic sheet may also be stuffed behind the boards to keep the ground from running through the gaps. The louvers permit drainage of water to relieve hydrostatic pressure on the sheeting and thus allow use of a lighter bracing system. The soldiers may be braced directly with horizontal or inclined struts, or wales and braces may be used.

Advantages of soldier-beam construction include fewer piles; the sheeting does not have to extend below the excavation bottom, as do sheet piles; and the soldiers can be driven more easily in hard ground than can sheet piles. Varying the spacing of the soldiers permits avoidance of underground utilities. Use of heavy sections for the piles allows wide spacing of wales and braces. But the soldiers and lagging, as well as sheet piles, are no substitute for underpinning; it is necessary to support and underpin even light adjoining structures.

*Liner-plate cofferdams* may be used for excavating circular shafts. The plates are placed in horizontal rings as excavation proceeds. Stamped from a steel plate usually about 16 in (40 cm) high and 3 ft (0.9 m) long, and light enough to be carried by one person, liner plates have inward-turned flanges along all edges. Top and bottom flanges provide a seat for successive rings. End flanges permit easy bolting of adjoining plates in a ring. The plates also are corrugated for added stiffness. Large-diameter cofferdams may be constructed by bracing the liner plates with steel beam rings.

*Vertical-lagging cofferdams*, with horizontal-ring bracing, also may be used for excavating circular shafts. The method is similar to that used for Chicago caissons. It is similarly restricted to soils that can stand without support in depths of 3–5 ft (0.9–1.5 m) for a short time.

# 40 Special Soil Topics

1. Pressure from Applied Loads:

## Nomenclature

<i>a</i>	acceleration	ft/sec <sup>2</sup>	m/s <sup>2</sup>
<i>a<sub>v</sub></i>	coefficient of compressibility	ft <sup>2</sup> /lbf	m <sup>2</sup> /N
<i>A</i>	area	ft <sup>2</sup>	m <sup>2</sup>
<i>B</i>	footing width	ft	m
<i>B</i>	trench width	ft	m
<i>c</i>	undrained shear strength (cohesion)	lbf/ft <sup>2</sup>	Pa
<i>C</i>	Marston's constant	—	—
<i>C<sub>a</sub></i>	coefficient of compression	—	—
<i>C<sub>c</sub></i>	compression index	—	—
<i>C<sub>p</sub></i>	Marston's constant (broad fill)	—	—
<i>C<sub>r</sub></i>	recompression index	—	—
<i>C<sub>v</sub></i>	coefficient of consolidation	—	—
CR	compression ratio	—	—
<i>d</i>	depth factor	—	—
<i>D</i>	depth to firm base below	ft	m
<i>D</i>	diameter of pipe	ft	m
<i>e</i>	void ratio	—	—
<i>F</i>	factor of safety	—	—
<i>g</i>	acceleration of gravity, 32.2 (9.81)	ft/sec <sup>2</sup>	m/s <sup>2</sup>
<i>h</i>	distance below water table	ft	m
<i>H</i>	depth or cut height	ft	m
<i>H</i>	layer thickness	ft	m
<i>I</i>	influence value	—	—
<i>K</i>	coefficient of permeability	ft/sec	m/s
<i>L</i>	length	ft	m
LF	load factor	—	—

LL	liquid limit	%	%
<i>N<sub>o</sub></i>	stability number	—	—
<i>p</i>	pressure	lbf/ft <sup>2</sup>	Pa
<i>p'</i>	effective pressure	lbf/ft <sup>2</sup>	Pa
<i>P</i>	load	lbf	N
<i>r</i>	radial distance	ft	m
<i>r</i>	radius of round footing	ft	m
<i>r<sub>d</sub></i>	stress reduction factor	—	—
RR	recompression ratio	—	—
<i>s</i>	inclined distance (depth)	ft	m
<i>S</i>	settlement	ft	m
SG	specific gravity	—	—
<i>t</i>	time	sec	s
<i>T<sub>v</sub></i>	time factor	—	—
<i>U<sub>z</sub></i>	degree of consolidation	—	—
<i>w</i>	load per unit length	lbf/ft	N/m
<i>w</i>	moisture content	—	—

## Symbols

<i>α</i>	secondary consolidation index	—	—
<i>β</i>	slope angle	deg	deg
<i>γ</i>	specific weight	lbf/ft <sup>3</sup>	n.a.
<i>μ</i>	pore pressure	lbf/ft <sup>2</sup>	Pa
<i>ρ</i>	density	lbm/ft <sup>3</sup>	kg/m <sup>3</sup>
<i>σ</i>	normal stress	lbf/ft <sup>2</sup>	Pa
<i>τ</i>	shear stress	lbf/ft <sup>2</sup>	Pa
<i>ϕ</i>	angle of internal friction	deg	deg

## Subscripts

app	applied (at the surface)
ave	average
<i>c</i>	compression
<i>d</i>	drainage
eff	effective
<i>h</i>	horizontal
<i>i</i>	inside
<i>n</i>	natural
<i>o</i>	original
<i>r</i>	recompression
<i>v</i>	vertical

## 1. PRESSURE FROM APPLIED LOADS: BOUSSINESQ'S EQUATION

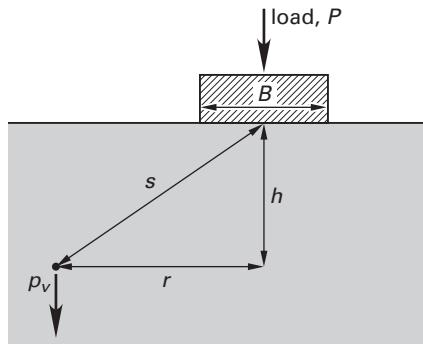

The increase in vertical pressure (stress),  $\Delta p_v$ , caused by an application of a point load,  $P$ , at the surface can be found from *Boussinesq's equation*. This equation assumes that the footing width,  $B$ , is small compared to the depth,  $h$ , and that the soil is semi-infinite, elastic, isotropic, and homogeneous. (See Fig. 40.1.) It is sometimes convenient

to solve Eq. 40.1 by using specially prepared *Boussinesq contour charts* included as App. 40.A and App. 40.B.

$$\Delta p_v = \frac{3h^3 P}{2\pi s^5}$$

$$= \left( \frac{3P}{2\pi h^2} \right) \left( \frac{1}{1 + \left( \frac{r}{h} \right)^2} \right)^{5/2} \quad [h > 2B] \quad 40.1$$

**Figure 40.1** Pressure at a Point

Not all situations are adequately described by the Boussinesq theory. The *Westergaard case* applies to layered materials as they exist in multilayered highway pavement sections. The effect of such layering is to reduce the stresses substantially below those predicted by the Boussinesq theory.

## 2. PRESSURE FROM APPLIED LOADS: ZONE OF INFLUENCE

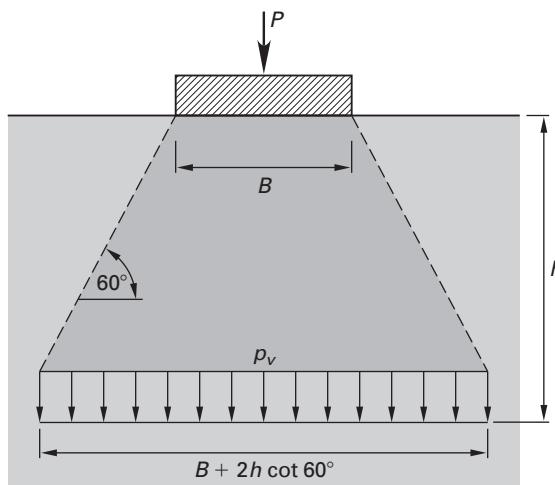

The approximate stress at a depth can be determined by assuming the geometry of the affected area (i.e., the *zone of influence*). Approximate methods can be reasonably accurate in nonlayered homogeneous soils when  $1.5 < h/B < 5$ .

The zone of influence is defined by the angle of the *influence cone*. This angle is typically assumed to be  $51^\circ$  for point loads and  $60^\circ$  from the horizontal for uniformly loaded circular and rectangular footings. (Accordingly, this method is sometimes referred to as the *60° method*.) Alternatively, since  $60^\circ$  is an approximation anyway, for ease of computation, the angle is taken as  $63.4^\circ$ , corresponding to a 2:1 (vertical:horizontal) influence cone angle.

For any depth, the area of the cone of influence is the area of the horizontal plane enclosed by the influence boundaries, as determined geometrically. (See Fig. 40.2.) For a rectangular  $B \times L$  footing, with the  $60^\circ$  method, the area of influence at depth  $h$  is

$$A = (B + 2(h \cot 60^\circ))(L + 2(h \cot 60^\circ)) \quad 40.2$$

**Figure 40.2** Zone of Influence

For a rectangular  $B \times L$  footing, assuming a 2:1 influence, the area of influence is

$$A = (B + h)(L + h) \quad 40.3$$

The increase in pressure at depth  $h$  is

$$\Delta p_v = \frac{P}{A} \quad 40.4$$

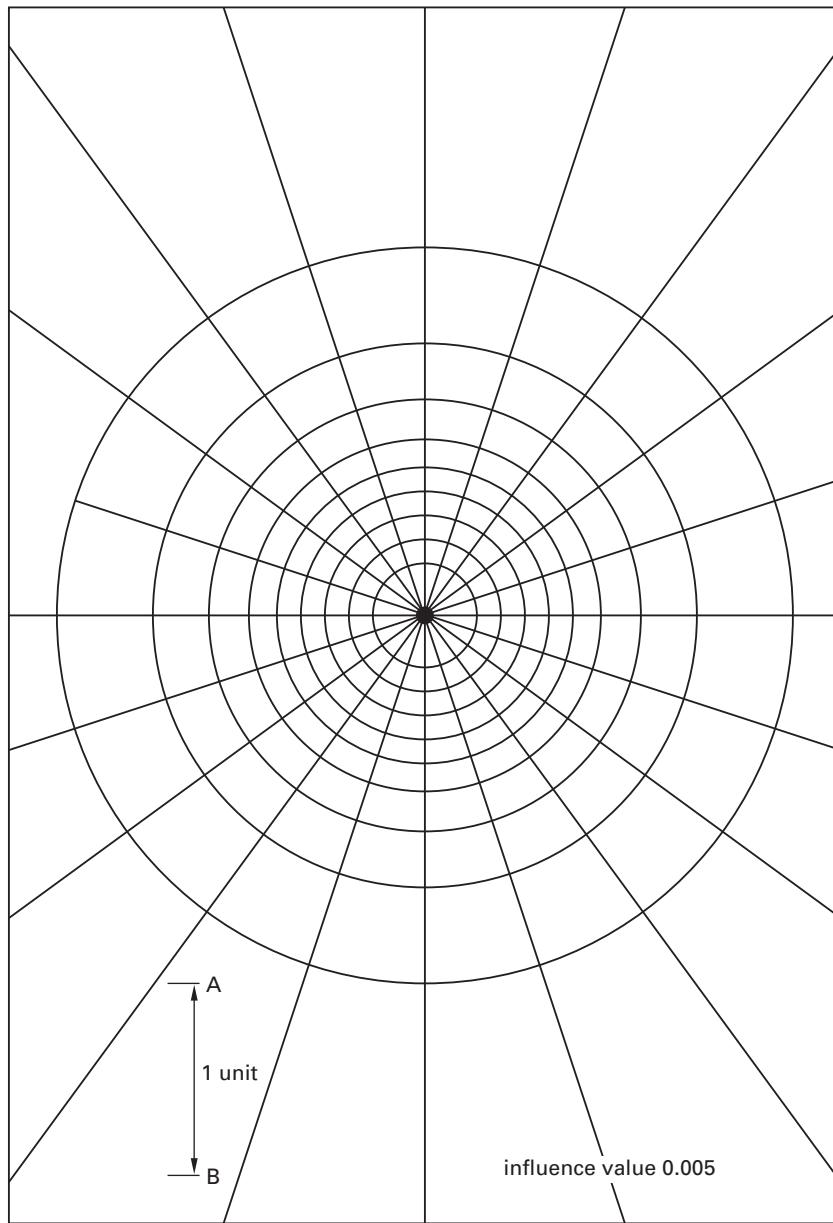

## 3. PRESSURE FROM APPLIED LOADS: INFLUENCE CHART

If a footing or mat foundation is oddly shaped or large compared to the depth where the unknown pressure is wanted, the vertical pressure at a point can be estimated by using an *influence chart* (*Newmark chart*). (See Fig. 40.3.) A Newmark influence chart is a graphical solution to the Boussinesq case. Each influence chart has an indicated scale (the "key") and an influence value that is equal to the reciprocal of the number of squares in the chart.

To use the influence chart, the implied scale is determined by making the indicated distance A-B equal to the depth at which the pressure is wanted. Using this scale, a plan view of the footing or mat foundation is drawn on a piece of tracing paper. The tracing paper is placed over the influence chart such that the center of the chart coincides with the location under the footing where the pressure is wanted. Then, the number of squares under the footing drawing is counted. Partial squares are counted as fractions. The pie-shaped areas in the center circle are counted as complete squares. The *influence value*,  $I$ , is read from the influence chart, and Eq. 40.5 is used to calculate the pressure.

$$\Delta p_v = I(\text{no. of squares})p_{app} \quad 40.5$$

**Figure 40.3** Influence Chart

#### 4. SETTLING

Settling is generally due to *consolidation* (i.e., a decrease in void fraction) of the supporting soil. There are three distinct periods of consolidation. (a) *Immediate settling*, also known as *elastic settling*, occurs immediately after the structure is constructed. Immediate settling is the major settling component in sandy soils. (b) In clayey soils, *primary consolidation* occurs gradually due to the extrusion of water from the void spaces. (c) *Secondary consolidation* occurs in clayey soils at a much slower rate after the primary consolidation has finished. Since plastic readjustment of the soil grains (including progressive fracture of the grains themselves) is the primary mechanism, the magnitude of secondary consolidation is considerably less than primary consolidation.

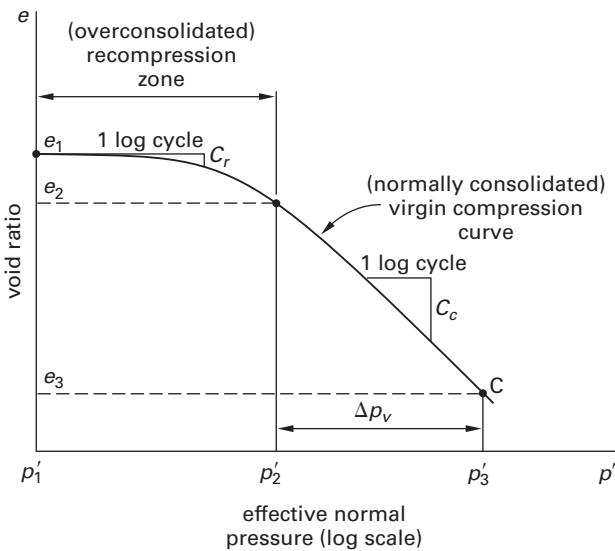

Since settling is greater for higher foundation pressures, specific settlement limits (e.g., 1 in) are directly related to the maximum allowable pressures. This, in turn, can be used to size footings and other foundations.

#### 5. CLAY CONDITION

For clays, the method used to calculate consolidation depends on the clay condition. Virgin clay that has never experienced vertical stress higher than its current condition is known as *normally consolidated clay*. Clay that has previously experienced a stress that is no longer present is known as *overconsolidated clay*. Figure 40.4 shows a typical *consolidation curve* showing void ratio,  $e$ , versus applied effective pressure,  $p'$  (or effective stress,  $\sigma'$ ), for a previously consolidated

clayey soil, graphed on an *e-log p* curve. The curve shows a *recompression segment* (*preconsolidated or overconsolidated segment*) and the *virgin compression branch* (*normally consolidated segment*).

**Figure 40.4** Consolidation Curve for Clay

If the vertical pressure is increased from  $p'_1$  to  $p'_2$ , the consolidation will be in the recompression zone, which has the lower slope,  $C_r$ .  $C_r$  is typically one-fifth to one-tenth of  $C_c$ . If the pressure is increased above  $p'_2$ , consolidation is more dramatic, as the slope,  $C_c$ , is higher. If the pressure is increased from  $p'_1$  to  $p'_3$ , the two consolidations are added together to obtain the total settlement.

## 6. CONSOLIDATION PARAMETERS

Along the recompression line, the *recompression index*,  $C_r$ , is the logarithmic slope of the recompression segment.  $C_c$  and  $C_r$  are reported as positive numbers even though the slopes of the lines they represent are negative.

$$C_r = \frac{-(e_1 - e_2)}{\log_{10} \frac{p'_1}{p'_2}} = \frac{e_2 - e_1}{\log_{10} \frac{p'_1}{p'_2}} \quad 40.6$$

The *compression index* is the logarithmic slope of the primary consolidation curve.  $p'_2 + \Delta p'_v$  is the total pressure after the load has been applied (or removed).

$$\begin{aligned} C_c &= \frac{-(e_2 - e_3)}{\log_{10} \frac{p'_2}{p'_3}} = \frac{e_3 - e_2}{\log_{10} \frac{p'_2}{p'_3}} \\ &= \frac{\Delta e}{\log_{10} \frac{p'_2}{p'_2 + \Delta p'_v}} \end{aligned} \quad 40.7$$

If necessary, the compression index can be estimated from other soil parameters, although these correlations are not highly accurate (i.e., have an error of 30% or more). For clays, a general expression is given by Eq. 40.8. The term  $e_o$  represents the “original” void ratio of the clay, often used as an estimate of the average void ratio over the range of interest. Referring to Fig. 40.4,  $e_o$  will either be  $e_1$  or  $e_2$ , depending on whether the clay is originally overconsolidated or normally consolidated, respectively.

$$C_c \approx 1.15(e_o - 0.35) \quad [\text{clays}] \quad 40.8$$

For normally consolidated inorganic soils (clays) with sensitivities less than 4,

$$C_c \approx 0.009(LL - 10) \quad 40.9$$

For organic soils (e.g., peat), the compression index depends on the natural moisture content.

$$C_c \approx 0.0155w \quad 40.10$$

For *varved clays* (i.e., clays that are layered with fine and coarse varieties),

$$C_c \approx (1 + e_o)(0.1 + 0.006(w_n - 25)) \quad 40.11$$

Some authorities define the *compression ratio*, CR (not to be confused with  $C_r$ ), and the *recompression ratio*, RR (also known as the *swell or swelling index*), as follows.

$$CR = \frac{C_c}{1 + e_o} \quad 40.12$$

$$RR = \frac{C_r}{1 + e_o} \quad 40.13$$

For saturated soils, the void ratio,  $e_o$ , can be calculated from the water content.

$$e_o = w_o(\text{SG}) \quad [\text{saturated}] \quad 40.14$$

## 7. PRIMARY CONSOLIDATION

When a clay layer is loaded to a higher pressure, water is “squeezed” from the voids. Water is lost over a long period of time, though the rate of loss decreases with time. The loss of water results in a consolidation of the clay layer and a settlement of the soil surface. The long-term consolidation due to water loss is the *primary consolidation*,  $S_{\text{primary}}$ . For an overconsolidated clay layer of thickness  $H$ , the consolidation is

$$\begin{aligned} S_{\text{primary}} &= \frac{H \Delta e}{1 + e_o} \\ &= \frac{HC_r \log_{10} \frac{p'_o + \Delta p'_v}{p'_o}}{1 + e_o} \\ &= H(RR) \log_{10} \frac{p'_o + \Delta p'_v}{p'_o} \quad [\text{overconsolidated}] \end{aligned} \quad 40.15$$

The primary consolidation in a normally consolidated clay layer of thickness  $H$  is

$$\begin{aligned} S_{\text{primary}} &= \frac{H \Delta e}{1 + e_o} \\ &= \frac{H C_c \log_{10} \frac{p'_o + \Delta p'_v}{p'_o}}{1 + e_o} \\ &= H (\text{CR}) \log_{10} \frac{p'_o + \Delta p'_v}{p'_o} \quad [\text{normally consolidated}] \end{aligned} \quad 40.16$$

$\Delta p'_v$  is the increase in effective vertical pressure. Boussinesq's equation, stress contour charts, or influence charts can be used to determine  $\Delta p'_v$ .

$p'_o$  is the original *effective pressure (effective stress)* at the midpoint of the clay layer and directly below the foundation. The average effective pressure depends on whether the layer is above or below the *ground water table (GWT)*.  $H$  is the layer thickness. In Eq. 40.16,  $p'$  is the effective pressure, exclusive of the pore pressure. Only the effective pressure causes consolidation.

$$p_v = \gamma_{\text{layer}} H \quad [\text{above GWT}] \quad 40.17$$

$$\begin{aligned} p'_v &= \gamma_{\text{layer}} H - \gamma_{\text{water}} h \\ &= p_v - \mu \quad [\text{below GWT}] \end{aligned} \quad 40.18$$

$$\mu = \gamma_{\text{water}} h \quad 40.19$$

The *pore pressure*,  $\mu$ , can be determined in a number of ways, including piezometer readings (i.e., the height of water in a standpipe).

## 8. PRIMARY CONSOLIDATION RATE

Consolidation of clay is a continuous process, though the rate decreases with time. The time for a single layer to reach a specific consolidation is given by Eq. 40.20.  $H_d$  is the full consolidated layer thickness if drainage is from one surface only (i.e., *single drainage* or *one-way drainage*). If drainage is through both the top and bottom surfaces (i.e., *double drainage* or *two-way drainage*),  $H_d$  is half the consolidated layer's thickness. The units of  $t$  will depend on the units of  $C_v$ .

$$t = \frac{T_v H_d^2}{C_v} \quad 40.20$$

The *coefficient of consolidation*,  $C_v$ , with typical units of  $\text{ft}^2/\text{day}$  ( $\text{m}^2/\text{d}$ ), is assumed to remain constant over small variations in the void ratio,  $e$ .  $C_v$  is evaluated in the laboratory by solving Eq. 40.20 for it, and using observed time and thickness from an oedometer test.

$$C_v = \frac{K(1 + e_o)}{a_v \gamma_{\text{water}}} \quad 40.21$$

The *coefficient of compressibility*,  $a_v$ , can be found from the void ratio and the effective pressure (stress) for any two different loadings. The coefficient of compressibility is

not really constant—it decreases with increasing stress. However, it is assumed constant over pressure ranges.

$$a_v = \frac{-(e_2 - e_1)}{p'_2 - p'_1} \quad 40.22$$

$T_v$  is a dimensionless *time factor* that depends on the *degree of consolidation*,  $U_z$ .  $U_z$  is the fraction of the total consolidation that is expected. For values of  $U_z$  larger than 0.60, Table 40.1 can be used. (See Fig. 40.5 for consolidation parameters.)

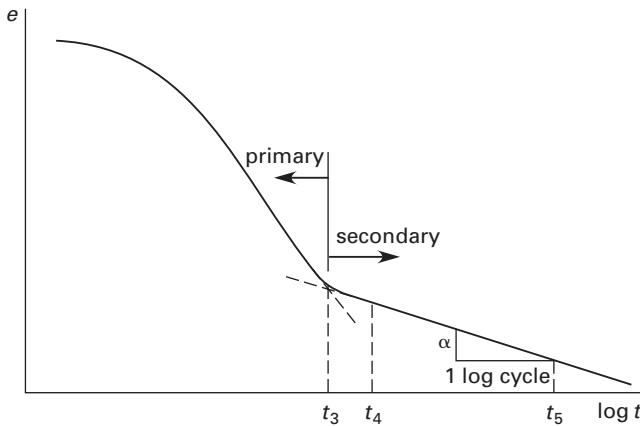

$$T_v = \frac{1}{4} \pi U_z^2 \quad [U_z < 0.60] \quad 40.23(a)$$

$$T_v = 1.781 - 0.933 \log(100(1 - U_z)) \quad [U_z \geq 0.60] \quad 40.23(b)$$

**Table 40.1** Approximate Time Factors

$U_z$	$T_v$
0.10	0.008
0.20	0.031
0.30	0.071
0.40	0.126
0.50	0.197
0.55	0.238
0.60	0.287
0.65	0.340
0.70	0.403
0.75	0.477
0.80	0.567

0.99	1.781
1.0	$\infty$

**Figure 40.5** Consolidation Parameters

## 9. SECONDARY CONSOLIDATION

Following the completion of primary consolidation (at  $T_v = 1$ ), the rate of consolidation decreases markedly.

The continued consolidation is known as *secondary consolidation*. Secondary consolidation is a gradual continuation of consolidation that continues long after the cessation of primary consolidation. Secondary consolidation may not occur at all, as is the case in granular soils. Secondary consolidation may be a major factor for inorganic clays and silts, as well as for highly organic soils.

Secondary consolidation can be identified on a chart of void ratio (or settlement) versus logarithmic time. The region of secondary consolidation is characterized by a distinct slope reduction. The plot can be used to obtain important parameters necessary to calculate the magnitude and rate of secondary consolidation.

The final void ratio,  $e_3$ , at the end of the primary consolidation period is read directly from the chart. The logarithmic slope of the secondary compression line is the *secondary compression index*,  $\alpha$ , which generally varies from 0 to 0.03, seldom exceeding 0.04.

$$\alpha = \frac{-(e_5 - e_4)}{\log \frac{t_5}{t_4}} \quad 40.24$$

The coefficient of secondary consolidation,  $C_\alpha$ , is given by Eq. 40.25.  $e_o$  is the "original" void ratio, often used as an approximation of the average void ratio over the range of interest.

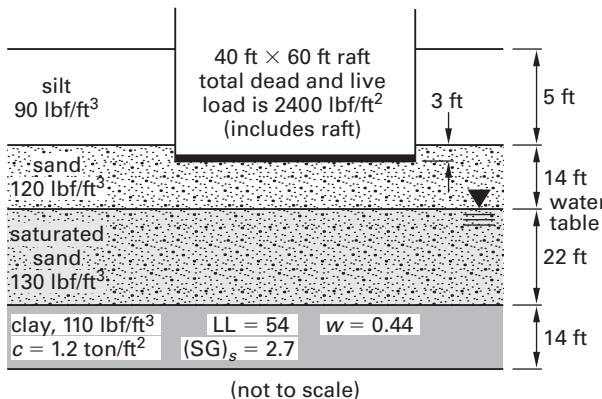

$$C_\alpha = \frac{\alpha}{1 + e_o} \quad 40.25$$

The secondary consolidation during the period  $t_4-t_5$  is

$$S_{\text{secondary}} = C_\alpha H \log_{10} \frac{t_5}{t_4} \quad 40.26$$

### Example 40.1

A 40 ft  $\times$  60 ft raft foundation on sand is constructed and loaded as shown. The sand has already settled. The clay layer is normally consolidated. (a) What long-term primary settlement can be expected at the center of the raft? (b) What long-term primary settlement can be expected at the corner of the raft?

### Solution

*step 1:* Only the clay will contribute to long-term settlement. Calculate the original pressure at the center of the clay layer because this represents the

average conditions in the clay. The pressure is developed from contributions of the various layers above the clay.

silt layer:  $(5 \text{ ft}) \left( 90 \frac{\text{lbf}}{\text{ft}^3} \right) = 450 \text{ lbf/ft}^2$

drained sand layer:  $(14 \text{ ft}) \left( 120 \frac{\text{lbf}}{\text{ft}^3} \right) = 1680 \text{ lbf/ft}^2$

submerged sand layer:  $(22 \text{ ft}) \left( 130 \frac{\text{lbf}}{\text{ft}^3} - 62.4 \frac{\text{lbf}}{\text{ft}^3} \right) = 1487 \text{ lbf/ft}^2$

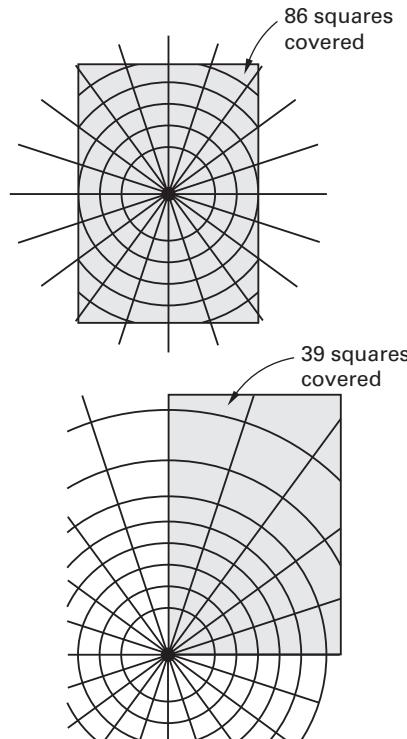

clay layer:  $\left( \frac{1}{2} \right) (14 \text{ ft}) \left( 110 \frac{\text{lbf}}{\text{ft}^3} - 62.4 \frac{\text{lbf}}{\text{ft}^3} \right) = 333 \text{ lbf/ft}^2$

total:  $p_o = 450 \frac{\text{lbf}}{\text{ft}^2} + 1680 \frac{\text{lbf}}{\text{ft}^2} + 1487 \frac{\text{lbf}}{\text{ft}^2} + 333 \frac{\text{lbf}}{\text{ft}^2}$   
 $= 3950 \text{ lbf/ft}^2$

*step 2:* The applied pressure at the base of the raft is the dead and live loading less the overburden due to the excavated sand and silt.

$$p_{\text{net,center}} = 2400 \frac{\text{lbf}}{\text{ft}^2} - (5 \text{ ft}) \left( 90 \frac{\text{lbf}}{\text{ft}^3} \right) - (3 \text{ ft}) \left( 120 \frac{\text{lbf}}{\text{ft}^3} \right)$$
 $= 1590 \text{ lbf/ft}^2$

Use Fig. 40.3 to calculate the pressure increase due to the loading. The distance from the bottom of the raft to the midpoint of the clay layer is 36 ft  $- 3 \text{ ft} + 7 \text{ ft} = 40 \text{ ft}$ . Using a scale of 1 in: 40 ft, the raft is 1 in  $\times$  1½ in. When the raft is centered over the influence chart, 86 squares are covered. When the raft's corner is placed over the center of the chart, 39 squares are covered.

The increases in midlayer pressures are given by Eq. 40.5.

$$\begin{aligned}\Delta p'_{v,\text{center}} &= I(\text{no. of squares})p_{\text{app}} \\ &= (0.005)(86)\left(1590 \frac{\text{lbf}}{\text{ft}^2}\right) \\ &= 684 \text{ lbf}/\text{ft}^2 \\ \Delta p'_{v,\text{corner}} &= (0.005)(39)\left(1590 \frac{\text{lbf}}{\text{ft}^2}\right) \\ &= 310 \text{ lbf}/\text{ft}^2\end{aligned}$$

*step 3:* Estimate the original void content of the clay. Use Eq. 40.14.

$$e_o \approx w(\text{SG}) = (0.44)(2.7) = 1.188$$

*step 4:* Estimate the compression index. Use Eq. 40.9.

$$\begin{aligned}C_c &\approx 0.009(\text{LL} - 10) \\ &= (0.009)(54 - 10) \\ &= 0.396\end{aligned}$$

*step 5:* The settlements are given by Eq. 40.16.

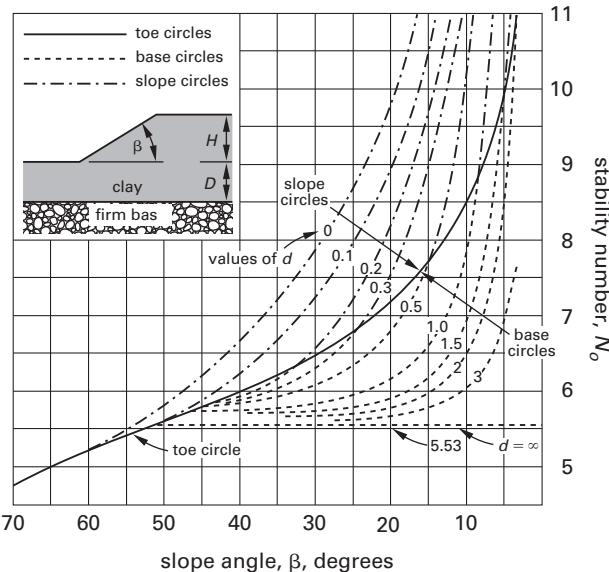

$$\begin{aligned}S_{\text{center}} &= \frac{HC_c \left( \log_{10} \frac{p'_o + \Delta p'_v}{p'_o} \right)}{1 + e_o} \\ &= \frac{(14 \text{ ft})(0.396) \left( \log_{10} \frac{3950 \frac{\text{lbf}}{\text{ft}^2} + 684 \frac{\text{lbf}}{\text{ft}^2}}{3950 \frac{\text{lbf}}{\text{ft}^2}} \right)}{1 + 1.188} \\ &= 0.176 \text{ ft} \\ S_{\text{corner}} &= \frac{(14 \text{ ft})(0.396) \left( \log_{10} \frac{3950 \frac{\text{lbf}}{\text{ft}^2} + 310 \frac{\text{lbf}}{\text{ft}^2}}{3950 \frac{\text{lbf}}{\text{ft}^2}} \right)}{1 + 1.188} \\ &= 0.083 \text{ ft}\end{aligned}$$

## 10. SLOPE STABILITY IN SATURATED CLAY

The maximum slope for cuts in cohesionless drained sand is the *angle of internal friction*,  $\phi$ , also known as the *angle of repose*. However, the maximum slope for cuts in cohesive soils is more difficult to determine. For saturated clay with  $\phi = 0^\circ$ , the *Taylor slope stability chart* (shown in Fig. 40.6) can be used to determine the factor of safety against slope failure. The Taylor chart makes the following assumptions: (a) There is no open water outside of the slope. (b) There are no surcharges

or tension cracks. (c) Shear strength is derived from cohesion only and is constant with depth. (d) Failure takes place as rotation on a circular arc.

**Figure 40.6** Taylor Slope Stability  
(undrained, cohesive soils;  $\phi = 0^\circ$ )

Source: *Soil Mechanics*, NAVFAC Design Manual DM-7.1, 1986, Fig. 2, p. 7.1-319.

The Taylor chart relates a dimensionless depth factor,  $d$ , to a dimensionless stability number,  $N_o$ . The depth factor,  $d$ , is the quotient of the vertical distance from the toe of the slope to the firm base below the clay layer,  $D$ , and the slope height,  $H$  (the depth of the cut).

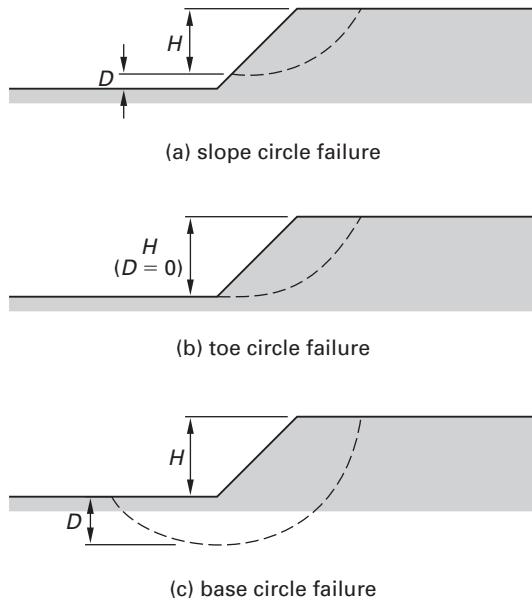

$$d = \frac{D}{H} \quad 40.27$$

Equation 40.28 gives the relationship between the *stability number* and the cohesive factor of safety. The effective specific weight is used when the clay is submerged. Otherwise, the bulk density is used. Generally, the saturated bulk density is used to account for worst-case loading. The minimum acceptable factor of safety is approximately 1.3–1.5.

$$F_{\text{cohesive}} = \frac{N_o c}{\gamma_{\text{eff}} H} \quad 40.28$$

$$\gamma_{\text{eff}} = \gamma_{\text{saturated}} - \gamma_{\text{water}} \quad [\text{submerged}] \quad 40.29$$

The Taylor chart shows that toe circle failures occur in slopes steeper than  $53^\circ$ . For slopes of less than  $53^\circ$ , *slope circle failure*, *toe circle failure*, or *base circle failure* may occur. (See Fig. 40.7.)

**Figure 40.7** Types of Slope Failures**Example 40.2**

A submerged trench is excavated in a layer of soft mud. The trench walls are sloped at a vertical:horizontal ratio of 1.5:1. The mud has a saturated density of 100 lbf/ft<sup>3</sup> and a cohesion of 400 lbf/ft<sup>2</sup>. A factor of safety against cohesive slope failure of 1.5 is required. (a) What type of failure will occur? (b) What depth of cut can be made?

*Solution*

(a) The cut angle is

$$\beta = \arctan \frac{1.5}{1} = 56^\circ$$

Since this is greater than 53°, the failure will be toe circle.

(b) From Fig. 40.6, the stability number for  $\beta = 56^\circ$  is approximately 5.4. Since the clay is submerged, use the effective unit weight.

$$\begin{aligned}\gamma_{\text{eff}} &= \gamma_{\text{saturated}} - \gamma_{\text{water}} \\ &= 100 \frac{\text{lbf}}{\text{ft}^3} - 62.4 \frac{\text{lbf}}{\text{ft}^3} \\ &= 37.6 \text{ lbf/ft}^3\end{aligned}$$

Solve Eq. 40.28 for depth of cut.

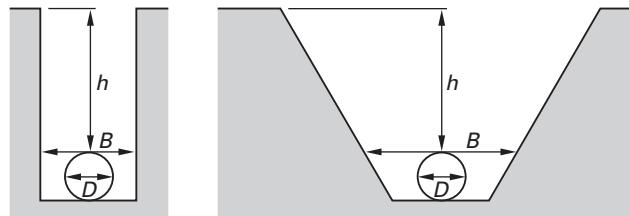

$$\begin{aligned}H &= \frac{N_o c}{F \gamma_{\text{eff}}} \\ &= \frac{(5.4)(400 \frac{\text{lbf}}{\text{ft}^2})}{(1.5)(37.6 \frac{\text{lbf}}{\text{ft}^3})} \\ &= 38.3 \text{ ft}\end{aligned}$$

**11. LOADS ON BURIED PIPES**

If a pipe is placed in an excavated trench and subsequently backfilled (as in Fig. 40.8), the pipe must be strong enough to support the vertical soil load in addition to any loads from surface surcharges. The magnitude of the load supported depends on the amount of backfill, type of soil, and pipe stiffness. For rigid pipes (e.g., concrete, cast iron, ductile iron, and older clay types) that cannot deform and that are placed in narrow trenches (e.g., 2–3 pipe diameters), the approximate dead load per unit length,  $w$ , can be calculated from *Marston's formula*, Eq. 40.30. Typical values of  $C$  and  $\gamma$  are given in Table 40.2.  $B$  is the trench width at the top of the pipe.

$$w = C \rho g B^2 \quad [\text{SI}] \quad 40.30(a)$$

$$w = C \gamma B^2 \quad [\text{U.S.}] \quad 40.30(b)$$

**Figure 40.8** Pipes in Backfilled Trenches**Table 40.2** Approximate Buried Pipe Loading Coefficients<sup>a,b</sup>

cohesion-less specific weight (lbf/ft <sup>3</sup> )	granular material 100	backfill material

		$h/B^c$	values of $C$		
1	100	0.82	0.84	0.86	0.88
2	100	1.40	1.45	1.50	1.55
3	100	1.80	1.90	2.00	2.10
4	100	2.05	2.22	2.33	2.49
5	100	2.20	2.45	2.60	2.80
6	100	2.35	2.60	2.78	3.04
7	100	2.45	2.75	2.95	3.23
8	100	2.50	2.80	3.03	3.37
10	100	2.55	2.92	3.17	3.56
12	100	2.60	2.97	3.24	3.68
$\infty$	100	2.60	3.00	3.25	3.80
					4.60

(Multiply lbf/ft<sup>3</sup> by 16.018 to obtain kg/m<sup>3</sup>.)

<sup>a</sup>Typical values are given. Other values may apply.

<sup>b</sup>Not for use with jacked conduit.

<sup>c</sup>Ratio of depth of backfill (measured from top of pipe) to trench width.

The *dead load pressure* is the dead load divided by the trench width at the pipe's top.

$$p = \frac{w}{B} \quad 40.31$$

*Flexible pipes* (e.g., steel, plastic, and copper) are able to develop a horizontal restraining pressure equal to the vertical pressure if the backfill is well compacted. There is evidence that flexible pipes shrink away from the soil under high compressive loads, thus reducing the soil pressure significantly.  $D$  is the pipe diameter.

$$w = C\rho gBD \quad [\text{SI}] \quad 40.32(a)$$

$$w = C\gamma BD \quad [\text{U.S.}] \quad 40.32(b)$$

If a pipe is placed on undisturbed ground and covered with fill (*broad fill* or *embankment fill*), the load is given by Eq. 40.33. Values of  $C_p$  are given in Table 40.3.

$$w = C_p \rho g D^2 \quad [\text{SI}] \quad 40.33(a)$$

$$w = C_p \gamma D^2 \quad [\text{U.S.}] \quad 40.33(b)$$

**Table 40.3** Typical Values of  $C_p$

$h/D$	rigid pipe, rigid surface, noncohesive backfill	flexible pipe, average conditions
1	1.2	1.1
2	2.8	2.6
3	4.7	4.0
4	6.7	5.4
6	11.0	8.2
8	16.0	11.0

Equation 40.30 shows that the trench width is an important factor in determining whether or not the pipe has sufficient capacity. For a given depth, as the trench width increases, so does the load on the pipe. There is a width, however, beyond which no additional load is carried by a pipe. The limiting trench width, known as the *transition trench width*, is found by setting Eq. 40.30 and Eq. 40.33 equal to each other.

$$B_{\text{transition}} = D \sqrt{\frac{C_p}{C}} \quad 40.34$$

Boussinesq's equation can be used to calculate the live load on a pipe due to an external loading at the surface. For traffic loads, or if the surface loading is sudden, and if there is less than 3 ft of cover on the pipe, the calculated load should be increased by a multiplicative *impact factor*. (See Table 40.4.)

## 12. ALLOWABLE PIPE LOADS

The loadbearing ability of concrete pipes is determined in three-edge bearing tests. The *D-load strength*, reported in pounds per foot of pipe length per foot of inside diameter,

**Table 40.4** Impact Factors for Buried Pipes

by depth, (ft (m))	general use
< 1 (0.3)	1.3
1–2 (0.3–0.6)	1.2
2–3 (0.6–0.9)	1.1
> 3 (> 0.9)	1.0

highway	1.5
railway	1.75
airfield runway	1.00
airfield taxiway, apron	1.50

(Multiply ft by 0.3048 to obtain m.)

is the crushing load that causes a 0.01 in (0.25 mm) wide crack. The *crushing strength* (*laboratory strength*, *cracking strength*, or *ultimate strength*) per unit length of pipe is calculated by multiplying the crushing load by the pipe's inside diameter.

$$\text{crushing strength} = (\text{D-load strength})D_i \quad 40.35$$

The allowable load for a given pipe is obtained by dividing the known crushing strength by a factor of safety and multiplying by a bedding load factor. The factor of safety,  $F$ , varies from 1.25 for flexible pipe to 1.50 for rigid (including reinforced concrete) pipe.

$$w_{\text{allowable}} = \left( \frac{\text{known pipe}}{\text{crushing strength}} \right) \left( \frac{LF}{F} \right) \quad [\text{analysis}] \quad 40.36$$

The *bedding load factor*, LF, depends on the bedding method. Class A bedding uses a concrete cradle. Class B bedding is compacted granular fill to half of the pipe's diameter. Class C is compacted granular fill or densely compacted backfill less than half the pipe's diameter. With class D, there is no bedding. The pipe is placed on a flat subgrade and backfilled. (See Table 40.5.)

## 13. SLURRY TRENCHES AND WALLS

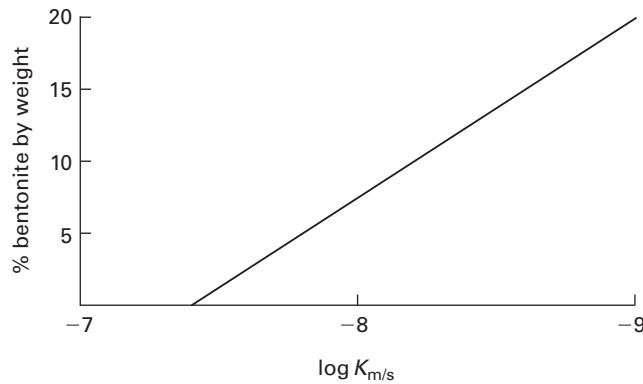

*Slurry trenches* are nonstructural barriers created by chemically solidifying soils and are used to dewater construction sites, contain hazardous groundwater contaminants, and hydraulically isolate holding ponds and lagoons. *Slurry walls* are reinforced semistructural walls

used where more seepage control is needed than can be provided by H-pile or sheet-pile construction. The terms *cut-off wall* and *containment wall* are ambiguous and could refer to either slurry trenches or slurry walls.

Large trenches are opened with a backhoe or other conventional equipment. Trenches 4–12 in (10–39 cm) wide can be opened hydraulically. A slurry trenching fluid containing 1–6% *bentonite* (a naturally occurring clay) by weight fills the trench during excavation. The trench is backfilled, often with a mixture of bentonite and previously excavated soil. If the backfill is soil, the term *soil bentonite (SB) slurry trench* is used. The backfill displaces the trenching fluid, and the trench is extended in a continuous operation. If the trench is filled with a bentonite and cement slurry, the term *cement bentonite slurry trench* is used. Trenches are “keyed” at the bottom by trenching some distance into an impermeable layer (i.e., an *aquiclude*) below.

Bentonite is not very chemically resistant, particularly when it is fully hydrated. Furthermore, when added at 10% by weight to native soil, its permeability is on the order of  $10^{-5}$ – $10^{-6}$  m/s, so a synthetic liner is required to contain hazardous waste. Log permeability decreases linearly with bentonite content, as Fig. 40.9 illustrates for a particular soil. Actual values depend on the nature of the soil and hydraulic head as well, as bentonite content.

**Figure 40.9** Typical Permeability Characteristics of a Bentonite-Treated Clayey-Sand (SC classification; 44% fines; 4 m head)

Slurry walls are constructed by excavating a trench, supporting the open trench with bentonite slurry to prevent ground collapse, inserting a prefabricated rebar cage, and displacing the slurry with cast-in-place *tremie concrete*.

#### 14. GEOTEXTILES

*Geotextiles* (also known as *filter cloth*, *reinforcing fabric*, and *support membrane*) are fabrics used to stabilize and retain soil. (*Geosynthetics* is a term more appropriately applied to the synthetic sheets used as impermeable barriers.) Geotextiles are synthetic fabrics made from wood pulp (rayon and acetate), silica (fiberglass), and petroleum (nylon-polyamide, polyolefin, polyester,

and polystyrene). Polyolefin includes polyethylene and polypropylene. There are both woven and nonwoven varieties. Modern geotextiles are not subject to biological and chemical degradation. Commercial geotextiles have weights of 4–22 oz/yd<sup>2</sup> (140–750 g/m<sup>2</sup>).

Geotextiles are used to prevent the mixing of dissimilar materials (e.g., an aggregate base and soil), which would reduce the support strength. Geotextiles provide a filtering function, allowing free passage of water while restraining soil movement. Other uses include pavement support, subgrade reinforcement, drainage, erosion control, and silt containment.

A significant fraction of all geotextiles is used in highway repair. A layer of geotextile spread at the base of a new roadway may reduce the amount of sand and gravel required while helping to control drainage. Geotextiles can also be used to prevent the infiltration of fine clays into underdrains. In another application, geotextiles strengthen flexible pavements when placed directly under the surface layer. An innovative use of geotextiles is to retard the onset of reflective cracking in flexible pavements.

*Nonwoven fabrics* appear to hold asphalt better than woven varieties. The mechanical properties of nonwoven fabrics are uniform in all directions. Nonwovens also have higher permeabilities. (Fabrics should have minimum permeabilities equal to the adjacent soil, and preferably at least ten times the soil's permeability.) However, *woven fabrics* are lower in cost and are often used for subgrade separation. Wovens have higher tensile strength, higher moduli, and lower elongation than nonwovens.

There is significant debate on the merits of woven versus nonwoven varieties. Most departments of transportation sidestep the woven-nonwoven issue by specifying minimum performance specifications and allowing contractors to make the selection. (See Table 40.6 for typical DOT minimum geotextile specifications.)

#### 15. SOIL NAILING

*Soil nailing* is a slope-stabilization method that involves installing closely spaced “nails” in the soil/rock face to increase its overall shear strength. Nails are actually straight lengths of 60 ksi or 75 ksi rebar, typically no. 7 to no. 10, with a length of 75–100% of the cut height. The nails are passive in that they are not pretensioned when they are installed. The nails become tensioned only when the soil deflects laterally. Nails are typically inclined downward from the insertion point at 15° from the horizontal, but may be inclined anywhere from 10–30° to avoid obstructions or utilities.

In practice, a structural concrete facing (e.g., *shotcrete*) is first placed on the face over a wire mesh support grid. This facing connects the nails and supports the soil between them. Then, holes are drilled through the

concrete facing and soil/rock behind on a 4–6 ft (1.2–1.8 m) grid. Nails are inserted and grouted using a portland cement grout to bond the nails to the surrounding soil.

## 16. TRENCHLESS METHODS

Open-cut methods of pipeline installation and replacement may be the least expensive methods, particularly when lines are close to the surface. Trenchless methods can be used to create and extend existing pipelines, primarily sewer lines, in other situations and where the disruption of trenching is not acceptable. Trenchless installation options include pipe jacking, microtunneling, auger boring, and impact ramming. Renovation options include sliplining, inversion lining, and bursting methods. One problem common to all forms of piping system renovation is that, in providing new lines, connections get sealed off and must be reopened with robotic cutters. Another problem with relining is a reduction in capacity, though some improvement may result from improved hydraulic properties of the lining.

## 17. LIQUEFACTION

*Liquefaction* is a sudden drop in shear strength that can occur in soils of saturated cohesionless particles such as sand. The lower shear strength is manifested as a drop in bearing capacity. Continued cycles of reversed shear in a saturated sand layer can cause pore pressures to

increase, which in turn decreases the effective stress and shear strength. When the shear strength drops to zero, the sand liquefies. In effect, the soil turns into a liquid, allowing everything it previously supported to sink.

Conditions most likely to contribute to or indicate a potential for liquefaction include (a) a lightly loaded sand layer within 50–65 ft (15–20 m) of the surface, (b) uniform particles of medium size, (c) saturated conditions below the water table, and (d) a low-penetration test value (i.e., a low *N*-value).

The *cyclic stress ratio* is a numerical rating of the potential for liquefaction in sands with depths up to 40 ft (12 m). This is the ratio of the average cyclic shear stress,  $\tau_{h,\text{ave}}$ , developed on the horizontal surfaces of the sand as a result of the earthquake loading to the initial vertical effective stress,  $\sigma'_o$ , acting on the sand layer before the earthquake forces were applied.  $a_{\max}$  is the maximum (effective peak) acceleration at the ground surface.  $\sigma_o$  is the total overburden pressure on the sand under consolidation.  $\sigma'_o$  is the initial effective overburden pressure.  $r_d$  is a stress reduction factor that varies from 1 at the ground surface to about 0.9 at a depth of 30 ft (9 m).

$$\frac{\tau_{h,\text{ave}}}{\sigma'_o} \approx 0.65 \left( \frac{a_{\max}}{g} \right) \left( \frac{\sigma_o}{\sigma'_o} \right) r_d \quad 40.37$$

The critical value of  $\tau_{h,\text{ave}}/\sigma'_o$  that causes liquefaction must be determined from field or laboratory testing. A factor of safety of 1.3–1.5 is typical.

### 1. INTRODUCTION TO STATICS

*Statics* is a part of the subject known as *engineering mechanics*.<sup>1</sup> It is the study of rigid bodies that are stationary. To be stationary, a rigid body must be in static equilibrium. In the language of statics, a stationary rigid body has no *unbalanced forces* or moments acting on it.

<sup>1</sup>Engineering mechanics also includes the subject of dynamics. Interestingly, the subject of mechanics of materials (i.e., strength of materials) is not part of engineering mechanics.

## 2. INTERNAL AND EXTERNAL FORCES

An *external force* is a force on a rigid body caused by other bodies. The applied force can be due to physical contact (i.e., pushing) or close proximity (e.g., gravitational, magnetic, or electrostatic forces). If unbalanced, an external force will cause motion of the body.

An *internal force* is one that holds parts of the rigid body together. Internal forces are the tensile and compressive forces within parts of the body as found from the product of stress and area. Although internal forces can cause deformation of a body, motion is never caused by internal forces.

## 3. UNIT VECTORS

A *unit vector* is a vector of unit length directed along a coordinate axis.<sup>2</sup> In the rectangular coordinate system, there are three unit vectors, **i**, **j**, and **k**, corresponding to the three coordinate axes, *x*, *y*, and *z*, respectively. (There are other methods of representing vectors, in addition to bold letters. For example, the unit vector **i** is represented as  $\bar{i}$  or  $\hat{i}$  in other sources.) Unit vectors are used in vector equations to indicate direction without affecting magnitude. For example, the vector representation of a 97 N force in the negative *x*-direction would be written as  $\mathbf{F} = -97\mathbf{i}$ .

## 4. CONCENTRATED FORCES

A *force* is a push or pull that one body exerts on another. A *concentrated force*, also known as a *point force*, is a vector having magnitude, direction, and location (i.e., point of application) in three-dimensional space. (See Fig. 41.1.) In this chapter, the symbols **F** and *F* will be used to represent the vector and its magnitude, respectively. (As with the unit vectors, the symbols **F**,  $\bar{F}$ , and  $\hat{F}$  are used in other sources to represent the same vector.)

The vector representation of a three-dimensional force is given by Eq. 41.1. Of course, vector addition is required.

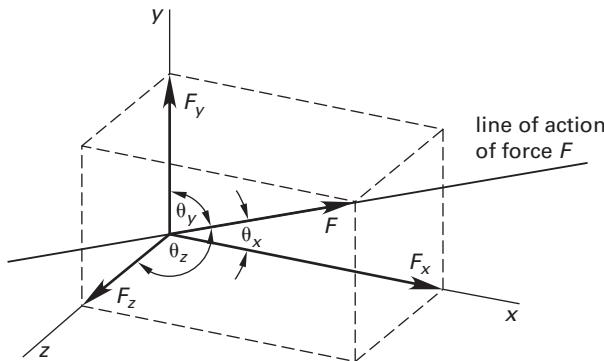

$$\mathbf{F} = F_x\mathbf{i} + F_y\mathbf{j} + F_z\mathbf{k} \quad 41.1$$

If **u** is a *unit vector* in the direction of the force, the force can be represented as

$$\mathbf{F} = Fu \quad 41.2$$

<sup>2</sup>Although polar, cylindrical, and spherical coordinate systems can have unit vectors also, this chapter is concerned only with the rectangular coordinate system.

Figure 41.1 Components and Direction Angles of a Force

The components of the force can be found from the *direction cosines*, the cosines of the true angles made by the force vector with the *x*, *y*, and *z*-axes.

$$F_x = F \cos \theta_x \quad 41.3$$

$$F_y = F \cos \theta_y \quad 41.4$$

$$F_z = F \cos \theta_z \quad 41.5$$

$$F = \sqrt{F_x^2 + F_y^2 + F_z^2} \quad 41.6$$

The *line of action* of a force is the line in the direction of the force extended forward and backward. The force, **F**, and its unit vector, **u**, are along the line of action.

## 5. MOMENTS

*Moment* is the name given to the tendency of a force to rotate, turn, or twist a rigid body about an actual or assumed pivot point. (Another name for moment is *torque*, although torque is used mainly with shafts and other power-transmitting machines.) When acted upon by a moment, unrestrained bodies rotate. However, rotation is not required for the moment to exist. When a restrained body is acted upon by a moment, there is no rotation.

An object experiences a moment whenever a force is applied to it.<sup>3</sup> Only when the line of action of the force passes through the center of rotation (i.e., the actual or assumed pivot point) will the moment be zero.

Moments have primary dimensions of length  $\times$  force. Typical units include foot-pounds, inch-pounds, and newton-meters.<sup>4</sup>

<sup>3</sup>The moment may be zero, as when the moment arm length is zero, but there is a (trivial) moment nevertheless.

<sup>4</sup>Units of kilogram-force-meter have also been used in metricated countries. Foot-pounds and newton-meters are also the units of energy. To distinguish between moment and energy, some authors reverse the order of the units, so pound-feet and meter-newtons become the units of moment. This convention is not universal and is unnecessary since the context is adequate to distinguish between the two.

## 6. MOMENT OF A FORCE ABOUT A POINT

Moments are vectors. The moment vector,  $\mathbf{M}_O$ , for a force about point O is the *cross product* of the force,  $\mathbf{F}$ , and the vector from point O to the point of application of the force, known as the *position vector*,  $\mathbf{r}$ . The scalar product  $|\mathbf{r}| \sin \theta$  is known as the *moment arm*,  $d$ .

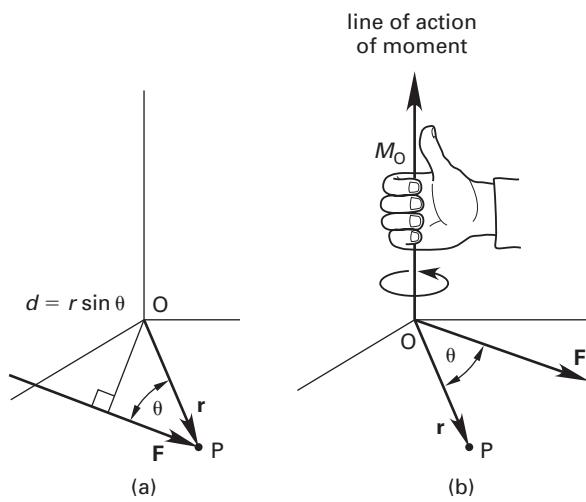

$$\mathbf{M}_O = \mathbf{r} \times \mathbf{F} \quad 41.7$$

$$M_O = |\mathbf{M}_O| = |\mathbf{r}| |\mathbf{F}| \sin \theta = d |\mathbf{F}| \quad [\theta \leq 180^\circ] \quad 41.8$$

The line of action of the moment vector is normal to the plane containing the force vector and the position vector. The sense (i.e., the direction) of the moment is determined from the *right-hand rule*.

*Right-hand rule:* Place the position and force vectors tail to tail. Close your right hand and position it over the pivot point. Rotate the position vector into the force vector, and position your hand such that your fingers curl in the same direction as the position vector rotates. Your extended thumb will coincide with the direction of the moment.<sup>5</sup> (See Fig. 41.2.)

Figure 41.2 Right-Hand Rule

## 7. VARIGNON'S THEOREM

*Varignon's theorem:* is a statement of how the total moment is derived from a number of forces acting simultaneously at a point.

*Varignon's theorem:* The sum of individual moments about a point caused by multiple concurrent forces is equal to the moment of the resultant force about the same point.

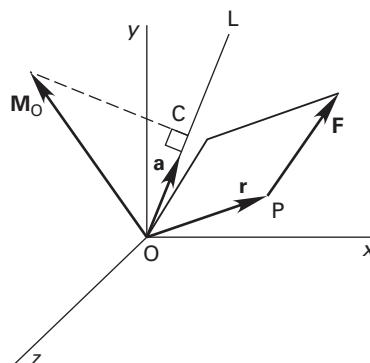

$$(\mathbf{r} \times \mathbf{F}_1) + (\mathbf{r} \times \mathbf{F}_2) + \dots = \mathbf{r} \times (\mathbf{F}_1 + \mathbf{F}_2 + \dots) \quad 41.9$$

<sup>5</sup>The direction of a moment also corresponds to the direction a right-hand screw would progress if it was turned in the direction that rotates  $\mathbf{r}$  into  $\mathbf{F}$ .

## 8. MOMENT OF A FORCE ABOUT A LINE

Most rotating machines (motors, pumps, flywheels, etc.) have a fixed rotational axis. That is, the machines turn around a line, not around a point. The moment of a force about the rotational axis is not the same as the moment of the force about a point. In particular, the moment about a line is a scalar.<sup>6</sup> (See Fig. 41.3.)

Figure 41.3 Moment of a Force About a Line

Moment  $M_{OL}$  of force  $\mathbf{F}$  about line  $OL$  is the projection,  $OC$ , of moment  $\mathbf{M}_O$  onto the line. Equation 41.10 gives the moment of a force about a line.  $\mathbf{a}$  is the unit vector directed along the line, and  $a_x$ ,  $a_y$ , and  $a_z$  are the direction cosines of the axis  $OL$ . Notice that Eq. 41.10 is a dot product (i.e., a scalar).

$$M_{OL} = \mathbf{a} \cdot \mathbf{M}_O = \mathbf{a} \cdot (\mathbf{r} \times \mathbf{F}) \\ = \begin{vmatrix} a_x & a_y & a_z \\ x_P - x_O & y_P - y_O & z_P - z_O \\ F_x & F_y & F_z \end{vmatrix} \quad 41.10$$

If point O is the origin, then Eq. 41.10 will reduce to Eq. 41.11.

$$M_{OL} = \begin{vmatrix} a_x & a_y & a_z \\ x & y & z \\ F_x & F_y & F_z \end{vmatrix} \quad 41.11$$

## 9. COMPONENTS OF A MOMENT

The direction cosines of a force (vector) can be used to determine the components of the moment about the coordinate axes.

$$M_x = M \cos \theta_x \quad 41.12$$

$$M_y = M \cos \theta_y \quad 41.13$$

$$M_z = M \cos \theta_z \quad 41.14$$

<sup>6</sup>Some sources say that the moment of a force about a line can be interpreted as a moment directed along the line. However, this interpretation does not follow from vector operations.

Alternatively, the following three equations can be used to determine the components of the moment from a force applied at point  $(x, y, z)$  referenced to an origin at  $(0, 0, 0)$ .

$$M_x = yF_z - zF_y \quad 41.15$$

$$M_y = zF_x - xF_z \quad 41.16$$

$$M_z = xF_y - yF_x \quad 41.17$$

The resultant moment magnitude can be reconstituted from its components.

$$M = \sqrt{M_x^2 + M_y^2 + M_z^2} \quad 41.18$$

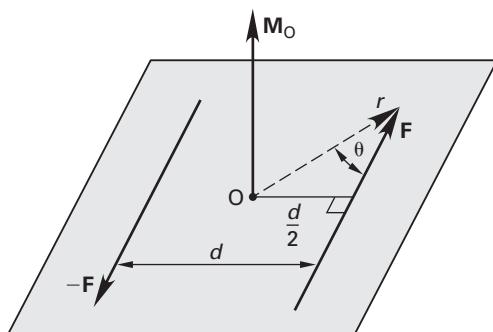

## 10. COUPLES

Any pair of equal, opposite, and parallel forces constitutes a *couple*. A couple is equivalent to a single moment vector. Since the two forces are opposite in sign, the  $x$ -,  $y$ -, and  $z$ -components of the forces cancel out. Therefore, a body is induced to rotate without translation. A couple can be counteracted only by another couple. A couple can be moved to any location within the plane without affecting the equilibrium requirements.

In Fig. 41.4, the equal but opposite forces produce a moment vector,  $\mathbf{M}_O$ , of magnitude  $Fd$ . The two forces can be replaced by this moment vector, which can be moved to any location on a body. (Such a moment is known as a *free moment*, *moment of a couple*, or *coupling moment*.)

$$M_O = 2rF \sin \theta = Fd \quad 41.19$$

**Figure 41.4** Couple

## 11. EQUIVALENCE OF FORCES AND FORCE-COUPLE SYSTEMS

If a force,  $F$ , is moved a distance,  $d$ , from the original point of application, a couple,  $M$ , equal to  $Fd$  must be added to counteract the induced couple. The combination of the moved force and the couple is known as a *force-couple system*. Alternatively, a force-couple system

can be replaced by a single force located a distance  $d = M/F$  away.

## 12. RESULTANT FORCE-COUPLE SYSTEMS

The equivalence described in the previous section can be extended to three dimensions and multiple forces. Any collection of forces and moments in three-dimensional space is statically equivalent to a single resultant force vector plus a single resultant moment vector. (Either or both of these resultants can be zero.)

The  $x$ -,  $y$ -, and  $z$ -components of the resultant force are the sums of the  $x$ -,  $y$ -, and  $z$ -components of the individual forces, respectively.

$$F_{R,x} = \sum_i (F \cos \theta_x)_i \quad 41.20$$

$$F_{R,y} = \sum_i (F \cos \theta_y)_i \quad 41.21$$

$$F_{R,z} = \sum_i (F \cos \theta_z)_i \quad 41.22$$

The resultant moment vector is more complex. It includes the moments of all system forces around the reference axes plus the components of all system moments.

$$M_{R,x} = \sum_i (yF_z - zF_y)_i + \sum_i (M \cos \theta_x)_i \quad 41.23$$

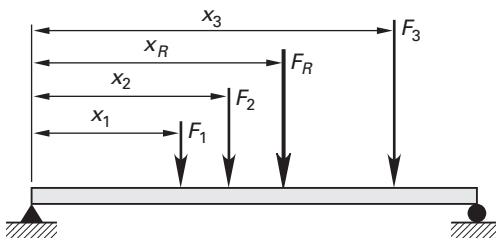

$$M_{R,y} = \sum_i (zF_x - xF_z)_i + \sum_i (M \cos \theta_y)_i \quad 41.24$$

$$M_{R,z} = \sum_i (xF_y - yF_x)_i + \sum_i (M \cos \theta_z)_i \quad 41.25$$

## 13. LINEAR FORCE SYSTEMS

A *linear force system* is one in which all forces are parallel and applied along a straight line. (See Fig. 41.5.) A straight beam loaded by several concentrated forces is an example of a linear force system.

**Figure 41.5** Linear Force System

For the purposes of statics, all of the forces in a linear force system can be replaced by an *equivalent resultant force*,  $F_R$ , equal to the sum of the individual forces.

The location of the equivalent force coincides with the location of the centroid of the force group.

$$F_R = \sum_i F_i \quad 41.26$$

$$x_R = \frac{\sum_i F_i x_i}{\sum_i F_i} \quad 41.27$$

$$F_R = \frac{wL}{2} \quad 41.32$$

$$x_R = \frac{2L}{3} \quad 41.33$$

increases from zero (at  $x = 0$ ) to  $w$  (at  $x = L$ ), as shown in Fig. 41.7.

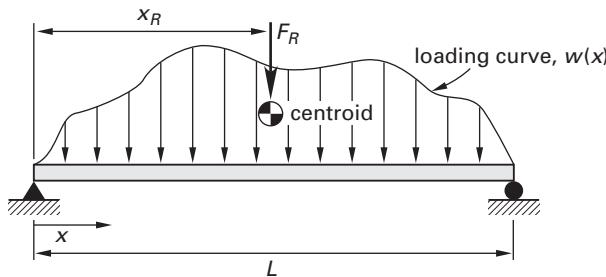

## 14. DISTRIBUTED LOADS

If an object is continuously loaded over a portion of its length, it is subject to a *distributed load*. Distributed loads result from *dead load* (i.e., self-weight), hydrostatic pressure, and materials distributed over the object.

If the load per unit length at some point  $x$  is  $w(x)$ , the statically equivalent concentrated load,  $F_R$ , can be found from Eq. 41.28. The equivalent load is the area under the loading curve. (See Fig. 41.6.)

$$F_R = \int_{x=0}^{x=L} w(x) dx \quad 41.28$$

**Figure 41.6** Distributed Loads on a Beam

The location,  $x_R$ , of the equivalent load is calculated from Eq. 41.29. The location coincides with the centroid of the area under the loading curve and is referred to in some problems as the *center of pressure*.

$$x_R = \frac{\int_{x=0}^{x=L} x w(x) dx}{F_R} \quad 41.29$$

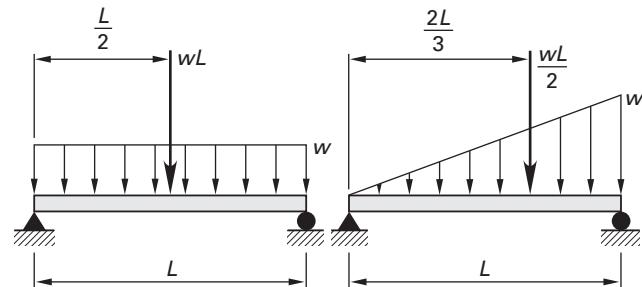

For a straight beam of length  $L$  under a uniform transverse loading of  $w$  pounds per foot (newtons per meter),

$$F_R = wL \quad 41.30$$

$$x_R = \frac{L}{2} \quad 41.31$$

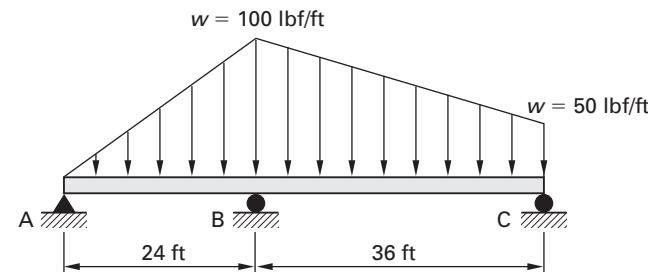

Equation 41.32 and Eq. 41.33 can be used for a straight beam of length  $L$  under a triangular distribution that

**Figure 41.7** Special Cases of Distributed Loading

### Example 41.1

Find the magnitude and location of the two equivalent forces on the two spans of the beam.

*Solution*

*Span A-B*

The area under the triangular loading curve is the total load on the span.

$$\begin{aligned} A &= \frac{1}{2}bh = \left(\frac{1}{2}\right)(24 \text{ ft})(100 \frac{\text{lbf}}{\text{ft}}) \\ &= 1200 \text{ lbf} \end{aligned}$$

The centroid of the loading triangle is located at

$$\begin{aligned} x_{R,A-B} &= \frac{2}{3}b = \left(\frac{2}{3}\right)(24 \text{ ft}) \\ &= 16 \text{ ft} \end{aligned}$$

*Span B-C*

The area under the loading curve consists of a uniform load of 50 lbf/ft over the entire span B-C, plus a triangular load that starts at zero at point C and

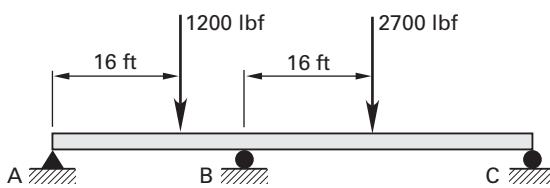

increases to 50 lbf/ft at point B. The area under the loading curve is

$$A = wL + \frac{1}{2}bh = \left(50 \frac{\text{lbf}}{\text{ft}}\right)(36 \text{ ft}) + \left(\frac{1}{2}\right)(36 \text{ ft})\left(50 \frac{\text{lbf}}{\text{ft}}\right) \\ = 2700 \text{ lbf}$$

From App. 42.A (reversing the axes to obtain a simpler expression), the centroid of the *trapezoidal loading curve* is located at

$$x_{R,B-C} = \left(\frac{h}{3}\right)\left(\frac{b+2t}{b+t}\right) = \left(\frac{36 \text{ ft}}{3}\right) \left( \frac{100 \frac{\text{lbf}}{\text{ft}} + 50 \frac{\text{lbf}}{\text{ft}}}{100 \frac{\text{lbf}}{\text{ft}} + 50 \frac{\text{lbf}}{\text{ft}}} \times (2)\left(50 \frac{\text{lbf}}{\text{ft}}\right)} \right)$$

$$= 16 \text{ ft from point B} \quad (20 \text{ ft from point C})$$

## 15. MOMENT FROM A DISTRIBUTED LOAD

The total force from a uniformly distributed load,  $w$ , over a distance,  $x$ , is  $wx$ . For the purposes of statics, the uniform load can be replaced by a concentrated force of  $wx$  located at the centroid of the distributed load, that is, at the midpoint,  $x/2$ , of the load. The moment taken about one end of the distributed load is

$$M_{\text{distributed load}} = \text{force} \times \text{distance} = wx\left(\frac{x}{2}\right) \\ = \frac{1}{2}wx^2 \quad 41.34$$

In general, the moment of a distributed load, uniform or otherwise, is the product of the total force and the distance to the centroid of the distributed load.

## 16. TYPES OF FORCE SYSTEMS

The complexity of methods used to analyze a statics problem depends on the configuration and orientation of the forces. Force systems can be divided into the following categories.

- *concurrent force system*: All of the forces act at the same point.
- *collinear force system*: All of the forces share the same line of action.
- *parallel force system*: All of the forces are parallel (though not necessarily in the same direction).

- *coplanar force system*: All of the forces are in a plane.
- *general three-dimensional system*: This category includes all other combinations of nonconcurrent, nonparallel, and noncoplanar forces.

## 17. CONDITIONS OF EQUILIBRIUM

An object is static when it is stationary. To be stationary, all of the forces on the object must be in equilibrium.<sup>7</sup> For an object to be in equilibrium, the resultant force and moment vectors must both be zero.

$$\mathbf{F}_R = \sum \mathbf{F} = 0 \quad 41.35$$

$$F_R = \sqrt{F_{R,x}^2 + F_{R,y}^2 + F_{R,z}^2} = 0 \quad 41.36$$

$$\mathbf{M}_R = \sum \mathbf{M} = 0 \quad 41.37$$

$$M_R = \sqrt{M_{R,x}^2 + M_{R,y}^2 + M_{R,z}^2} = 0 \quad 41.38$$

Since the square of any nonzero quantity is positive, Eq. 41.39 through Eq. 41.44 follow directly from Eq. 41.36 and Eq. 41.38.

$$F_{R,x} = 0 \quad 41.39$$

$$F_{R,y} = 0 \quad 41.40$$

$$F_{R,z} = 0 \quad 41.41$$

$$M_{R,x} = 0 \quad 41.42$$

$$M_{R,y} = 0 \quad 41.43$$

$$M_{R,z} = 0 \quad 41.44$$

Equation 41.39 through Eq. 41.44 seem to imply that six simultaneous equations must be solved in order to determine whether a system is in equilibrium. While this is true for general three-dimensional systems, fewer equations are necessary with most problems. Table 41.1 can be used as a guide to determine which equations are most helpful in solving different categories of problems.

**Table 41.1** Number of Equilibrium Conditions Required to Solve Different Force Systems

type of force system	two-dimensional	three-dimensional
general	3	6
coplanar	3	3
concurrent	2	3
parallel	2	3
coplanar, parallel	2	2
coplanar, concurrent	2	2
collinear	1	1

## 18. TWO- AND THREE-FORCE MEMBERS

Members limited to loading by two or three forces are special cases of equilibrium. A *two-force member* can be in equilibrium only if the two forces have the same line

<sup>7</sup>The term *static equilibrium*, though widely used, is redundant.

of action (i.e., are collinear) and are equal but opposite. In most cases, two-force members are loaded axially, and the line of action coincides with the member's longitudinal axis. By choosing the coordinate system so that one axis coincides with the line of action, only one equilibrium equation is needed.

A *three-force member* can be in equilibrium only if the three forces are concurrent or parallel. Stated another way, the force polygon of a three-force member in equilibrium must close on itself.

## 19. REACTIONS

The first step in solving most statics problems is to determine the reaction forces (i.e., the *reactions*) supporting the body. The manner in which a body is supported determines the type, location, and direction of the reactions. Conventional symbols are often used to define the type of support (such as pinned, roller, etc.). Examples of the symbols are shown in Table 41.2.

For beams, the two most common types of supports are the roller support and the pinned support. The *roller support*, shown as a cylinder supporting the beam, supports vertical forces only. Rather than support a horizontal force, a roller support simply rolls into a new equilibrium position. Only one equilibrium equation (i.e., the sum of vertical forces) is needed at a roller support. Generally, the terms *simple support* and *simply supported* refer to a roller support.

The *pinned support*, shown as a pin and clevis, supports both vertical and horizontal forces. Two equilibrium equations are needed.

Generally, there will be vertical and horizontal components of a reaction when one body touches another. However, when a body is in contact with a *frictionless surface*, there is no frictional force component parallel to the surface. The reaction is normal to the contact surfaces. The assumption of frictionless contact is particularly useful when dealing with systems of spheres and cylinders in contact with rigid supports. Frictionless contact is also assumed for roller and rocker supports.<sup>8</sup>

## 20. DETERMINACY

When the equations of equilibrium are independent, a rigid body force system is said to be *statically determinate*. A statically determinate system can be solved for all unknowns, which are usually reactions supporting the body.

When the body has more supports than are necessary for equilibrium, the force system is said to be *statically indeterminate*. In a statically indeterminate system, one or more of the supports or members can be removed or

<sup>8</sup>Frictionless surface contact, which requires only one equilibrium equation, should not be confused with a frictionless pin connection, which requires two equilibrium equations. A pin connection with friction introduces a moment at the connection, increasing the number of required equilibrium equations to three.

**Table 41.2** Types of Two-Dimensional Supports

type of support	reactions and moments	number of unknowns*
simple, roller, rocker, ball, or frictionless surface	reaction normal to surface, no moment	1
cable in tension, or link	reaction in line with cable or link, no moment	1
frictionless guide or collar	reaction normal to rail, no moment	1
built-in, fixed support	two reaction components, one moment	3
frictionless hinge, pin connection, or rough surface	reaction in any direction, no moment	2

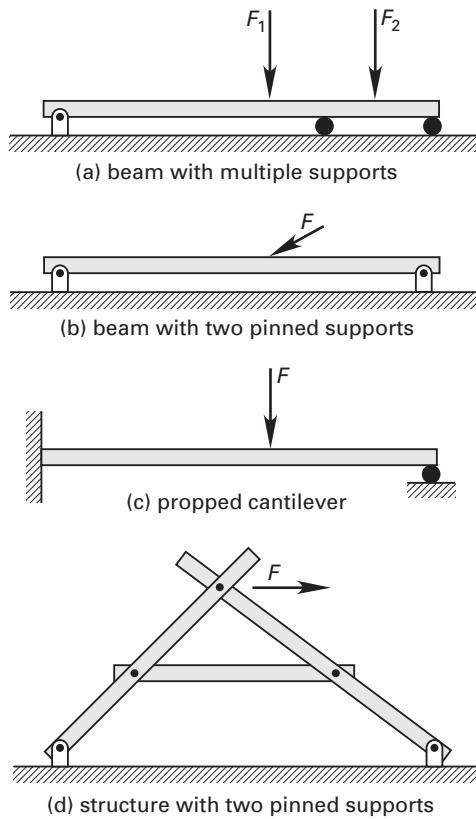

\*The number of unknowns is valid for two-dimensional problems only.

reduced in restraint without affecting the equilibrium position.<sup>9</sup> Those supports and members are known as *redundant members*. The number of redundant members

<sup>9</sup>An example of a support reduced in restraint is a pinned joint replaced by a roller joint. The pinned joint restrains the body vertically and horizontally, requiring two equations of equilibrium. The roller joint restrains the body vertically only and requires one equilibrium equation.

is known as the *degree of indeterminacy*. Figure 41.8 illustrates several common indeterminate structures.

**Figure 41.8 Examples of Indeterminate Systems**

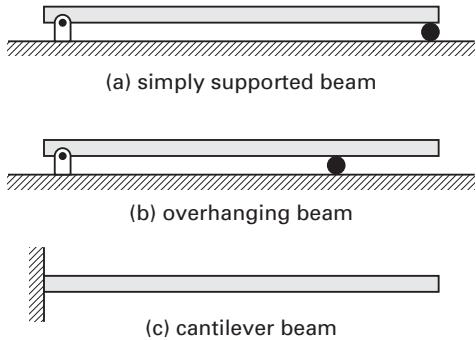

A statically indeterminate body requires additional equations to supplement the equilibrium equations. The additional equations typically involve deflections and depend on mechanical properties of the body.

## 21. TYPES OF DETERMINATE BEAMS

Figure 41.9 illustrates the terms used to describe determinate beam types.

**Figure 41.9 Types of Determinate Beams**

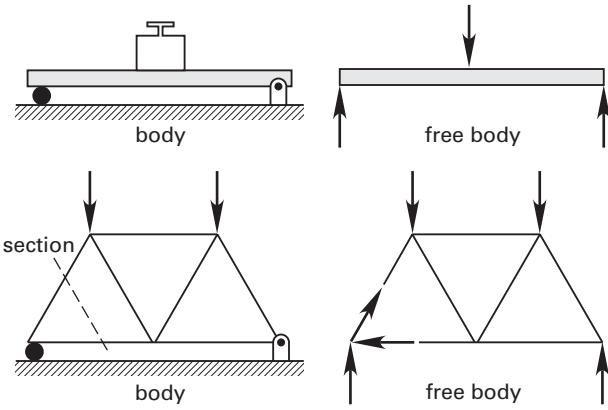

## 22. FREE-BODY DIAGRAMS

A *free-body diagram* is a representation of a body in equilibrium. It shows all applied forces, moments, and reactions. Free-body diagrams do not consider the internal structure or construction of the body, as Fig. 41.10 illustrates.

Since the body is in equilibrium, the resultants of all forces and moments on the free body are zero. In order to maintain equilibrium, any portions of the body that are removed must be replaced by the forces and moments those portions impart to the body. Typically, the body is isolated from its physical supports in order to help evaluate the reaction forces. In other cases, the body may be sectioned (i.e., cut) in order to determine the forces at the section.

**Figure 41.10 Bodies and Free Bodies**

## 23. FINDING REACTIONS IN TWO DIMENSIONS

The procedure for finding determinate reactions in two-dimensional problems is straightforward. Determinate structures will have either a roller support and a pinned support or two roller supports.

*step 1:* Establish a convenient set of coordinate axes. (To simplify the analysis, one of the coordinate directions should coincide with the direction of the forces and reactions.)

*step 2:* Draw the free-body diagram.

*step 3:* Resolve the reaction at the pinned support (if any) into components normal and parallel to the coordinate axes.

*step 4:* Establish a positive direction of rotation (e.g., clockwise) for the purpose of taking moments.

*step 5:* Write the equilibrium equation for moments about the pinned connection. (By choosing the pinned connection as the point about which to take moments, the pinned connection reactions do not enter into the equation.) This will usually determine the vertical reaction at the roller support.

*step 6:* Write the equilibrium equation for the forces in the vertical direction. Usually, this equation will have two unknown vertical reactions.

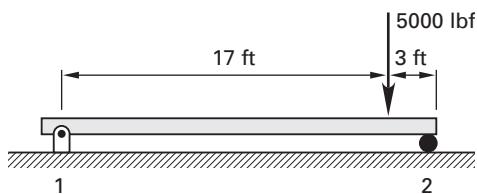

*step 7:* Substitute the known vertical reaction from step 5 into the equilibrium equation from step 6. This will determine the second vertical reaction.

*step 8:* Write the equilibrium equation for the forces in the horizontal direction. Since there is a maximum of one unknown reaction component in the horizontal direction, this step will determine that component.

*step 9:* If necessary, combine the vertical and horizontal force components at the pinned connection into a resultant reaction.

### Example 41.2

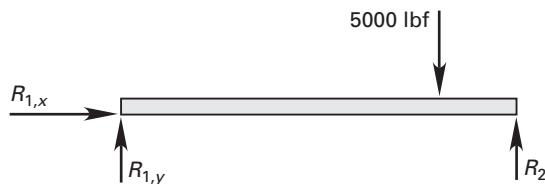

Determine the reactions,  $R_1$  and  $R_2$ , on the following beam.

*Solution*

*step 1:* The  $x$ - and  $y$ -axes are established parallel and perpendicular to the beam.

*step 2:* The free-body diagram is

*step 3:*  $R_1$  is a pinned support, so it has two components,  $R_{1,x}$  and  $R_{1,y}$ .

*step 4:* Assume clockwise moments are positive.

*step 5:* Take moments about the left end and set them equal to zero. Use Eq. 41.37.

$$\sum M_{\text{left end}} = (5000 \text{ lbf})(17 \text{ ft}) - R_2(20 \text{ ft}) = 0 \\ R_2 = 4250 \text{ lbf}$$

*step 6:* The equilibrium equation for the vertical direction is given by Eq. 41.40.

$$\sum F_y = R_{1,y} + R_2 - 5000 \text{ lbf} = 0$$

*step 7:* Substituting  $R_2$  into the vertical equilibrium equation,

$$R_{1,y} + 4250 \text{ lbf} - 5000 \text{ lbf} = 0 \\ R_{1,y} = 750 \text{ lbf}$$

*step 8:* There are no applied forces in the horizontal direction. Therefore, the equilibrium equation is given by Eq. 41.39.

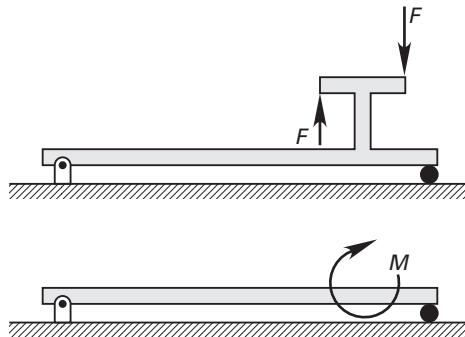

$$\sum F_x = R_{1,x} + 0 = 0 \\ R_{1,x} = 0$$

### 24. COUPLES AND FREE MOMENTS

Once a couple on a body is known, the derivation and source of the couple are irrelevant. When the moment on a body is 80 N·m, it makes no difference whether the force is 40 N with a lever arm of 2 m, or 20 N with a lever arm of 4 m, and so on. Therefore, the point of application of a couple is disregarded when writing the moment equilibrium equation. For this reason, the term *free moment* is used synonymously with *couple*.

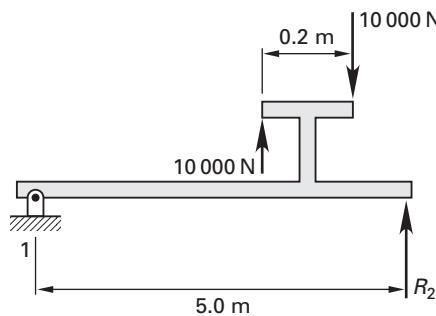

Figure 41.11 illustrates two diagrammatic methods of indicating the application of a free moment.

**Figure 41.11** Free Moments

### Example 41.3

What is the reaction,  $R_2$ , for the beam shown?

**Solution**

The two couple forces are equal and cancel each other as they come down the stem of the tee bracket. There are no applied vertical forces.

The couple has a value given by Eq. 41.7.

$$M = rF = (0.2 \text{ m})(10\,000 \text{ N}) = 2000 \text{ N}\cdot\text{m} \quad [\text{clockwise}]$$

Choose clockwise as the direction for positive moments. Taking moments about the pinned connection and using Eq. 41.37,

$$\begin{aligned} \sum M &= 2000 \text{ N}\cdot\text{m} - R_2(5 \text{ m}) = 0 \\ R_2 &= 400 \text{ N} \end{aligned}$$

**25. INFLUENCE LINES FOR REACTIONS**

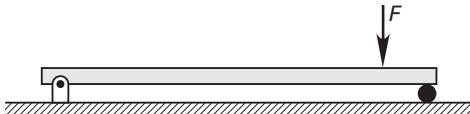

An *influence line* (also known as an *influence graph* and *influence diagram*) is a graph of the magnitude of a reaction as a function of the load placement.<sup>10</sup> The *x*-axis of the graph corresponds to the location on the body (along the length of a beam). The *y*-axis corresponds to the magnitude of the reaction.

By convention (and to generalize the graph for use with any load), the load is taken as one force unit. Therefore, for an actual load of  $F$  units, the actual reaction,  $R$ , is the product of the actual load and the influence line ordinate.

$$R = F \times \text{influence line ordinate} \quad 41.45$$

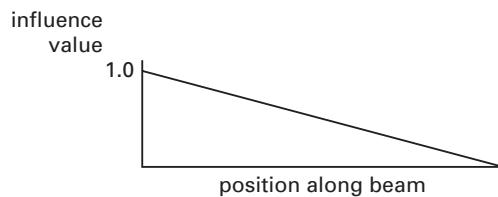

**Example 41.4**

Draw the influence line for the left reaction for the beam shown.

**Solution**

If the unit load is at the left end, the left reaction will be 1.0. If the unit load is at the right end, it will be supported entirely by the right reaction, so the left reaction will be zero. The influence line for the left reaction varies linearly for intermediate load placement.

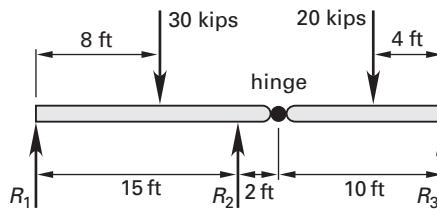

<sup>10</sup>Influence diagrams can also be drawn for moments, shears, and deflections.

**26. HINGES**

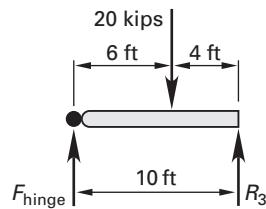

*Hinges* are added to structures to prevent translation while permitting rotation. A frictionless hinge can support a force, but it cannot transmit a moment. Since the moment is zero at a hinge, a structure can be sectioned at the hinge and the remainder of the structure can be replaced by only a force.

**Example 41.5**

Calculate the reaction,  $R_3$ , and the hinge force on the two-span beam shown.

**Solution**

At first, this beam may appear to be statically indeterminate since it has three supports. However, the moment is known to be zero at the hinge, so the hinged portion of the span can be isolated.

Reaction  $R_3$  is found by taking moments about the hinge. Assume clockwise moments are positive.

$$\begin{aligned} \sum M_{\text{hinge}} &= (20,000 \text{ lbf})(6 \text{ ft}) - R_3(10 \text{ ft}) = 0 \\ R_3 &= 12,000 \text{ lbf} \end{aligned}$$

The hinge force is found by summing vertical forces on the isolated section.

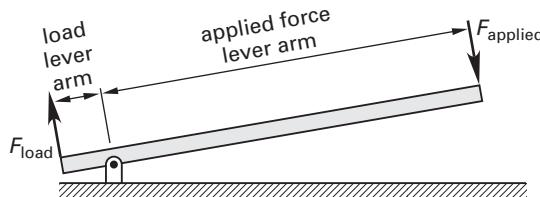

$$\begin{aligned} \sum F_y &= F_{\text{hinge}} + 12,000 \text{ lbf} - 20,000 \text{ lbf} = 0 \\ F_{\text{hinge}} &= 8000 \text{ lbf} \end{aligned}$$

## 27. LEVERS

A *lever* is a simple mechanical machine able to increase an applied force. The ratio of the load-bearing force to applied force (i.e., the *effort*) is known as the *mechanical advantage* or *force amplification*. As Fig. 41.12 shows, the mechanical advantage is equal to the ratio of lever arms.

$$\begin{aligned} \text{mechanical advantage} &= \frac{F_{\text{load}}}{F_{\text{applied}}} = \frac{\text{applied force lever arm}}{\text{load lever arm}} \\ &= \frac{\text{distance moved by applied force}}{\text{distance moved by load}} \end{aligned} \quad 41.46$$

Figure 41.12 Lever

## 28. PULLEYS

A *pulley* (also known as a *sheave*) is used to change the direction of an applied tensile force. A series of pulleys working together (known as a *block and tackle*) can also provide *pulley advantage* (i.e., *mechanical advantage*). A *hoist* is any device used to raise or lower an object. A hoist may contain one or more pulleys.

If the pulley is attached by a bracket or cable to a fixed location, it is said to be a *fixed pulley*. If the pulley is attached to a load, or if the pulley is free to move, it is known as a *free pulley*.

Most simple problems disregard friction and assume that all ropes are parallel.<sup>11</sup> In such cases, the pulley advantage is equal to the number of ropes coming to and going from the load-carrying pulley. The diameters of the pulleys are not factors in calculating the pulley advantage. (See Table 41.3.)

In other cases, a *loss factor*,  $\epsilon$ , is used to account for rope rigidity. For most wire ropes and chains with 180° contact, the loss factor at low speeds varies between 1.03 and 1.06. The loss factor is the reciprocal of the *pulley efficiency*,  $\eta$ .

$$\epsilon = \frac{\text{applied force}}{\text{load}} = \frac{1}{\eta} \quad 41.47$$

<sup>11</sup>Although the term *rope* is used here, the principles apply equally well to wire rope, cables, chains, belts, and so on.

Table 41.3 Mechanical Advantages of Rope-Operated Machines

	fixe sheave	free sheave	ordinary pulley block ( $n$ sheaves)	differential pulley block
$F_{\text{ideal}}$	$W$	$\frac{W}{2}$	$\frac{W}{n}$	$\left(\frac{W}{2}\right)\left(1 - \frac{d}{D}\right)$
$F$ to raise load	$\epsilon W$	$\frac{\epsilon W}{1 + \epsilon}$	$\frac{\epsilon^n(\epsilon - 1)W}{\epsilon^n - 1}$	$\frac{(\epsilon^2 - \frac{d}{D})W}{1 + \epsilon}$
$F$ to lower load	$\frac{W}{\epsilon}$	$\frac{W}{1 + \epsilon}$	$\left(\frac{1 - 1}{1 - \epsilon^n}\right)W$	$\left(\frac{\epsilon W}{1 + \epsilon}\right)\left(\frac{1}{\epsilon^2} - \frac{d}{D}\right)$
ratio of distance of force to distance of load	1	2	$n$	$\frac{2D}{D - d}$

## 29. AXIAL MEMBERS

An *axial member* is capable of supporting axial forces only and is loaded only at its joints (i.e., ends). This type of performance can be achieved through the use of frictionless bearings or smooth pins at the ends. Since the ends are assumed to be pinned (i.e., rotation-free), an axial member cannot support moments. The weight of the member is disregarded or is included in the joint loading.

An axial member can be in either tension or compression. It is common practice to label forces in axial members as (T) or (C) for tension or compression, respectively. Alternatively, tensile forces can be written as positive numbers, while compressive forces are written as negative numbers.

The members in simple trusses are assumed to be axial members. Each member is identified by its endpoints, and the force in a member is designated by the symbol for the two endpoints. For example, the axial force in a member connecting points C and D will be written as **CD**. Similarly, **EF**<sub>y</sub> is the *y*-component of the force in the member connecting points E and F.

For equilibrium, the resultant forces at the two joints must be equal, opposite, and collinear. This applies to the total (resultant) force as well as to the *x*- and *y*-components at those joints.

### 30. FORCES IN AXIAL MEMBERS

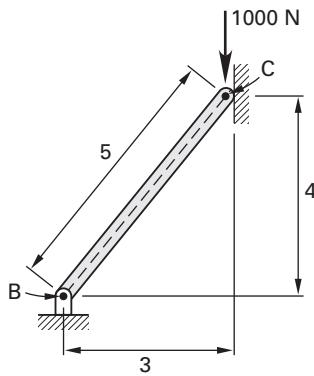

The line of action of a force in an axial member coincides with the longitudinal axis of the member. Depending on the orientation of the coordinate axis system, the direction of the longitudinal axis will have both  $x$ - and  $y$ -components. Therefore, the force in an axial member will generally have both  $x$ - and  $y$ -components.

The following four general principles are helpful in determining the force in an axial member.

- A horizontal member carries only horizontal loads. It cannot carry vertical loads.
- A vertical member carries only vertical loads. It cannot carry horizontal loads.
- The vertical component of an axial member's force is equal to the vertical component of the load applied to the member.
- The total and component forces in an inclined member are proportional to the sides of the triangle outlined by the member and the coordinate axes.<sup>12</sup>

#### Example 41.6

Member BC is an inclined axial member pinned at B and sliding frictionless at C, and oriented as shown. A vertical 1000 N force is applied to the top end. What are the  $x$ - and  $y$ -components of the force in member BC? What is the total force in the member?

*Solution*

From the third principle,

$$\mathbf{BC}_y = 1000 \text{ N}$$

From the fourth principle,

$$\begin{aligned}\mathbf{BC}_x &= \frac{3}{4}\mathbf{BC}_y = \left(\frac{3}{4}\right)(1000 \text{ N}) \\ &= 750 \text{ N}\end{aligned}$$

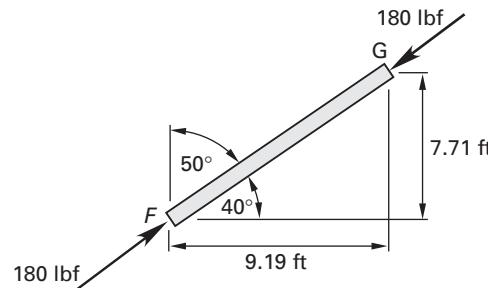

<sup>12</sup>This is an application of the principle of similar triangles.

The resultant force in member BC can be calculated from the Pythagorean theorem. However, it is easier to use the fourth principle.

$$\begin{aligned}\mathbf{BC} &= \frac{5}{4}\mathbf{BC}_y = \left(\frac{5}{4}\right)(1000 \text{ N}) \\ &= 1250 \text{ N}\end{aligned}$$

#### Example 41.7

The 12 ft long axial member FG supports an axial force of 180 lbf. What are the  $x$ - and  $y$ -components of the applied force?

*Solution*

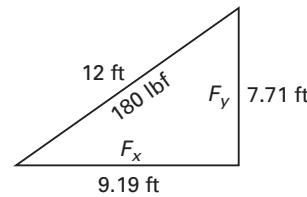

*method 1: direction cosines*

The  $x$ - and  $y$ -direction angles are  $40^\circ$  and  $90^\circ - 40^\circ = 50^\circ$ , respectively.

$$\mathbf{FG}_x = (180 \text{ lbf})\cos 40^\circ = 137.9 \text{ lbf}$$

$$\mathbf{FG}_y = (180 \text{ lbf})\cos 50^\circ = 115.7 \text{ lbf}$$

*method 2: similar triangles*

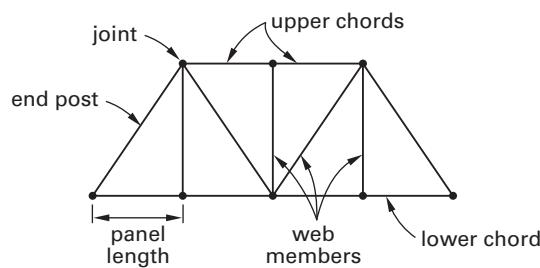

$$\mathbf{FG}_x = \left(\frac{9.19 \text{ ft}}{12 \text{ ft}}\right)(180 \text{ lbf}) = 137.9 \text{ lbf}$$

$$\mathbf{FG}_y = \left(\frac{7.71 \text{ ft}}{12 \text{ ft}}\right)(180 \text{ lbf}) = 115.7 \text{ lbf}$$

### 31. TRUSSES

A truss or frame is a set of *pin-connected axial members* (i.e., *two-force members*). The connection points are known as *joints*. Member weights are disregarded, and truss loads are applied only at joints. A *structural cell* consists of all members in a closed loop of members. For the truss to be stable (i.e., to be a *rigid truss*), all of the structural cells must be triangles. Figure 41.13 identifies *chords*, *end posts*, *panels*, and other elements of a typical bridge truss.

**Figure 41.13** Parts of a Bridge Truss

A *trestle* is a braced structure spanning a ravine, gorge, or other land depression in order to support a road or rail line. Trestles usually are indeterminate, have multiple earth contact points, have redundant members, and are more difficult to evaluate than simple trusses.

Several types of trusses have been given specific names. Some of the more common types of named trusses are shown in Fig. 41.14.

Truss loads are considered to act only in the plane of a truss. Trusses are analyzed as two-dimensional structures. Forces in truss members hold the various truss parts together and are known as *internal forces*. The internal forces are found by applying equations of equilibrium to appropriate free-body diagrams.

Although free-body diagrams of truss members can be drawn, this is not usually done. Instead, free-body diagrams of the pins (i.e., the joints) are drawn. A pin in compression will be shown with force arrows pointing toward the pin, away from the member. (Similarly, a pin in tension will be shown with force arrows pointing away from the pin, toward the member.)<sup>13</sup>

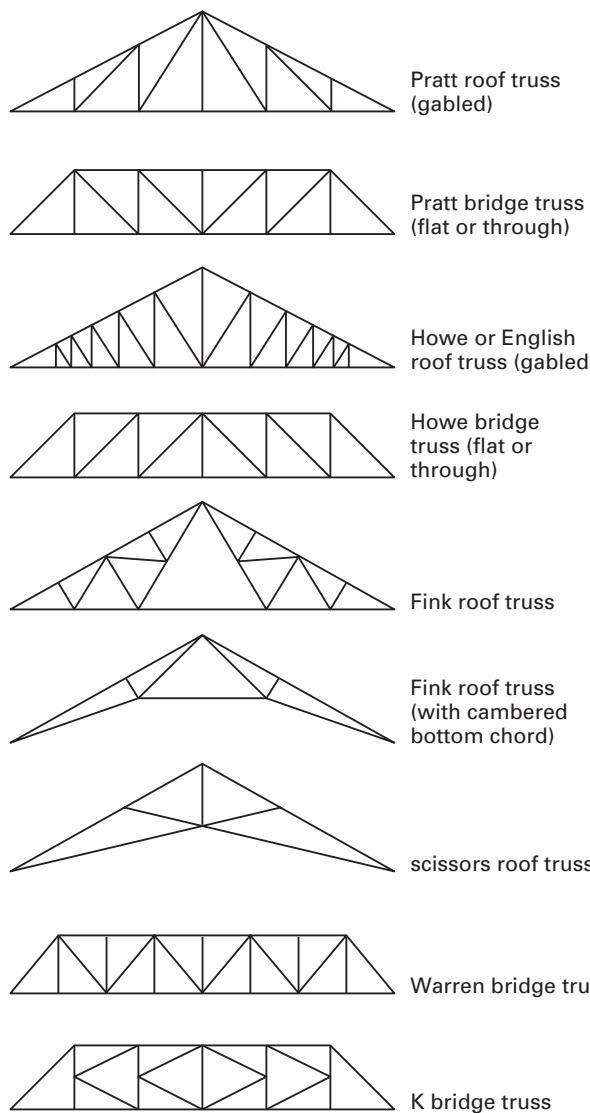

With typical bridge trusses supported at the ends and loaded downward at the joints, the upper chords are almost always in compression, and the end panels and lower chords are almost always in tension.

## 32. DETERMINATE TRUSSES

A truss will be statically determinate if Eq. 41.48 holds.

$$\text{no. of members} = 2(\text{no. of joints}) - 3 \quad 41.48$$

If the left-hand side is greater than the right-hand side (i.e., there are *redundant members*), the truss is statically indeterminate. If the left-hand side is less than the right-hand side, the truss is unstable and will collapse under certain types of loading.

**Figure 41.14** Special Types of Trusses

<sup>13</sup>The method of showing tension and compression on a truss drawing may appear incorrect. This is because the arrows show the forces on the pins, not on the members.

Equation 41.48 is a special case of the following general criterion.

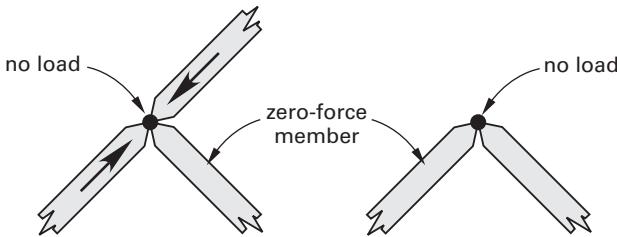

$$\begin{aligned} & \text{no. of members} \\ & + \text{no. of reactions} \\ & - 2(\text{no. of joints}) = 0 \quad [\text{determinate}] \\ & > 0 \quad [\text{indeterminate}] \\ & < 0 \quad [\text{unstable}] \end{aligned} \quad 41.49$$

Furthermore, Eq. 41.48 is a necessary, but not sufficient, condition for truss stability. It is possible to arrange the members in such a manner as to not contribute to truss stability. This will seldom be the case in actual practice, however.

### 33. ZERO-FORCE MEMBERS

Forces in truss members can sometimes be determined by inspection. One of these cases is where there are *zero-force members*. A third member framing into a joint already connecting two collinear members carries no internal force unless there is a load applied at that joint. Similarly, both members forming an apex of the truss are zero-force members unless there is a load applied at the apex. (See Fig. 41.15.)

**Figure 41.15** Zero-Force Members

### 34. METHOD OF JOINTS

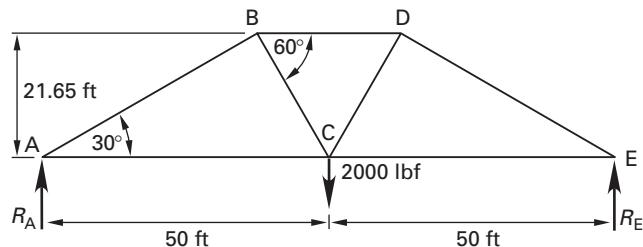

The *method of joints* is one of three methods that can be used to find the internal forces in each truss member. This method is useful when most or all of the truss member forces are to be calculated. Because this method advances from joint to adjacent joint, it is inconvenient when a single isolated member force is to be calculated.

The method of joints is a direct application of the equations of equilibrium in the  $x$ - and  $y$ -directions. Traditionally, the method starts by finding the reactions supporting the truss. Next, the joint at one of the reactions is evaluated, which determines all the member forces framing into the joint. Then, knowing one or more of the member forces from the previous step, an adjacent joint is analyzed. The process is repeated until all the unknown quantities are determined.

At a joint, there may be up to two unknown member forces, each of which can have dependent  $x$ - and  $y$ -components.<sup>14</sup> Since there are two equilibrium equations, the two unknown forces can be determined. Even though determinate, however, the sense of a force will often be unknown. If the sense cannot be determined by logic, an arbitrary decision can be made. If the incorrect direction is chosen, the calculated force will be negative.

#### Example 41.8

Use the method of joints to calculate the force **BD** in the truss shown.

*Solution*

First, find the reactions. Assume clockwise is positive and take moments about point A.

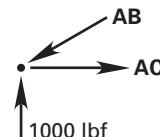

$$\sum M_A = (2000 \text{ lbf})(50 \text{ ft}) - R_E(50 \text{ ft} + 50 \text{ ft}) = 0 \\ R_E = 1000 \text{ lbf}$$

Since the sum of forces in the  $y$ -direction is also zero,

$$\sum F_y = R_A + 1000 \text{ lbf} - 2000 \text{ lbf} = 0 \\ R_A = 1000 \text{ lbf}$$

There are three unknowns at joint B (and also at D). The analysis must start at joint A (or E) where there are only two unknowns (forces **AB** and **AC**).

The free-body diagram of pin A is shown. The direction of  $R_A$  is known to be upward. The directions of forces **AB** and **AC** can be assumed, but logic can be used to determine them. Only the vertical component of **AB** can oppose  $R_A$ . Therefore, **AB** is directed downward. (This means that member AB is in compression.) Similarly, **AC** must oppose the horizontal component of **AB**, so **AC** is directed to the right. (This means that member AC is in tension.)

Resolve force **AB** into horizontal and vertical components using trigonometry, direction cosines, or similar triangles. ( $R_A$  and **AC** are already parallel to an axis.) Then, use the equilibrium equations to determine the forces.

By inspection,  $AB_y = 1000 \text{ lbf}$ .

$$AB_y = AB \sin 30^\circ$$

$$1000 \text{ lbf} = AB(0.5)$$

$$AB = 2000 \text{ lbf} \quad (\text{C})$$

$$AB_x = AB \cos 30^\circ$$

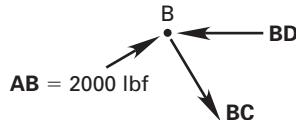

$$= (2000 \text{ lbf})(0.866)$$

$$= 1732 \text{ lbf}$$

Now, draw the free-body diagram of pin B. (Notice that the direction of force **AB** is toward the pin, just as it

<sup>14</sup>Occasionally, there will be three unknown member forces. In that case, an additional equation must be derived from an adjacent joint.

was for pin A.) Although the true directions of the forces are unknown, they can be determined logically. The direction of force **BC** is chosen to counteract the vertical component of force **AB**. The direction of force **BD** is chosen to counteract the horizontal components of forces **AB** and **BC**.

**AB**<sub>x</sub> and **AB**<sub>y</sub> are already known. Resolve the force **BC** into horizontal and vertical components.

$$\mathbf{BC}_x = \mathbf{BC} \sin 30^\circ = \mathbf{BC}(0.5)$$

$$\mathbf{BC}_y = \mathbf{BC} \cos 30^\circ = \mathbf{BC}(0.866)$$

Now, write the equations of equilibrium for point B.

$$\sum F_x = 1732 \text{ lbf} + 0.5\mathbf{BC} - \mathbf{BD} = 0$$

$$\sum F_y = 1000 \text{ lbf} - 0.866\mathbf{BC} = 0$$

From the second equation, **BC** = 1155 lbf. Substituting this into the first equation,

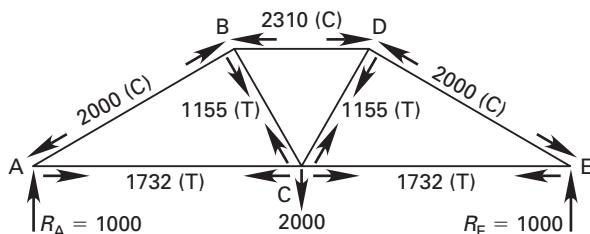

$$1732 \text{ lbf} + (0.5)(1155 \text{ lbf}) - \mathbf{BD} = 0$$

$$\mathbf{BD} = 2310 \text{ lbf} \quad (\text{C})$$

Since **BD** turned out to be positive, its direction was chosen correctly.

The direction of the arrow indicates that the member is compressing the pin. Consequently, the pin is compressing the member. Member **BD** is in compression.

If the process is continued, all forces can be determined. However, the truss is symmetrical, and it is not necessary to evaluate every joint to calculate all forces.

### 35. CUT-AND-SUM METHOD

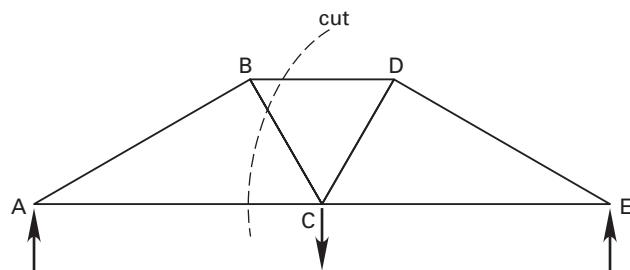

The *cut-and-sum method* can be used to find forces in inclined members. This method is strictly an application of the vertical equilibrium condition ( $\sum F_y = 0$ ).

The method starts by finding all of the support reactions on a truss. Then, a cut is made through the truss in such a way as to pass through one inclined or vertical

member only. (At this point, it should be clear that the vertical component of the inclined member must balance all of the external vertical forces.) The equation for vertical equilibrium is written for the free body of the remaining truss portion.

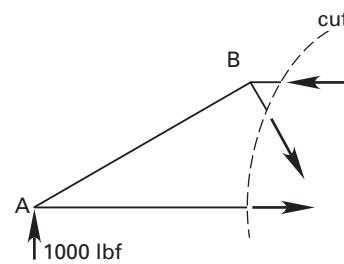

### Example 41.9

Find the force in member **BC** for the truss in Ex. 41.8.

#### Solution

The reactions were determined in Ex. 41.8. The truss is cut in such a way as to pass through member **BC** but through no other inclined member. The free body of the remaining portion of the truss is

The vertical equilibrium equation is

$$\begin{aligned} \sum F_y &= R_A - \mathbf{BC}_y = 1000 \text{ lbf} - 0.866\mathbf{BC} \\ &= 0 \\ \mathbf{BC} &= 1155 \text{ lbf} \quad (\text{T}) \end{aligned}$$

### 36. METHOD OF SECTIONS

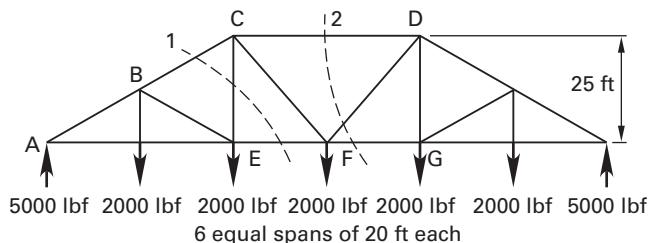

The *method of sections* is a direct approach to finding forces in any truss member. This method is convenient when only a few truss member forces are unknown.

As with the previous two methods, the first step is to find the support reactions. Then, a cut is made through the truss, passing through the unknown member.<sup>15</sup> Finally, all three conditions of equilibrium are applied as needed to the remaining truss portion. (Since there are three equilibrium equations, the cut cannot pass through more than three members in which the forces are unknown.)

<sup>15</sup>Knowing where to cut the truss is the key part of this method. Such knowledge is developed only by practice.

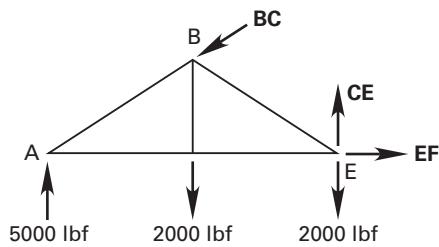

**Example 41.10**

Find the forces in members CD and CE. The support reactions have already been determined.

*Solution*

To find the force **CE**, the truss is cut at section 1.

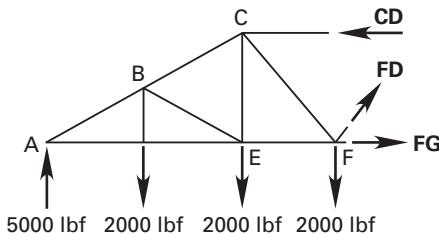

Taking moments about point A will eliminate all of the unknown forces except **CE**. Assume clockwise moments are positive.

$$\sum M_A = (2000 \text{ lbf})(20 \text{ ft}) + (2000 \text{ lbf})(40 \text{ ft}) - (40 \text{ ft})\mathbf{CE} = 0$$

$$\mathbf{CE} = 3000 \text{ lbf (T)}$$

To find the force **CD**, the truss is cut at section 2.

Taking moments about point F will eliminate all unknowns except **CD**. Assume clockwise moments are positive.

$$\begin{aligned} \sum M_F &= (5000 \text{ lbf})(60 \text{ ft}) - (25 \text{ ft})\mathbf{CD} \\ &\quad - (2000 \text{ lbf})(20 \text{ ft}) - (2000 \text{ lbf})(40 \text{ ft}) = 0 \\ \mathbf{CD} &= 7200 \text{ lbf (C)} \end{aligned}$$

**37. SUPERPOSITION OF LOADS**

*Superposition* is a term used to describe the process of determining member forces by considering loads one at

a time. Suppose, for example, that the force in member FG is unknown and that the truss carries three loads. If the method of superposition is used, the force in member FG (call it **FG**<sub>1</sub>) is determined with only the first load acting on the truss. **FG**<sub>2</sub> and **FG**<sub>3</sub> are similarly found. The true member force **FG** is found by adding **FG**<sub>1</sub>, **FG**<sub>2</sub>, and **FG**<sub>3</sub>.

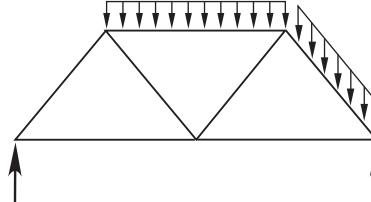

Superposition should be used with discretion since trusses can change shape under load. If a truss deflects such that the load application points are significantly different from those in the undeflected truss, superposition cannot be used for that truss.

In simple truss analysis, change of shape under load is neglected. Superposition, therefore, can be assumed to apply.

**38. TRANSVERSE TRUSS MEMBER LOADS**

Truss members are usually designed as axial members, not as beams. Trusses are traditionally considered to be loaded at joints only. Figure 41.16, however, illustrates cases of nontraditional *transverse loading* that can actually occur. For example, a truss member's own weight would contribute to a uniform load, as would a severe ice buildup.

**Figure 41.16** Transverse Truss Member Loads

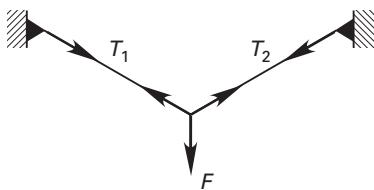

Transverse loads add two solution steps to a truss problem. First, the truss member must be individually considered as a beam simply supported at its pinned connections, and the reactions needed to support the transverse loading must be found. These reactions become additional loads applied to the truss joints, and the truss can then be evaluated in the normal manner.

The second step is to check the structural adequacy (deflection, bending stress, shear stress, buckling, etc.) of the truss member under transverse loading.

**39. CABLES CARRYING CONCENTRATED LOADS**

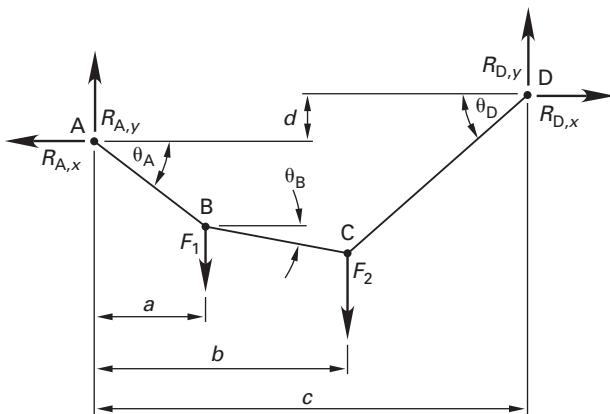

An *ideal cable* is assumed to be completely flexible, massless, and incapable of elongation. It acts as an axial two-force tension member between points of concentrated loading. In fact, the term *tension* or *tensile force* is commonly used in place of "member force" when dealing with cables. (See Fig. 41.17.)

**Figure 41.17** Cable with Concentrated Load

The methods of joints and sections used in truss analysis can be used to determine the tensions in cables carrying concentrated loads. After separating the reactions into  $x$ - and  $y$ -components, it is particularly useful to sum moments about one of the reaction points. All cables will be found to be in tension, and (with vertical loads only) the horizontal tension component will be the same in all cable segments. Unlike the case of a rope passing over a series of pulleys, however, the total tension in the cable will not be the same in every cable segment.

### Example 41.11

What are the tensions **AB**, **BC**, and **CD**?

*Solution*

Separate the two reactions into  $x$ - and  $y$ -components. (The total reactions  $R_A$  and  $R_D$  are also the tensions **AB** and **CD**, respectively.)

$$R_{A,x} = -\mathbf{AB} \cos \theta_A$$

$$R_{A,y} = -\mathbf{AB} \sin \theta_A$$

$$R_{D,x} = -\mathbf{CD} \cos \theta_D$$

$$R_{D,y} = -\mathbf{CD} \sin \theta_D$$

Next, take moments about point A to find **CD**. Assume clockwise to be positive.

$$\sum M_A = aF_1 + bF_2 - d\mathbf{CD}_x + c\mathbf{CD}_y = 0$$

None of the applied loads are in the  $x$ -direction, so the only horizontal loads are the  $x$ -components of the reactions. To find tension **AB**, take the entire cable

as a free body. Then, sum the external forces in the  $x$ -direction.

$$\sum F_x = R_{D,x} - R_{A,x} = 0$$

$$\mathbf{CD} \cos \theta_D = \mathbf{AB} \cos \theta_A$$

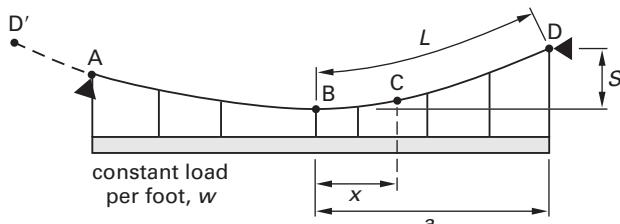

The  $x$ -component of force is the same in all cable segments. To find **BC**, sum the  $x$ -direction forces at point B.

$$\sum F_x = \mathbf{BC}_x - \mathbf{AB}_x = 0$$

$$\mathbf{BC} \cos \theta_B = \mathbf{AB} \cos \theta_A$$

### 40. PARABOLIC CABLES

If the distributed load per unit length,  $w$ , on a cable is constant with respect to the horizontal axis (as is the load from a bridge floor), the cable will be parabolic in shape.<sup>16</sup> This is illustrated in Fig. 41.18.

**Figure 41.18** Parabolic Cable

The maximum sag is designated as  $S$ . If the location of the maximum sag (i.e., the lowest cable point) is known, the horizontal component of tension,  $H$ , can be found by taking moments about a reaction point. If the cable is cut at the maximum sag point, B, the cable tension on the free body will be horizontal since there is no vertical component to the cable. Cutting the cable in Fig. 41.18 at point B and taking moments about point D will determine the minimum cable tension,  $H$ .

$$\sum M_D = wa\left(\frac{a}{2}\right) - HS = 0 \quad 41.50$$

$$H = \frac{wa^2}{2S} \quad 41.51$$

$$w = mg \quad [\text{SI}] \quad 41.52(a)$$

$$w = \frac{mg}{g_c} \quad [\text{U.S.}] \quad 41.52(b)$$

<sup>16</sup>The parabolic case can also be assumed with cables loaded only by their own weight (e.g., telephone and trolley wires) if both ends are at the same elevations and if the sag is no more than 10% of the distance between supports.

Since the load is vertical everywhere, the horizontal component of tension is constant everywhere in the cable. The tension,  $T_C$ , at any point C can be found by applying the equilibrium conditions to the cable segment BC.

$$T_{C,x} = H = \frac{wa^2}{2S} \quad 41.53$$

$$T_{C,y} = wx \quad 41.54$$

$$\begin{aligned} T_C &= \sqrt{T_{C,x}^2 + T_{C,y}^2} \\ &= w\sqrt{\left(\frac{a^2}{2S}\right)^2 + x^2} \end{aligned} \quad 41.55$$

The angle of the cable at any point is

$$\tan \theta = \frac{wx}{H} \quad 41.56$$

The tension and angle are maximum at the supports.

If the lowest sag point, point B, is used as the origin, the shape of the cable is

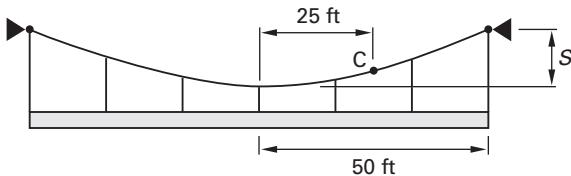

$$y(x) = \frac{wx^2}{2H} \quad 41.57$$

The approximate length of the cable from the lowest point to the support (i.e., length BD) is

$$L \approx a \left( 1 + \frac{2}{3} \left( \frac{S}{a} \right)^2 - \frac{2}{5} \left( \frac{S}{a} \right)^4 \right) \quad 41.58$$

### Example 41.12

A pedestrian foot bridge has two suspension cables and a flexible floor weighing 28 lbf/ft. The span of the bridge is 100 ft. When the bridge is empty, the tension at point C is 1500 lbf. Assuming a parabolic shape, what is the maximum cable sag,  $S$ ?

*Solution*

Since there are two cables, the floor weight per suspension cable is

$$\begin{aligned} w &= \frac{28 \text{ lbf}}{2 \text{ ft}} \\ &= 14 \text{ lbf/ft} \end{aligned}$$

From Eq. 41.55,

$$T_C = w\sqrt{\left(\frac{a^2}{2S}\right)^2 + x^2}$$

$$\begin{aligned} 1500 \text{ lbf} &= 14 \frac{\text{lbf}}{\text{ft}} \sqrt{\left(\frac{(50 \text{ ft})^2}{2S}\right)^2 + (25 \text{ ft})^2} \\ S &= 12 \text{ ft} \end{aligned}$$

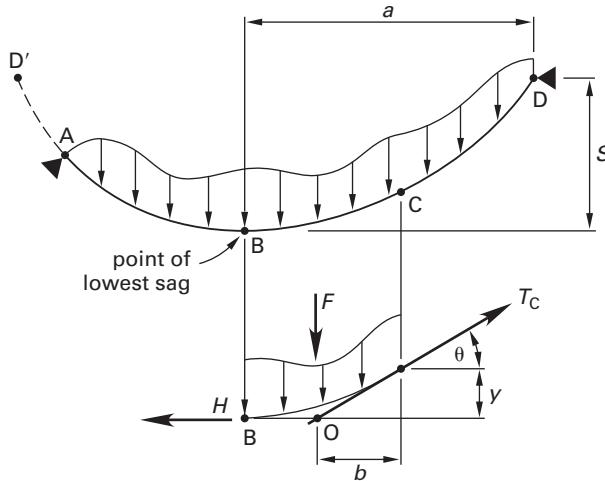

### 41. CABLES CARRYING DISTRIBUTED LOADS

An idealized tension cable with a distributed load is similar to a linkage made up of a very large number of axial members. The cable is horizontal at the point of lowest sag. There is no vertical tension component, and the cable tension is minimum. By similar reasoning, the cable tension is maximum at the supports.

Since the load is vertical everywhere, the horizontal component of cable tension is constant along the cable. The cable is horizontal at the point of lowest sag. There is no vertical tension component, and the cable tension is minimum. By similar reasoning, the cable tension is maximum at the supports.

Figure 41.19 illustrates a general cable with a distributed load. The shape of the cable will depend on the relative distribution of the load. A free-body diagram of segment BC is also shown.

**Figure 41.19** Cable with Distributed Load

$F$  is the resultant of the distributed load on segment BC,  $T$  is the cable tension at point C, and  $H$  is the tension at the point of lowest sag (i.e., the point of minimum tension). Since segment BC taken as a free body is a three-force member, the three forces ( $H$ ,  $F$ , and  $T$ ) must

be concurrent to be in equilibrium. The horizontal component of tension can be found by taking moments about point C.

$$\sum M_C = Fb - Hy = 0 \quad 41.59$$

$$H = \frac{Fb}{y} \quad 41.60$$

Also,  $\tan \theta = y/b$ . So,

$$H = \frac{F}{\tan \theta} \quad 41.61$$

The basic equilibrium conditions can be applied to the free-body cable segment BC to determine the tension in the cable at point C.

$$\sum F_x = T_C \cos \theta - H = 0 \quad 41.62$$

$$\sum F_y = T_C \sin \theta - F = 0 \quad 41.63$$

The resultant tension at point C is

$$T_C = \sqrt{H^2 + F^2} \quad 41.64$$

## 42. CATENARY CABLES

If the distributed load is constant along the length of the cable, as it is with a loose cable loaded by its own weight, the cable will have the shape of a *catenary*. A vertical axis catenary's shape is determined by Eq. 41.65, where  $c$  is a constant and  $\cosh$  is the *hyperbolic cosine*. The quantity  $x/c$  is in radians.<sup>17</sup>

$$y(x) = c \cosh \frac{x}{c} \quad 41.65$$

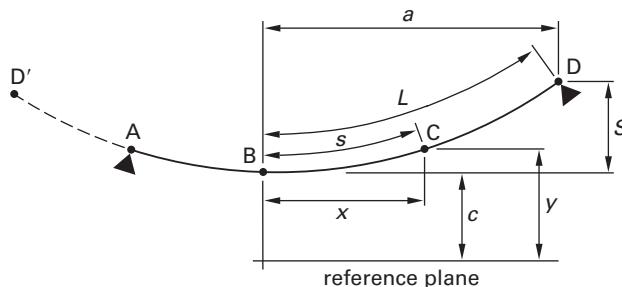

Referring to Fig. 41.20, the vertical distance,  $y$ , to any point C on the catenary is measured from a reference plane located a distance  $c$  below the point of greatest sag, point B. The distance  $c$  is known as the *parameter of the catenary*. Although the value of  $c$  establishes the location of the  $x$ -axis, the value of  $c$  does not correspond to any physical distance, nor is the reference plane the ground level.

In order to define the cable shape and determine cable tensions, it is necessary to have enough information to calculate  $c$ . For example, if  $a$  and  $S$  are known, Eq. 41.68 can be solved by trial and error for  $c$ .<sup>18</sup> Once  $c$  is known, the cable geometry and forces are determined by the remaining equations.

<sup>17</sup>In order to use Eq. 41.65 through Eq. 41.68, you must reset your calculator from degrees to radians.

<sup>18</sup>Because obtaining the solution may require trial and error, it will be advantageous to assume a parabolic shape if the cable is taut. (See Ftn. 16.) The error will generally be small.

Figure 41.20 Catenary Cable

For any point C, the equations most useful in determining the shape of the catenary are

$$y = \sqrt{s^2 + c^2} = c \cosh \frac{x}{c} \quad 41.66$$

$$s = c \sinh \frac{x}{c} \quad 41.67$$

$$\text{sag} = S = y_D - c = c \left( \cosh \frac{a}{c} - 1 \right) \quad 41.68$$

$$\tan \theta = \frac{s}{c} \quad 41.69$$

The equations most useful in determining the cable tensions are

$$H = wc \quad 41.70$$

$$F = ws \quad 41.71$$

$$T = wy \quad 41.72$$

$$\tan \theta = \frac{ws}{H} \quad 41.73$$

$$\cos \theta = \frac{H}{T} \quad 41.74$$

### Example 41.13

A cable 100 m long is loaded by its own weight. The maximum sag is 25 m, and the supports are on the same level. What is the distance between the supports?

*Solution*

Since the two supports are on the same level, the cable length,  $L$ , between the point of maximum sag and support D is half of the total length.

$$L = \frac{100 \text{ m}}{2} = 50 \text{ m}$$

Combining Eq. 41.66 and Eq. 41.68 for point D (with  $S = 25 \text{ m}$ ),

$$y_D = c + S = \sqrt{L^2 + c^2}$$

$$c + 25 \text{ m} = \sqrt{(50 \text{ m})^2 + c^2}$$

$$c = 37.5 \text{ m}$$

Substituting  $a$  for  $x$  and  $L = 50$  for  $s$  in Eq. 41.67,

$$s = c \sinh \frac{x}{c}$$

$$50 \text{ m} = (37.5 \text{ m}) \sinh \frac{a}{37.5}$$

$$a = 41.2 \text{ m}$$

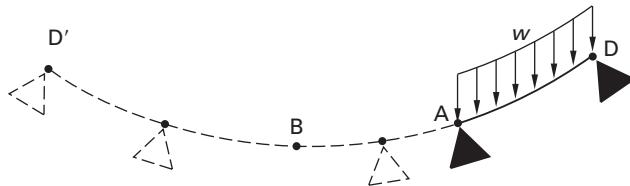

The distance between supports is

$$2a = (2)(41.2 \text{ m}) = 82.4 \text{ m}$$

### 43. CABLES WITH ENDS AT DIFFERENT ELEVATIONS

A cable will be asymmetrical if its ends are at different elevations. In some cases, as shown in Fig. 41.21, the cable segment will not include the lowest point, B. However, if the location of the theoretical lowest point can be derived, the positions and elevations of the cable supports will not affect the analysis. The same procedure is used in proceeding from theoretical point B to either support. In fact, once the theoretical shape of a cable has been determined, the supports can be relocated anywhere along the cable line without affecting the equilibrium of the supported segment.

**Figure 41.21** Asymmetrical Segment of Symmetrical Cable

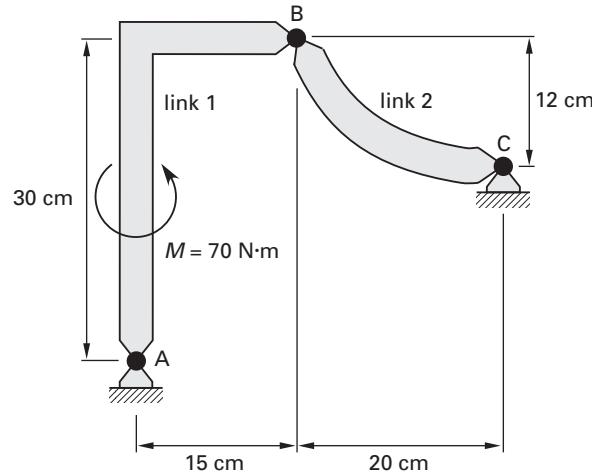

### 44. TWO-DIMENSIONAL MECHANISMS

A two-dimensional mechanism (*machine*) is a nonrigid structure. Although parts of the mechanism move, the relationships between forces in the mechanism can be determined by statics. In order to determine an unknown force, one or more of the mechanism components must be considered as a free body. All input forces and reactions must be included on this free body. In general, the resultant force on such a free body will not be in the direction of the member.

Several free bodies may be needed for complicated mechanisms. Sign conventions of acting and reacting forces must be strictly adhered to when determining the effect of one component on another.

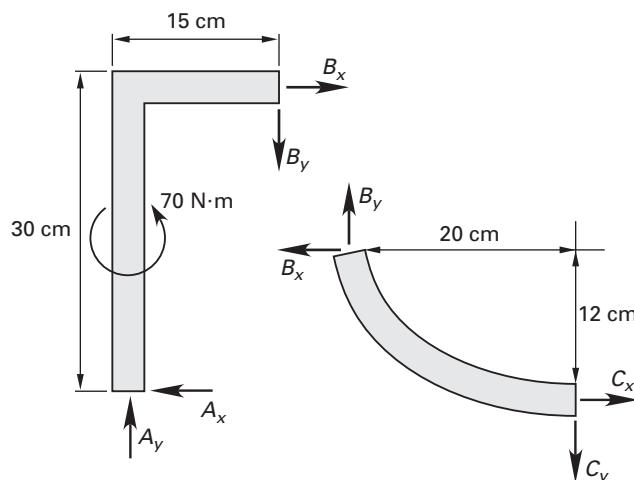

### Example 41.14

A 70 N·m couple is applied to the mechanism shown. All connections are frictionless hinges. What are the  $x$ - and  $y$ -components of the reactions at B?

*Solution*

Isolate links 1 and 2 and draw their free bodies.

Assume clockwise moments are positive. Take moments about point A on link 1.

$$\sum M_A = B_x(0.3 \text{ m}) + B_y(0.15 \text{ m}) - 70 \text{ N}\cdot\text{m} = 0$$

Assume clockwise moments are positive. Take moments about point C on link 2.

$$\sum M_C = B_y(0.20 \text{ m}) - B_x(0.12 \text{ m}) = 0$$

Solving these two equations simultaneously determines the force at joint B.

$$B_x = 179 \text{ N}$$

$$B_y = 108 \text{ N}$$

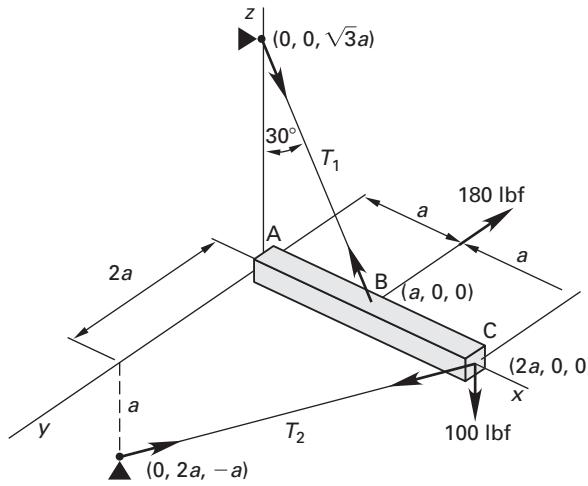

## 45. EQUILIBRIUM IN THREE DIMENSIONS

The basic equilibrium equations can be used with vector algebra to solve a three-dimensional statics problem. When a manual calculation is required, however, it is often more convenient to write the equilibrium equations for one orthogonal direction at a time, thereby avoiding the use of vector notation and reducing the problem to two dimensions. The following method can be used to analyze a three-dimensional structure.

- step 1:* Establish the  $(0, 0, 0)$  origin for the structure.
- step 2:* Determine the  $(x, y, z)$  coordinates of all load and reaction points.
- step 3:* Determine the  $x$ -,  $y$ -, and  $z$ -components of all loads and reactions. This is accomplished by using direction cosines calculated from the  $(x, y, z)$  coordinates.
- step 4:* Draw a *coordinate free-body diagram* of the structure for each of the three coordinate axes. Include only forces, reactions, and moments that affect the coordinate free body.
- step 5:* Apply the basic two-dimensional equilibrium equations.

### Example 41.15

Beam AC is supported at point A by a frictionless ball joint and at points B and C by cables. A 100 lbf load is applied vertically to point C, and a 180 lbf load is applied horizontally to point B. What are the cable tensions,  $T_1$  and  $T_2$ ?

### Solution

- step 1:* Point A has already been established as the origin.
- step 2:* The locations of all support and load points are shown on the illustration.

*step 3:* By inspection, for the 180 lbf horizontal load at point B,

$$F_x = 0$$

$$F_y = -180 \text{ lbf}$$

$$F_z = 0$$

By inspection, for the 100 lbf vertical load at point C,

$$F_x = 0$$

$$F_y = 0$$

$$F_z = -100 \text{ lbf}$$

The length of cable 1 is

$$\begin{aligned} L_1 &= \sqrt{x^2 + y^2 + z^2} \\ &= \sqrt{(a-0)^2 + (0-0)^2 + (0-\sqrt{3}a)^2} \\ &= 2a \end{aligned}$$

The direction cosines of the force from cable 1 at point B are

$$\cos \theta_x = \frac{d_x}{L_1} = \frac{0-a}{2a} = -0.5$$

$$\cos \theta_y = \frac{d_y}{L_1} = \frac{0-0}{2a} = 0$$

$$\cos \theta_z = \frac{d_z}{L_1} = \frac{\sqrt{3}a-0}{2a} = 0.866$$

Therefore, the components of the tension in cable 1 are

$$T_{1,x} = -0.5 T_1$$

$$T_{1,y} = 0$$

$$T_{1,z} = 0.866 T_1$$

Similarly, for cable 2,

$$\begin{aligned} L_2 &= \sqrt{x^2 + y^2 + z^2} \\ &= \sqrt{(2a-0)^2 + (0-2a)^2 + (0-(-a))^2} \\ &= 3a \end{aligned}$$

The direction cosines for the force from cable 2 at point C are

$$\cos \theta_x = \frac{d_x}{L_2} = \frac{0 - 2a}{3a} = -0.667$$

$$\cos \theta_y = \frac{d_y}{L_2} = \frac{2a - 0}{3a} = 0.667$$

$$\cos \theta_z = \frac{d_z}{L_2} = \frac{-a - 0}{3a} = -0.333$$

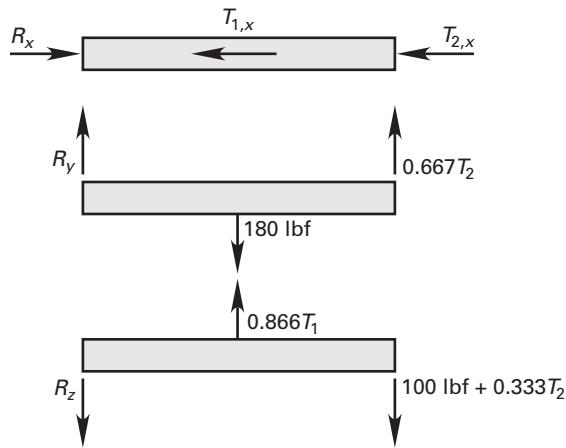

Therefore, the components of the tension in cable 2 are

$$T_{2,x} = -0.667 T_2$$

$$T_{2,y} = 0.667 T_2$$

$$T_{2,z} = -0.333 T_2$$

*step 4:* The three coordinate free-body diagrams are

*step 5:* Tension  $T_2$  can be found by taking moments about point A on the  $y$ -coordinate free body.

$$\sum M_A = (0.667 T_2)2a - (180 \text{ lbf})a = 0$$

$$T_2 = 135 \text{ lbf}$$

Tension  $T_1$  can be found by taking moments about point A on the  $z$ -coordinate free body.

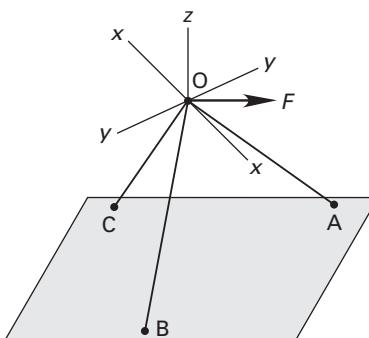

$$\begin{aligned} \sum M_A &= (0.866 T_1)a - (0.333)(135 \text{ lbf})2a \\ &\quad - (100 \text{ lbf})2a = 0 \end{aligned}$$

$$T_1 = 335 \text{ lbf}$$

## 46. TRIPODS

A *tripod* is a simple three-dimensional truss (frame) that consists of three axial members. (See Fig. 41.22.) One end of each member is connected at the *apex* of the tripod, while the other ends are attached to the supports. All connections are assumed to allow free rotation in all directions.

Figure 41.22 Tripod

The general solution procedure given in the preceding section can be made more specific for tripods.

*step 1:* Establish the apex as the origin.

*step 2:* Determine the  $x$ -,  $y$ -, and  $z$ -components of the force applied to the apex.

*step 3:* Determine the  $(x, y, z)$  coordinates of points A, B, and C—the three support points.

*step 4:* Determine the length of each tripod leg from the coordinates of the support points.

$$L = \sqrt{x^2 + y^2 + z^2} \quad 41.75$$

*step 5:* Determine the direction cosines for the leg forces at the apex. For leg A, for example,

$$\cos \theta_{A,x} = \frac{x_A}{L} \quad 41.76$$

$$\cos \theta_{A,y} = \frac{y_A}{L} \quad 41.77$$

$$\cos \theta_{A,z} = \frac{z_A}{L} \quad 41.78$$

*step 6:* Write the  $x$ -,  $y$ -, and  $z$ -components of each leg force in terms of the direction cosines. For leg A, for example,

$$F_{A,x} = F_A \cos \theta_{A,x} \quad 41.79$$

$$F_{A,y} = F_A \cos \theta_{A,y} \quad 41.80$$

$$F_{A,z} = F_A \cos \theta_{A,z} \quad 41.81$$

*step 7:* Write the three sum-of-forces equilibrium equations for the apex.

$$F_{A,x} + F_{B,x} + F_{C,x} + F_x = 0 \quad 41.82$$

$$F_{A,y} + F_{B,y} + F_{C,y} + F_y = 0 \quad 41.83$$

$$F_{A,z} + F_{B,z} + F_{C,z} + F_z = 0 \quad 41.84$$

*step 5:* See step 4.

*step 6:* The equilibrium equations are

$$0.3015F_A + 0F_B - 0.5146F_C + 1000 = 0$$

$$-0.3015F_A + 0.2874F_B + 0.5146F_C = 0$$

$$-0.9046F_A - 0.9579F_B - 0.6861F_C = 0$$

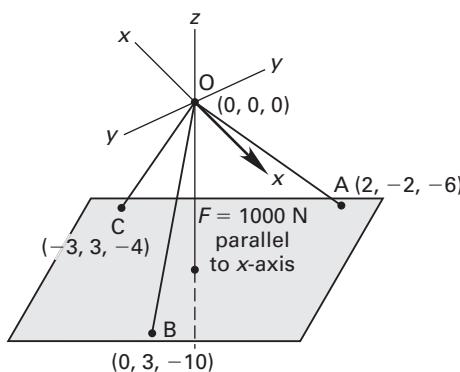

The solution to these simultaneous equations is

$$F_A = +1531 \text{ N (T)}$$

$$F_B = -3480 \text{ N (C)}$$

$$F_C = +2841 \text{ N (T)}$$

*step 7:* See step 6.

*Solution*

*step 1:* The origin is at the apex.

*step 2:* By inspection,  $F_x = +1000 \text{ N}$ . All other components are zero.

*step 3:* The coordinates of the tripod support are given.

*step 4:* The lengths and direction cosines for the tripod legs have been calculated and are presented in the following table.

member	$x^2$	$y^2$	$z^2$	$L^2$	$L$	$\cos \theta_x$	$\cos \theta_y$	$\cos \theta_z$

## 1. CENTROID OF AN AREA

The *centroid of an area* is analogous to the center of gravity of a homogeneous body.<sup>1</sup> The centroid is often described as the point at which a thin homogeneous plate would balance. This definition, however, combines the definitions of centroid and center of gravity and

implies that gravity is required to identify the centroid, which is not true.

The location of the centroid of an area bounded by the *x*- and *y*-axes and the mathematical function  $y = f(x)$  can be found by the *integration method* and by using Eq. 42.1 through Eq. 42.4. The centroidal location depends only on the geometry of the area and is identified by the coordinates  $(x_c, y_c)$ . Some references place a bar over the coordinates of the centroid to indicate an average point, such as  $(\bar{x}, \bar{y})$ .

$$x_c = \frac{\int x dA}{A} \quad 42.1$$

$$y_c = \frac{\int y dA}{A} \quad 42.2$$

$$A = \int f(x) dx \quad 42.3$$

$$dA = f(x)dx = g(y)dy \quad 42.4$$

The locations of the centroids of *basic shapes*, such as triangles and rectangles, are well known. The most common basic shapes have been included in App. 42.A. There should be no need to derive centroidal locations for these shapes by the integration method.

The centroid of a complex area can be found from Eq. 42.5 and Eq. 42.6 if the area can be divided into the basic shapes in App. 42.A. This process is simplified when all or most of the subareas adjoin the reference axis. Example 42.1 illustrates this method.

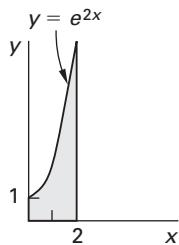

$$x_c = \frac{\sum_i A_i x_{c,i}}{\sum_i A_i} \quad 42.5$$

$$y_c = \frac{\sum_i A_i y_{c,i}}{\sum_i A_i} \quad 42.6$$

<sup>1</sup>The analogy has been simplified. A three-dimensional body also has a centroid. The centroid and center of gravity will coincide when the body is homogeneous.

**Example 42.1**

An area is bounded by the  $x$ - and  $y$ -axes, the line  $x = 2$ , and the function  $y = e^{2x}$ . Find the  $x$ -component of the centroid.

*Solution*

First, use Eq. 42.3 to find the area.

$$\begin{aligned} A &= \int f(x) dx = \int_{x=0}^{x=2} e^{2x} dx \\ &= \frac{1}{2}e^{2x} \Big|_0^2 = 27.3 - 0.5 \\ &= 26.8 \text{ units}^2 \end{aligned}$$

Since  $y$  is a function of  $x$ ,  $dA$  must be expressed in terms of  $x$ . From Eq. 42.4,

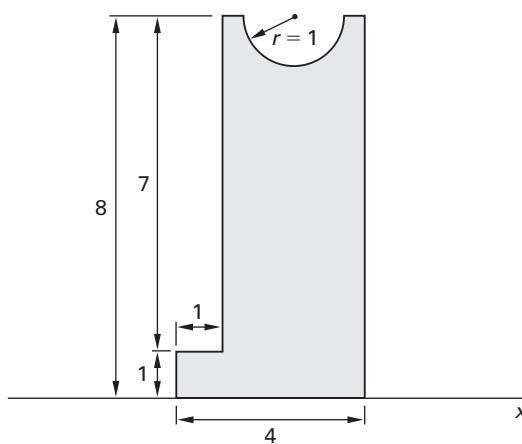

$$dA = f(x)dx = e^{2x}dx$$

Finally, use Eq. 42.1 to find  $x_c$ .

$$\begin{aligned} x_c &= \frac{\int x dA}{A} = \frac{1}{26.8} \int_{x=0}^{x=2} xe^{2x} dx \\ &= \left( \frac{1}{26.8} \right) \left( \frac{1}{2}xe^{2x} - \frac{1}{4}e^{2x} \Big|_0^2 \right) \\ &= 1.54 \text{ units} \end{aligned}$$

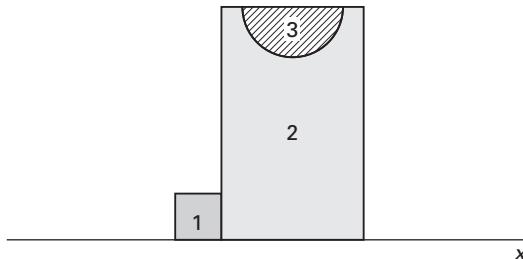

**Example 42.2**

Find the  $y$ -coordinate of the centroid of the area shown.

*Solution*

The  $x$ -axis is the reference axis. The area is divided into basic shapes of a  $1 \times 1$  square, a  $3 \times 8$  rectangle, and a half-circle of radius 1. (The area could also be divided into  $1 \times 4$  and  $3 \times 7$  rectangles and the half-circle, but then the  $3 \times 7$  rectangle would not adjoin the  $x$ -axis.)

First, calculate the areas of the basic shapes. Notice that the half-circle area is negative since it represents a cutout.

$$\begin{aligned} A_1 &= (1.0)(1.0) = 1.0 \text{ units}^2 \\ A_2 &= (3.0)(8.0) = 24.0 \text{ units}^2 \\ A_3 &= -\frac{1}{2}\pi r^2 = -\frac{1}{2}\pi(1.0)^2 = -1.57 \text{ units}^2 \end{aligned}$$

Next, find the  $y$ -components of the centroids of the basic shapes. Most are found by inspection, but App. 42.A can be used for the half-circle. The centroidal location for the half-circle is positive.

$$\begin{aligned} y_{c,1} &= 0.5 \text{ units} \\ y_{c,2} &= 4.0 \text{ units} \\ y_{c,3} &= 8.0 - 0.424 = 7.576 \text{ units} \end{aligned}$$

Finally, use Eq. 42.6.

$$\begin{aligned} y_c &= \frac{\sum A_i y_{c,i}}{\sum A_i} \\ &= \frac{(1.0)(0.5) + (24.0)(4.0) + (-1.57)(7.576)}{1.0 + 24.0 - 1.57} \\ &= 3.61 \text{ units} \end{aligned}$$

**2. FIRST MOMENT OF THE AREA**

The quantity  $\int x dA$  is known as the *first moment of the area* or *first area moment* with respect to the  $y$ -axis. Similarly,  $\int y dA$  is known as the first moment of the area with respect to the  $x$ -axis. By rearranging Eq. 42.1 and Eq. 42.2, the first moment of the area can be calculated from the area and centroidal distance.

$$Q_y = \int x dA = x_c A \quad 42.7$$

$$Q_x = \int y dA = y_c A \quad 42.8$$

In basic engineering, the two primary applications of the first moment concept are to determine centroidal locations and shear stress distributions. In the latter application, the first moment of the area is known as the *statical moment*.

### 3. CENTROID OF A LINE

The location of the *centroid of a line* can be defined by Eq. 42.9 and Eq. 42.10, which are analogous to the equations used for centroids of areas.

$$x_c = \frac{\int x dL}{L} \quad 42.9$$

$$y_c = \frac{\int y dL}{L} \quad 42.10$$

Since equations of lines are typically in the form  $y = f(x)$ ,  $dL$  must be expressed in terms of  $x$  or  $y$ .

$$dL = \left( \sqrt{\left(\frac{dy}{dx}\right)^2 + 1} \right) dx \quad 42.11$$

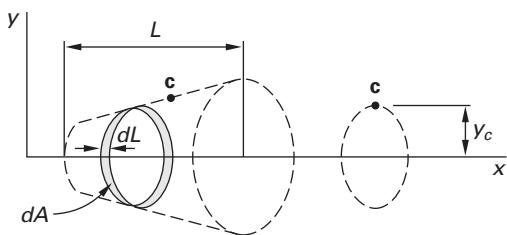

$$dL = \left( \sqrt{\left(\frac{dx}{dy}\right)^2 + 1} \right) dy \quad 42.12$$

### 4. THEOREMS OF PAPPUS-GULDINUS

The *Theorems of Pappus-Guldinus* define the surface and volume of revolution (i.e., the surface area and volume generated by revolving a curve around a fixed axis).

- *Theorem I:* The area of a surface of revolution is equal to the product of the length of the generating curve and the distance traveled by the centroid of the curve while the surface is being generated. (See Fig. 42.1.)

**Figure 42.1** Surface of Revolution

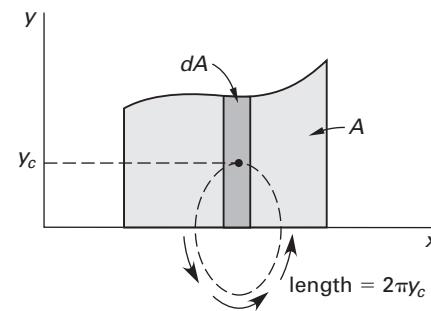

When a part,  $dL$ , of a line,  $L$ , is revolved about the  $x$ -axis, a differential ring having surface area  $dA$  is generated.

$$dA = 2\pi y dL \quad 42.13$$

$$A = \int dA = 2\pi \int y dL = 2\pi y_c L \quad 42.14$$

- *Theorem II:* The volume of a surface of revolution is equal to the generating area times the distance traveled by the centroid of the area in generating the volume. (See Fig. 42.2.)

**Figure 42.2** Volume of Revolution

When a differential plane area,  $dA$ , is revolved about the  $x$ -axis and does not intersect the  $y$ -axis, it generates a ring of volume  $dV$ .

$$dV = \pi y^2 dx = \pi y dA \quad 42.15$$

$$V = 2\pi y_c A \quad 42.16$$

### 5. MOMENT OF INERTIA OF AN AREA

The *moment of inertia*,  $I$ , of an area is needed in mechanics of materials problems. It is convenient to think of the moment of inertia of a beam's cross-sectional area as a measure of the beam's ability to resist bending. Given equal loads, a beam with a small moment of inertia will bend more than a beam with a large moment of inertia.

Since the moment of inertia represents a resistance to bending, it is always positive. Since a beam can be unsymmetrical (e.g., a rectangular beam) and can be stronger in one direction than another, the moment of inertia depends on orientation. Therefore, a reference axis or direction must be specified.

The moment of inertia taken with respect to one of the axes in the rectangular coordinate system is sometimes referred to as the *rectangular moment of inertia*.

The symbol  $I_x$  is used to represent a moment of inertia with respect to the  $x$ -axis. Similarly,  $I_y$  is the moment of inertia with respect to the  $y$ -axis.  $I_x$  and  $I_y$  do not normally combine and are not components of some resultant moment of inertia.

Any axis can be chosen as the reference axis, and the value of the moment of inertia will depend on the reference selected. The moment of inertia taken with respect to an axis passing through the area's centroid is known

as the *centroidal moment of inertia*,  $I_{cx}$  or  $I_{cy}$ . The centroidal moment of inertia is the smallest possible moment of inertia for the shape.

The *integration method* can be used to calculate the moment of inertia of a function that is bounded by the  $x$ - and  $y$ -axes and a curve  $y = f(x)$ . From Eq. 42.17 and Eq. 42.18, it is apparent why the moment of inertia is also known as the *second moment of the area* or *second area moment*.

$$I_x = \int y^2 dA \quad 42.17$$

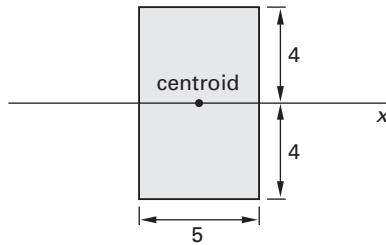

$$I_y = \int x^2 dA \quad 42.18$$

$$dA = f(x)dx = g(y)dy \quad 42.19$$

The moments of inertia of the *basic shapes* are well known and are listed in App. 42.A.

### Example 42.3

What is the centroidal moment of inertia with respect to the  $x$ -axis of a rectangle 5.0 units wide and 8.0 units tall?

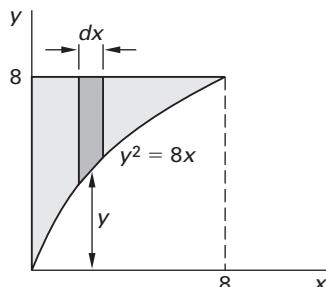

*Solution*

Since the centroidal moment of inertia is needed, the reference line passes through the centroid. So, from App. 42.A, the centroidal moment of inertia is

$$I_{cx} = \frac{bh^3}{12} = \frac{(5)(8)^3}{12} = 213.3 \text{ units}^4$$

### Example 42.4

What is the moment of inertia with respect to the  $y$ -axis of the area bounded by the  $y$ -axis, the line  $y = 8.0$ , and the parabola  $y^2 = 8x$ ?

*Solution*

This problem is more complex than it first appears, since the area is above the curve, bounded not by  $y = 0$  but by  $y = 8$ . In particular,  $dA$  must be determined correctly.

$$y = \sqrt{8x}$$

Use Eq. 42.4.

$$\begin{aligned} dA &= (8 - f(x))dx = (8 - y)dx \\ &= (8 - \sqrt{8x})dx \end{aligned}$$

Equation 42.18 is used to calculate the moment of inertia with respect to the  $y$ -axis.

$$\begin{aligned} I_y &= \int x^2 dA = \int_0^8 x^2(8 - \sqrt{8x})dx \\ &= \frac{8}{3}x^3 - \left(\frac{4\sqrt{2}}{7}\right)x^{7/2} \Big|_0^8 \\ &= 195.0 \text{ units}^4 \end{aligned}$$

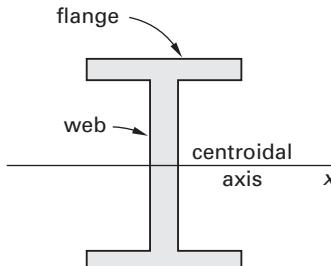

## 6. PARALLEL AXIS THEOREM

If the moment of inertia is known with respect to one axis, the moment of inertia with respect to another parallel axis can be calculated from the *parallel axis theorem*, also known as the *transfer axis theorem*. In Eq. 42.20,  $d$  is the distance between the centroidal axis and the second, parallel axis.

$$I_{\text{parallel axis}} = I_c + A d^2 \quad 42.20$$

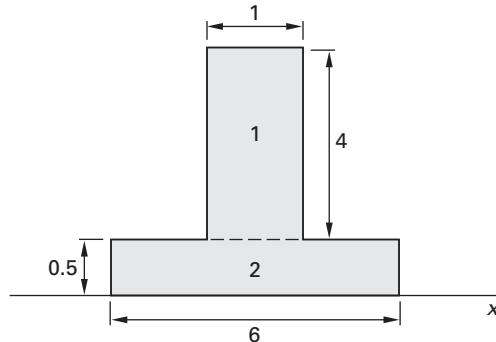

The second term in Eq. 42.20 is often much larger than the first term. Areas close to the centroidal axis do not affect the moment of inertia significantly. This principle is exploited by structural steel shapes (such as is shown in Fig. 42.3) that derive bending resistance from *flanges* located away from the centroidal axis. The *web* does not contribute significantly to the moment of inertia.

Figure 42.3 Structural Steel W-Shape

**Example 42.5**

Find the moment of inertia about the  $x$ -axis for the inverted-T area shown.

*Solution*

The area is divided into two basic shapes: 1 and 2. From App. 42.A, the moment of inertia of basic shape 2 with respect to the  $x$ -axis is

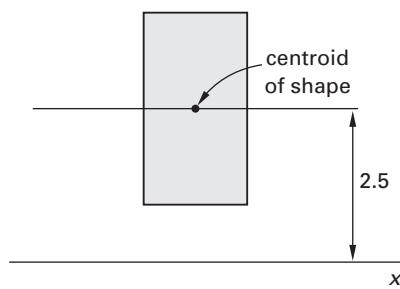

$$I_{x,2} = \frac{bh^3}{3} = \frac{(6.0)(0.5)^3}{3} = 0.25 \text{ units}^4$$

The moment of inertia of basic shape 1 about its own centroid is

$$I_{cx,1} = \frac{bh^3}{12} = \frac{(1)(4)^3}{12} = 5.33 \text{ units}^4$$

The  $x$ -axis is located 2.5 units from the centroid of basic shape 1. From the parallel axis theorem, Eq. 42.20, the moment of inertia of basic shape 1 about the  $x$ -axis is

$$\begin{aligned} I_{x,1} &= I_{cx,1} + A_1 d_1^2 = 5.33 + (4)(2.5)^2 \\ &= 30.33 \text{ units}^4 \end{aligned}$$

The total moment of inertia of the T-area is

$$\begin{aligned} I_x &= I_{x,1} + I_{x,2} = 30.33 \text{ units}^4 + 0.25 \text{ units}^4 \\ &= 30.58 \text{ units}^4 \end{aligned}$$

**Example 42.6**

Find the moment of inertia about the horizontal centroidal axis for the inverted-T area shown in Ex. 42.5.

*Solution*

The first step is to find the location of the centroid. The areas and centroidal locations (with respect to the  $x$ -axis) of the two basic shapes are

$$A_1 = (4.0)(1.0) = 4.0 \text{ units}^2$$

$$A_2 = (0.5)(6.0) = 3.0 \text{ units}^2$$

$$y_{c,1} = 2.5 \text{ units}$$

$$y_{c,2} = 0.25 \text{ units}$$

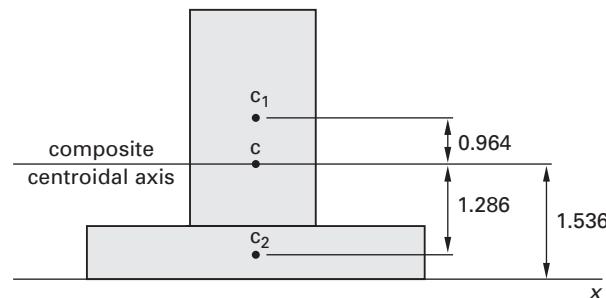

From Eq. 42.6, the composite centroid is located at

$$\begin{aligned} y_c &= \frac{A_1 y_{c,1} + A_2 y_{c,2}}{A_1 + A_2} = \frac{(4.0)(2.5) + (3.0)(0.25)}{4.0 + 3.0} \\ &= 1.536 \text{ units} \end{aligned}$$

The distances between the centroids of the basic shapes and the composite shape are

$$d_1 = 2.5 - 1.536 = 0.964 \text{ units}$$

$$d_2 = 1.536 - 0.25 = 1.286 \text{ units}$$

The centroidal moments of inertia of the basic shapes with respect to an axis parallel to the  $x$ -axis are

$$I_{cx,1} = \frac{bh^3}{12} = \frac{(1)(4)^3}{12} = 5.33 \text{ units}^4$$

$$I_{cx,2} = \frac{bh^3}{12} = \frac{(6)(0.5)^3}{12} = 0.0625 \text{ units}^4$$

Using Eq. 42.20, the centroidal moment of inertia of the inverted-T area is

$$\begin{aligned} I_{cx} &= I_{cx,1} + A_1 d_1^2 + I_{cx,2} + A_2 d_2^2 \\ &= 5.33 + (4.0)(0.964)^2 + 0.0625 + (3.0)(1.286)^2 \\ &= 14.07 \text{ units}^4 \end{aligned}$$

## 7. POLAR MOMENT OF INERTIA

The *polar moment of inertia*,  $J$ , is required in torsional shear stress calculations.<sup>2</sup> It can be thought of as a measure of an area's resistance to torsion (twisting). The definition of a polar moment of inertia of a two-dimensional area requires three dimensions because the reference axis for a polar moment of inertia of a plane area is perpendicular to the plane area.

The polar moment of inertia is derived from Eq. 42.21.

$$J = \int (x^2 + y^2) dA \quad 42.21$$

It is often easier to use the *perpendicular axis theorem* to quickly calculate the polar moment of inertia.

- *perpendicular axis theorem*: The polar moment of inertia of a plane area about an axis normal to the plane is equal to the sum of the moments of inertia about any two mutually perpendicular axes lying in the plane and passing through the given axis.

$$J = I_x + I_y \quad 42.22$$

Since the two perpendicular axes can be chosen arbitrarily, it is most convenient to use the centroidal moments of inertia.

$$J = I_{cx} + I_{cy} \quad 42.23$$

### Example 42.7

What is the centroidal polar moment of inertia of a circular area of radius  $r$ ?

*Solution*

From App. 42.A, the centroidal moment of inertia of a circle with respect to the  $x$ -axis is

$$I_{cx} = \frac{\pi r^4}{4}$$

Since the area is symmetrical,  $I_{cy}$  and  $I_{cx}$  are the same. From Eq. 42.23,

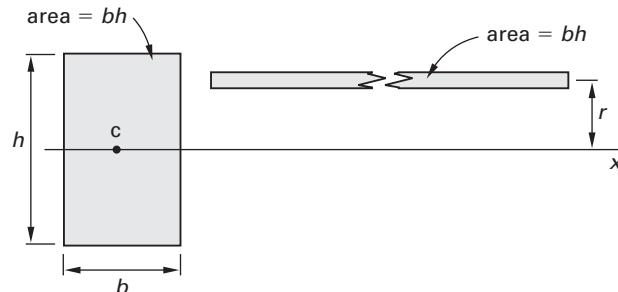

$$J_c = I_{cx} + I_{cy} = \frac{\pi r^4}{4} + \frac{\pi r^4}{4} = \frac{\pi r^4}{2}$$

## 8. RADIUS OF GYRATION

Every nontrivial area has a centroidal moment of inertia. Usually, some portions of the area are close to the centroidal axis and other portions are farther away. The *transverse radius of gyration*, or just *radius of gyration*,  $r$ , is an imaginary distance from the centroidal axis at which the entire area can be assumed to exist without affecting the moment of inertia. Despite the name

"radius," the radius of gyration is not limited to circular shapes or to polar axes. This concept is illustrated in Fig. 42.4.

**Figure 42.4** Radius of Gyration

The method of calculating the radius of gyration is based on the parallel axis theorem. If all of the area is located a distance,  $r$ , from the original centroidal axis, there will be no  $I_c$  term in Eq. 42.20. Only the  $Ad^2$  term will contribute to the moment of inertia.

$$I = r^2 A \quad 42.24$$

$$r = \sqrt{\frac{I}{A}} \quad 42.25$$

The concept of *least radius of gyration* comes up frequently in column design problems. (The column will tend to buckle about an axis that produces the smallest radius of gyration.) Usually, finding the least radius of gyration for symmetrical section will mean solving Eq. 42.25 twice: once with  $I_x$  to find  $r_x$  and once with  $I_y$  to find  $r_y$ . The smallest value of  $r$  is the least radius of gyration.

The analogous quantity in the polar system is

$$r = \sqrt{\frac{J}{A}} \quad 42.26$$

Just as the polar moment of inertia,  $J$ , can be calculated from the two rectangular moments of inertia, the polar radius of gyration can be calculated from the two rectangular radii of gyration.

$$r^2 = r_x^2 + r_y^2 \quad 42.27$$

### Example 42.8

What is the radius of gyration of the rectangular shape in Ex. 42.3?

*Solution*

The area of the rectangle is

$$A = bh = (5)(8) = 40 \text{ units}^2$$

<sup>2</sup>The symbols  $I_z$  and  $I_{xy}$  are also encountered. However, the symbol  $J$  is more common.

From Eq. 42.25, the radius of gyration is

$$r_x = \sqrt{\frac{I_x}{A}} = \sqrt{\frac{213.3 \text{ units}^4}{40 \text{ units}^2}} = 2.31 \text{ units}$$

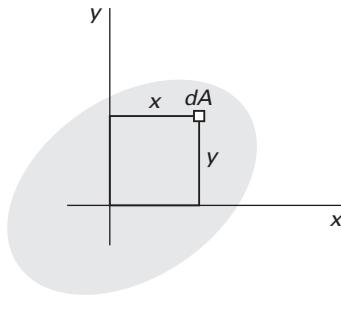

2.31 units is the distance from the centroidal  $x$ -axis that an infinitely long strip with an area of 40 square units would have to be located in order to have a moment of inertia of 213.3 units<sup>4</sup>.

## 9. PRODUCT OF INERTIA

The *product of inertia*,  $P_{xy}$ , of a two-dimensional area is useful when relating properties of areas evaluated with respect to different axes. It is found by multiplying each differential element of area by its  $x$ - and  $y$ -coordinate and then summing over the entire area. (See Fig. 42.5.)

$$P_{xy} = \int xy \, dA \quad 42.28$$

**Figure 42.5** Calculating the Product of Inertia

The product of inertia is zero when either axis is an axis of symmetry. Since the axes can be chosen arbitrarily, the area may be in one of the negative quadrants, and the product of inertia may be negative.

The parallel axis theorem for products of inertia, as shown in Fig. 42.6, is given by Eq. 42.29. (Both axes are allowed to move to new positions.)  $x'_c$  and  $y'_c$  are the coordinates of the centroid in the new coordinate system.

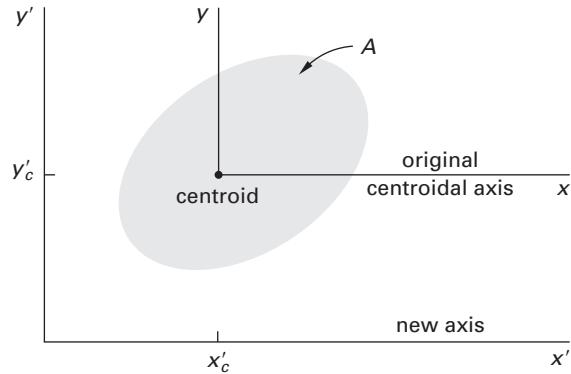

$$P_{x'y'} = P_{c,xy} + x'_c y'_c A \quad 42.29$$

## 10. SECTION MODULUS

In the analysis of beams, the outer compressive (or tensile) surface is known as the *extreme fiber*. The distance,  $c$ , from the centroidal axis of the beam cross section to the extreme fiber is the distance to the extreme fiber. The *section modulus*,  $S$ , combines the centroidal moment of inertia and the distance to the extreme fiber.

$$S = \frac{I_c}{c} \quad 42.30$$

**Figure 42.6** Parallel Axis Theorem for Products of Inertia

## 11. ROTATION OF AXES

Figure 42.7 shows rotation of the  $x-y$  axes through an angle,  $\theta$ , into a new set of  $u-v$  axes, without rotating the area. If the moments and product of inertia of the area are known with respect to the old  $x-y$  axes, the new properties can be calculated from Eq. 42.31 through Eq. 42.33.

$$\begin{aligned} I_u &= I_x \cos^2 \theta - 2P_{xy} \sin \theta \cos \theta + I_y \sin^2 \theta \\ &= \frac{1}{2}(I_x + I_y) + \frac{1}{2}(I_x - I_y)\cos 2\theta \\ &\quad - P_{xy} \sin 2\theta \end{aligned} \quad 42.31$$

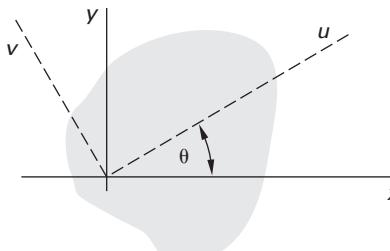

$$\begin{aligned} I_v &= I_x \sin^2 \theta + 2P_{xy} \sin \theta \cos \theta + I_y \cos^2 \theta \\ &= \frac{1}{2}(I_x + I_y) - \frac{1}{2}(I_x - I_y)\cos 2\theta \\ &\quad + P_{xy} \sin 2\theta \end{aligned} \quad 42.32$$

$$\begin{aligned} P_{uv} &= I_x \sin \theta \cos \theta + P_{xy}(\cos^2 \theta - \sin^2 \theta) \\ &\quad - I_y \sin \theta \cos \theta \\ &= \frac{1}{2}(I_x - I_y) \sin 2\theta + P_{xy} \cos 2\theta \end{aligned} \quad 42.33$$

Since the polar moment of inertia about a fixed axis perpendicular to any two orthogonal axes in the plane is constant, the polar moment of inertia is unchanged by the rotation.

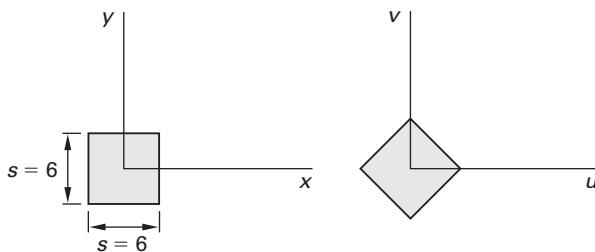

$$J_{xy} = I_x + I_y = I_u + I_v = J_{uv} \quad 42.34$$

**Figure 42.7** Rotation of Axes

**Example 42.9**

What is the centroidal area moment of inertia of a  $6 \times 6$  square that is rotated  $45^\circ$  from its “flat” orientation?

*Solution*

From App. 42.A, the centroidal moments of inertia with respect to the  $x$ - and  $y$ -axes are

$$I_x = I_y = \frac{s^4}{12} = \frac{(6)^4}{12} = 108 \text{ units}^4$$

Since the centroidal  $x$ - and  $y$ -axes are axes of symmetry, the product of inertia is zero.

Use Eq. 42.31.

$$\begin{aligned} I_u &= I_x \cos^2 \theta - 2P_{xy} \sin \theta \cos \theta + I_y \sin^2 \theta \\ &= (108)\cos^2 45^\circ - 0 + (108)\sin^2 45^\circ \\ &= 108 \text{ units}^4 \end{aligned}$$

The centroidal moment of inertia of a square is the same regardless of rotation angle.

## 12. PRINCIPAL AXES FOR AREA PROPERTIES

Referring to Fig. 42.7, there is one angle,  $\theta$ , that will maximize the moment of inertia,  $I_u$ . This angle can be found from calculus by setting  $dI_u/d\theta = 0$ . The resulting equation defines two angles, one that maximizes  $I_u$  and one that minimizes  $I_u$ .

$$\tan 2\theta = \frac{-2P_{xy}}{I_x - I_y} \quad 42.35$$

The two angles that satisfy Eq. 42.35 are  $90^\circ$  apart. The set of  $u$ - $v$  axes defined by Eq. 42.35 are known as *principal axes*. The moments of inertia about the principal axes are defined by Eq. 42.36 and are known as the *principal moments of inertia*.

$$I_{\max,\min} = \frac{1}{2}(I_x + I_y) \pm \sqrt{\frac{1}{4}(I_x - I_y)^2 + P_{xy}^2} \quad 42.36$$

## 13. MOHR'S CIRCLE FOR AREA PROPERTIES

Once  $I_x$ ,  $I_y$ , and  $P_{xy}$  are known, *Mohr's circle* can be drawn to graphically determine the moments of inertia about the principal axes. The procedure for drawing Mohr's circle is given as follows.

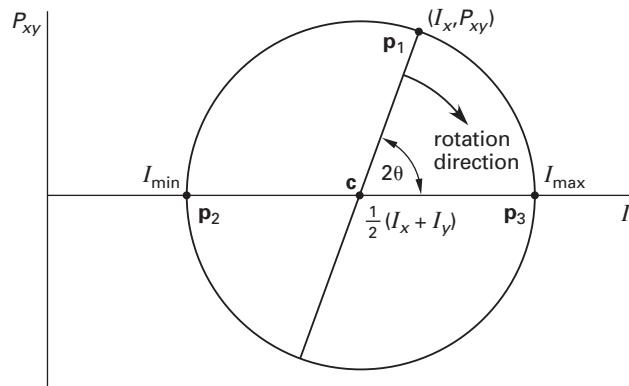

*step 1:* Determine  $I_x$ ,  $I_y$ , and  $P_{xy}$  for the existing set of axes.

*step 2:* Draw a set of  $I$ - $P_{xy}$  axes.

*step 3:* Plot the center of the circle, point  $c$ , by calculating distance  $c$  along the  $I$ -axis. (See Fig. 42.8.)

$$c = \frac{1}{2}(I_x + I_y) \quad 42.37$$

**Figure 42.8** Mohr's Circle

*step 4:* Plot the point  $p_1 = (I_x, P_{xy})$ .

*step 5:* Draw a line from point  $p_1$  through center  $c$  and extend it an equal distance below the  $I$ -axis. This is the diameter of the circle.

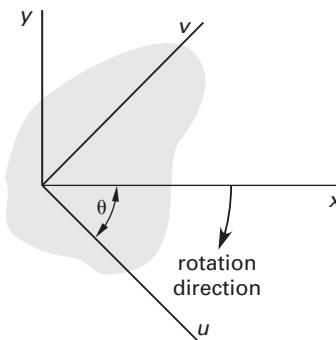

*step 6:* Using the center  $c$  and point  $p_1$ , draw the circle. An alternate method of constructing the circle is to draw a circle of radius  $r$ .

$$r = \sqrt{\frac{1}{4}(I_x - I_y)^2 + P_{xy}^2} \quad 42.38$$

*step 7:* Point  $p_2$  defines  $I_{\min}$ . Point  $p_3$  defines  $I_{\max}$ .

*step 8:* Determine the angle  $\theta$  as half of the angle  $2\theta$  on the circle. This angle corresponds to  $I_{\max}$ . (The axis giving the minimum moment of inertia is perpendicular to the maximum axis.) The sense of this angle and the sense of the rotation are the same. That is, the direction that the diameter would have to be turned in order to coincide with the  $I_{\max}$ -axis has the same sense as the rotation of the  $x$ - $y$  axes needed to form the principal  $u$ - $v$  axes. (See Fig. 42.9.)

## 1. CLASSIFICATION OF MATERIALS

When used to describe engineering materials, the terms "strong" and "tough" are not synonymous. Similarly, "weak," "soft," and "brittle" have different engineering meanings. A *strong material* has a high ultimate strength, whereas a *weak material* has a low ultimate strength. A *tough material* will yield greatly before breaking, whereas a *brittle material* will not. (A brittle material is one whose strain at fracture is less than approximately 0.05 (5%).) A *hard material* has a high modulus of elasticity, whereas a *soft material* does not. Figure 43.1 illustrates some of the possible combinations of these classifications.

**Figure 43.1** Types of Engineering Materials

## 2. TENSILE TEST

Many useful material properties are derived from the results of a standard *tensile test*. In this test, a prepared material sample (i.e., a *specimen*) is axially loaded in tension, and the resulting elongation,  $\delta$ , is measured as the load,  $F$ , increases. A *load-elongation curve* of tensile test data for a ductile ferrous material (e.g., low-carbon steel or other BCC transition metal) is shown in Fig. 43.2.

**Figure 43.2** Typical Tensile Test Results for a Ductile Material

When elongation is plotted against the applied load, the graph is applicable only to an object with the same length and area as the test specimen. To generalize the test results, the data are converted to stresses and strains by the use of Eq. 43.1 and Eq. 43.2.<sup>1</sup>

*Engineering stress*,  $s$  (usually called *stress*), is the load per unit original area. Typical engineering stress units are  $\text{lbf/in}^2$  and MPa. *Engineering strain*,  $e$  (usually called *strain*), is the elongation of the test specimen expressed as a percentage or decimal fraction of the

<sup>1</sup>The most common *test specimen* in the United States has a length of 2.00 in and a diameter of 0.505 in. Since the cross-sectional area of this 0.505 bar is  $0.2 \text{ in}^2$ , the stress in  $\text{lbf/in}^2$  is calculated by multiplying the force in pounds by five.

original length. The units in/in and m/m are also used for strain.

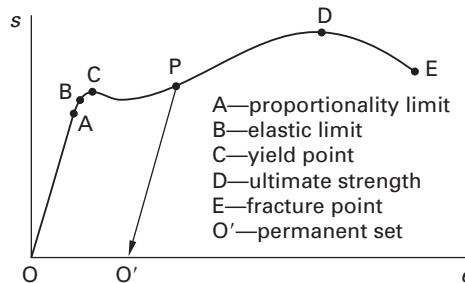

$$s = \frac{F}{A_o} \quad 43.1$$

$$e = \frac{\delta}{L_o} \quad 43.2$$

If the stress-strain data are plotted, the shape of the resulting line will be essentially the same as the force-elongation curve, although the scales will differ.

Segment O-A in Fig. 43.3 is a straight line. The relationship between the stress and strain in this linear region is given by *Hooke's law*, Eq. 43.3. The slope of line segment O-A is the *modulus of elasticity*,  $E$ , also known as *Young's modulus*. Table 43.1 lists approximate values of the modulus of elasticity for materials at room temperature. The modulus of elasticity will be lower at higher temperatures. For steel at higher temperatures, the modulus of elasticity is reduced approximately as shown in Table 43.2.

$$s = Ee \quad 43.3$$

**Figure 43.3** Typical Stress-Strain Curve for Steel**Table 43.1** Approximate Modulus of Elasticity of Representative Materials at Room Temperature

material	$\text{lbf/in}^2$	GPa
aluminum alloys	$10-11 \times 10^6$	70-80

cast iron, ductile	$22-25 \times 10^6$	150-170
cast iron, malleable	$26-27 \times 10^6$	180-190
copper alloys	$17-18 \times 10^6$	110-112
glass	$7-12 \times 10^6$	50-80
magnesium alloys	$6.5 \times 10^6$	45
molybdenum	$47 \times 10^6$	320
nickel alloys	$26-30 \times 10^6$	180-210
steel, hard*	$30 \times 10^6$	210
steel, soft*	$29 \times 10^6$	200
steel, stainless	$28-30 \times 10^6$	190-210
titanium	$15-17 \times 10^6$	100-110

(Multiply  $\text{lbf/in}^2$  by  $6.895 \times 10^{-6}$  to obtain GPa.)

\*Common values are given.

**Table 43.2** Approximate Reduction of Steel's Modulus of Elasticity at Higher Temperatures

temperature		
°F	°C	% of original value
70	20	100%
400	200	90%
800	425	75%
1000	540	65%
1200	650	60%

The stress at point A in Fig. 43.3 is known as the *proportionality limit* (i.e., the maximum stress for which the linear relationship is valid). Strain in the *proportional region* is called *proportional strain*.

The *elastic limit*, point B in Fig. 43.3, is slightly higher than the proportionality limit. As long as the stress is kept below the elastic limit, there will be no *permanent set* (permanent deformation) when the stress is removed. Strain that disappears when the stress is removed is known as *elastic strain*, and the stress is said to be in the *elastic region*. When the applied stress is removed, the *recovery* is 100%, and the material follows the original curve back to the origin.

If the applied stress exceeds the elastic limit, the recovery will be along a line parallel to the straight line portion of the curve, as shown in line segment P-O'. The strain that results (line O-O') is *permanent set* (i.e., a permanent deformation). The terms *plastic strain* and *inelastic strain* are used to distinguish this behavior from elastic strain.

For steel, the *yield point*, point C, is very close to the elastic limit. For all practical purposes, the *yield strength* or *yield stress*,  $S_y$  (or  $S_{yt}$  to indicate yield in tension), can be taken as the stress that accompanies the beginning of plastic strain. Yield strengths are reported in lbf/in<sup>2</sup>, ksi, and MPa.<sup>2</sup> Table 43.3 presents comparative yield strengths for common metal alloys.

Figure 43.3 does not show the full complexity of the stress-strain curve near the yield point. Rather than being smooth, the curve is ragged near the yield point. At the upper yield strength, there is a pronounced drop (i.e., "drop of beam") in load-carrying ability to a plateau yield strength after the initial yielding occurs. The plateau value is known as the *lower yield strength* and is commonly reported as the yield strength. Figure 43.4 shows upper and lower yield strengths.

The *ultimate strength* or *tensile strength*,  $S_u$  (or  $S_{ut}$  to indicate an ultimate tensile strength), point D in Fig. 43.3, is the maximum stress the material can support without failure. Appendix 43.A and App. 43.B present yield and ultimate strengths for a wide variety of materials.

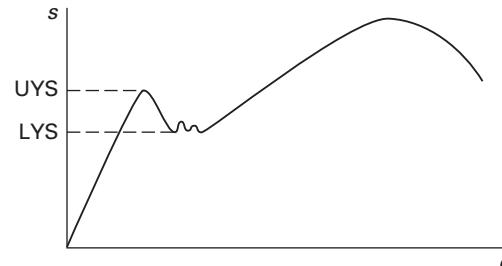

The *breaking strength* or *fracture strength*,  $S_f$ , is the stress at which the material actually fails (point E in Fig. 43.3). For ductile materials, the breaking strength

<sup>2</sup>A *kip* is a thousand pounds. *ksi* is the abbreviation for kips per square inch (thousands of lbf/in<sup>2</sup>).

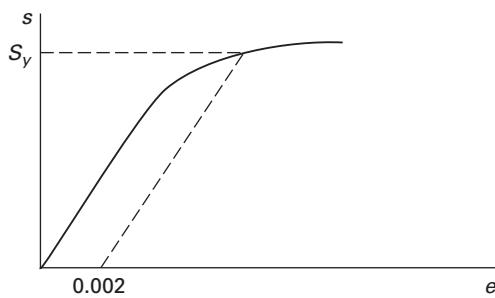

**Figure 43.4** Upper and Lower Yield Strengths

is less than the ultimate strength due to the necking down in the cross-sectional area that accompanies high plastic strains.

### 3. STRESS-STRAIN CHARACTERISTICS OF NONFERROUS METALS

Most nonferrous materials, such as aluminum, magnesium, copper, and other FCC and HCP metals, do not have well-defined yield points. The stress-strain curve starts to bend at low stresses, as illustrated by Fig. 43.5. In such cases, the yield strength is commonly defined as the stress that will cause a 0.2% *parallel offset* (i.e., a plastic strain of 0.002) for metals and 2% parallel offset for plastics.<sup>3</sup> However, the yield strength can also be defined by other offset values (e.g., 0.1% for metals and 1.0% for plastics).

<sup>3</sup>The 0.2% parallel offset strength is also known as the *proof stress*.

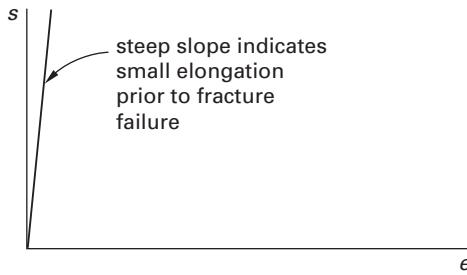

**Figure 43.5** Typical Stress-Strain Curve for a Nonferrous Metal

The yield strength is found by extending a line from the offset strain value parallel to the linear portion of the curve until it intersects the curve.

With nonferrous metals, the difference between parallel offset and total strain characteristics is important. Sometimes, the yield point will be defined as the stress accompanying 0.5% total strain (i.e., a strain of 0.005) determined by extending a line from the stress-strain curve vertically downward to the strain axis.

#### 4. STRESS-STRAIN CHARACTERISTICS OF BRITTLE MATERIALS

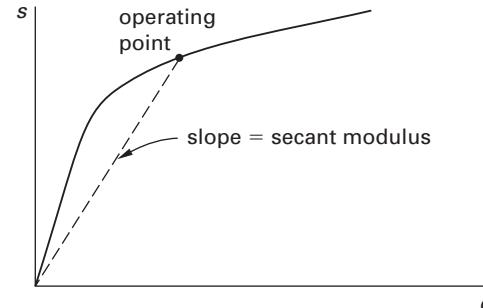

Brittle materials, such as glass, cast iron, and ceramics, can support only small strains before they fail catastrophically (i.e., without warning). As the stress is increased, the elongation is linear and Hooke's law (given in Eq. 43.3) can be used to predict the strain. Failure occurs within the linear region, and there is very little, if any, necking down. Since the failure occurs at a low strain, brittle materials are not ductile. Figure 43.6 is typical of the stress-strain curve of a brittle material.

**Figure 43.6** Stress-Strain Curve of a Brittle Material

#### 5. SECANT MODULUS

The modulus of elasticity,  $E$ , is usually determined from the steepest portion of the stress-strain curve. (This avoids the difficulty of locating the starting part of the curve.) For materials with variable modulus of elasticity, or for linear materials operating in the nonlinear region, the *secant modulus* gives the average ratio of stress to strain. The secant modulus is the slope of the straight line connecting the origin and the point of

operation. Some designs using elastomers, concrete, and prestressing wire may be based on the secant modulus. (See Fig. 43.7.)

**Figure 43.7** Secant Modulus

#### 6. POISSON'S RATIO

As a specimen elongates axially during a tensile test, it will also decrease slightly in diameter or breadth. For any specific material, the percentage decrease in diameter, known as the *lateral strain*, will be a fraction of the *axial strain*. The ratio of the lateral strain to the axial strain is known as *Poisson's ratio*,  $\nu$ , which is approximately 0.3 for most metals. (See Table 43.4.)

$$\nu = \frac{e_{\text{lateral}}}{e_{\text{axial}}} = \frac{\frac{\Delta D}{D_o}}{\frac{\delta}{L_o}} \quad 43.4$$

Poisson's ratio applies only to elastic strain. When the stress is removed, the lateral strain disappears along with the axial strain.

**Table 43.4** Approximate Values of Poisson's Ratio

material	Poisson's ratio
rubber	0.49
thermosetting plastics	0.40–0.45
aluminum	0.32–0.34 (0.33)*
magnesium	0.35
copper	0.33–0.36 (0.33)*
titanium	0.34
brass	0.33–0.36
stainless steel	0.30
steel	0.26–0.30 (0.30)*
nickel	0.30
beryllium	0.27
cast iron	0.21–0.33 (0.27)*
glass ( $\text{SiO}_2$ )	0.21–0.27 (0.23)*
diamond	0.20

\*commonly used for design

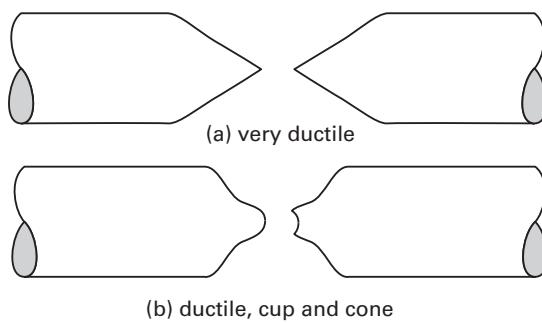

## 7. STRAIN HARDENING AND NECKING DOWN

When the applied stress exceeds the yield strength, the specimen will experience plastic deformation and will strain harden. (Plastic deformation is primarily due to the shear stress-induced movement of dislocations.) Since the specimen volume is constant (i.e.,  $A_oL_o = AL$ ), the cross-sectional area decreases. Initially, the strain hardening more than compensates for the decrease in area, so the material's strength increases and the engineering stress increases with larger strains.

Eventually, a point is reached when the available strain hardening and increase in strength cannot keep up with the decrease in cross-sectional area. The specimen then begins to neck down (at some local weak point), and all subsequent plastic deformation is concentrated at the neck. The cross-sectional area decreases even more rapidly thereafter since only a small portion of the specimen volume is strain hardening. The engineering stress decreases to failure.

Figure 43.8 shows necking down in two different specimens tested to failure. Very ductile materials pull out to a point, while most moderately ductile materials exhibit a *cup-and-cone* failure. (Failed brittle materials, not shown, do not exhibit any significant reduction in area.)

**Figure 43.8** Types of Tensile Ductile Failure

## 8. TRUE STRESS AND STRAIN

Engineering stress, given by Eq. 43.1, is calculated for all stress levels from the original cross-sectional area. However, during a tensile test, the area of a specimen decreases as the stress increases. The decrease is only slight in the elastic region but is much more significant after plastic deformation begins.

If the instantaneous area is used to calculate the stress, the stress is known as *true stress* or *physical stress*,  $\sigma$ . Equation 43.5 assumes a homogeneous strain distribution along the gage length and that there is no change in total volume with strain, which are valid up to the point of necking. ( $q = (A_o - A)/A_o$ , the fractional reduction

in area, used in Eq. 43.5, is expressed as a number between 0 and 1.)

$$\begin{aligned}\sigma &= \frac{F}{A} = \frac{F}{\left(1 - \frac{A_o - A}{A_o}\right)A_o} = \frac{F}{(1 - q)A_o} \\ &= \frac{s}{1 - q} \\ &= s(1 + e) \quad [\text{prior to necking, circular specimen}]\end{aligned}\quad 43.5$$

For circular or square specimens prior to necking, Eq. 43.5 may be written as Eq. 43.6.

$$\sigma = \frac{s}{(1 - \nu e)^2} \quad 43.6$$

Engineering strain, given by Eq. 43.2, is calculated from the original length, although the actual length increases during the tensile test. The *true strain*, *physical strain*, or *log strain*,  $\epsilon$ , is found from Eq. 43.7.

$$\begin{aligned}\epsilon &= \int_{L_o}^L \frac{dL}{L} = \ln \frac{L}{L_o} \\ &= \ln(1 + e) \quad [\text{prior to necking}]\end{aligned}\quad 43.7$$

Since the plastic deformation occurs through a shearing process, there is essentially no volume decrease during elongation.

$$A_o L_o = A L \quad 43.8$$

Therefore, true strain can be calculated from the cross-sectional areas and, for a circular specimen, from diameters. If necking down has occurred, true strain must be calculated from the areas or diameters, not the lengths.

$$\epsilon = \ln \frac{A_o}{A} = \ln \left( \frac{D_o}{D} \right)^2 = 2 \ln \frac{D_o}{D} \quad 43.9$$

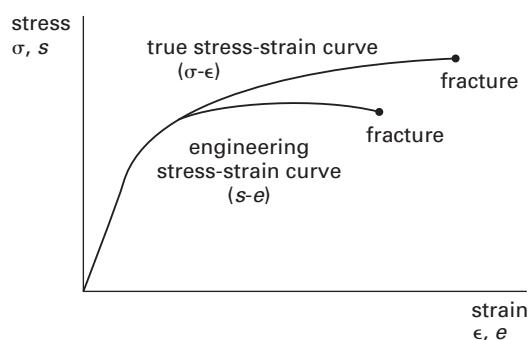

A graph of true stress and true strain is known as a *flow curve*. Log  $\sigma$  can also be plotted against log  $\epsilon$ , resulting in a straight-line relationship.

The flow curve of many metals in the plastic region can be expressed by Eq. 43.10, known as a *power curve*.  $K$  is known as the *strength coefficient*, and  $n$  is the *strain-hardening exponent*. Values of both vary greatly with material, composition, and heat treatment.  $n$  can vary from 0 (for a perfectly inelastic solid) to 1.0 (for an elastic solid). Typical values are between 0.1 and 0.5. For annealed steel with 0.05% carbon, for example,  $K \approx 77,000$  psi (530 MPa) and  $n = 0.26$ .

$$\sigma = K \epsilon^n \quad 43.10$$

Figure 43.9 compares engineering and true stresses and strains for a ferrous alloy. As can be seen, the two curves coincide throughout the elastic region. Although true stress and strain are more accurate, almost all engineering work is based on engineering

**Figure 43.9** True and Engineering Stresses and Strains for a Ferrous Alloy

stress and strain, which is justifiable for two reasons: (a) design using ductile materials is limited to the elastic region where engineering and true values differ little, and (b) the reduction in area of most parts at their service stresses is not known; only the original area is known.

### Example 43.1

The engineering stress in a solid tension member was 47,000 lbf/in<sup>2</sup> at failure. The reduction in area was 80%. What were the true stress and strain at failure?

*Solution*

Since engineering stress,  $s$ , is  $F/A_o$ , from Eq. 43.5 the true stress is

$$\sigma = \frac{s}{1-q} = \frac{47,000 \text{ lbf}}{1-0.80} = 235,000 \text{ lbf/in}^2$$

From Eq. 43.9, the true strain is

$$\epsilon = \ln \left( \frac{1}{1-0.80} \right) = 1.61 \quad (161\%)$$

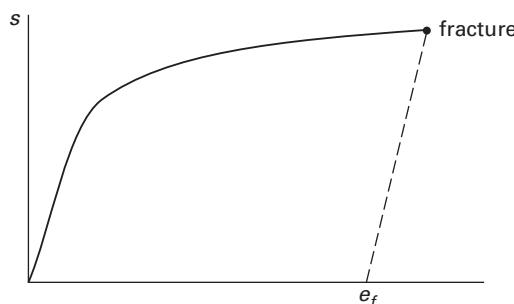

## 9. DUCTILITY

A material that deforms and elongates a great deal before failure is said to be a *ductile material*.<sup>4</sup> (Steel, for example, is a ductile material.) The *percent elongation*, short for *percent elongation at failure*, is the total plastic strain at failure. (See Fig. 43.10.) (Percent elongation does not include the elastic strain, because even at ultimate failure the material snaps back an amount equal to the elastic strain.)

$$\begin{aligned} \text{percent elongation} &= \frac{L_f - L_o}{L_o} \times 100\% \\ &= e_f \times 100\% \end{aligned} \quad 43.11$$

<sup>4</sup>The words “brittle” and “ductile” are antonyms.

**Figure 43.10** Percent Elongation

The value of the final strain to be used in Eq. 43.11 is found by extending a line from the failure point downward to the strain axis, parallel to the linear portion of the curve. This is equivalent to putting the two broken specimen pieces together and measuring the total length.

Highly ductile materials exhibit large percent elongations. However, percent elongation is not the same as *ductility*.

$$\text{ductility} = \frac{\text{ultimate failure strain}}{\text{yielding strain}} \quad 43.12$$

The *reduction in area* (at the point of failure),  $q_f$ , expressed as a percentage or decimal fraction, is a third measure of a material's ductility. The reduction in area due to necking down will be 50% or greater for ductile materials and less than 10% for brittle materials.<sup>5</sup>

$$q_f = \frac{A_o - A_f}{A_o} \times 100\% \quad 43.13$$

## 10. STRAIN ENERGY

*Strain energy*, also known as *internal work*, is the energy per unit volume stored in a deformed material. The strain energy is equivalent to the work done by the applied tensile force. Simple work is calculated as the product of a force moving through a distance.

$$\text{work} = \text{force} \times \text{distance} = \int F dL \quad 43.14$$

$$\text{work per unit volume} = \int \frac{F dL}{AL} = \int_0^{\epsilon_{\text{final}}} \sigma d\epsilon \quad 43.15$$

This work per unit volume corresponds to the area under the true stress-strain curve. Units are in-lbf/in<sup>3</sup> (i.e., inch-pounds (a unit of energy) per cubic inch (a unit of volume)), usually shortened to lbf/in<sup>2</sup>, or J/m<sup>3</sup> (i.e., joules per cubic meter), less frequently shown as Pa. (Equation 43.15 cannot be simplified further because stress is not proportional to strain for the entire curve.)

<sup>5</sup>*Notch-brittle materials* have reductions in area that are moderate (e.g., 25–35%) when tested in the usual manner, but close to zero when the test specimen is given a small notch or crack.

## 11. RESILIENCE

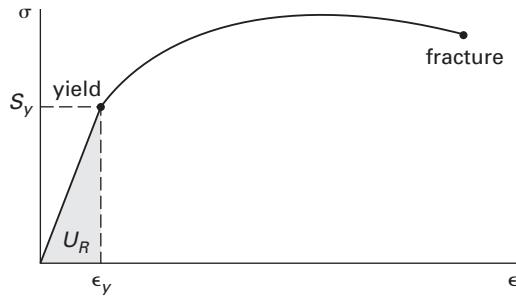

A *resilient material* is able to absorb and release *strain energy* without permanent deformation. *Resilience* is measured by the *modulus of resilience*, also known as the *elastic toughness*, which is the strain energy per unit volume required to reach the yield point. This is represented by the area under the stress-strain curve up to the yield point. Since the stress-strain curve is essentially a straight line up to that point, the area is triangular.

$$U_R = \int_0^{\epsilon_y} \sigma d\epsilon = E \int_0^{\epsilon_y} \epsilon d\epsilon = \frac{E\epsilon_y^2}{2}$$

$$= \frac{S_y \epsilon_y}{2} \quad 43.16$$

The modulus of resilience (shown in Fig. 43.11) varies greatly for steel. It can be more than ten times higher for high-carbon spring steel ( $U_R = 320 \text{ lbf/in}^2$ , 2.2 MPa) than for low-carbon steel ( $U_R = 20 \text{ lbf/in}^2$ , 0.14 MPa).

**Figure 43.11** Modulus of Resilience

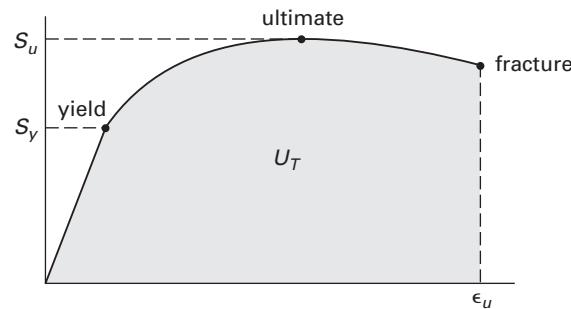

## 12. TOUGHNESS

A *tough material* will be able to withstand occasional high stresses without fracturing. Products subjected to sudden loading, such as chains, crane hooks, railroad couplings, and so on, should be tough. One measure of a material's *toughness* is the *modulus of toughness* (i.e., the strain energy or work per unit volume required to cause fracture). (See Fig. 43.12.) This is the total area under the stress-strain curve, given the symbol  $U_T$ . Since the area is irregular, the modulus of toughness cannot be exactly calculated by a simple formula. However, the modulus of toughness of ductile materials (with large strains at failure) can be approximately calculated from either Eq. 43.17 or Eq. 43.18.

$$U_T \approx S_u \epsilon_u \quad [\text{ductile}] \quad 43.17$$

$$U_T \approx \left( \frac{S_y + S_u}{2} \right) \epsilon_u \quad [\text{ductile}] \quad 43.18$$

**Figure 43.12** Modulus of Toughness

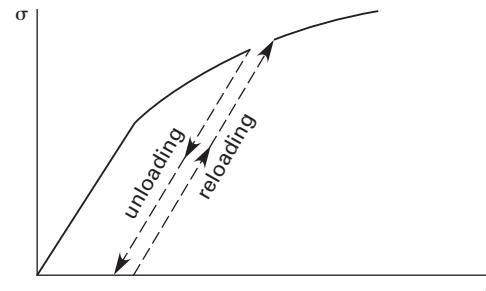

For brittle materials, the stress-strain curve may be either linear or parabolic. If the curve is parabolic, Eq. 43.19 approximates the modulus of toughness.

$$U_T \approx \frac{2}{3} S_u \epsilon_u \quad [\text{brittle}] \quad 43.19$$

## 13. UNLOADING AND RELOADING

If the load is removed after a specimen is stressed elastically, the material will return to its original state. If the load is removed after a specimen is stressed into the plastic region, the *unloading curve* will follow a sloped path back to zero stress. The slope of the unloading curve will be equal to the original modulus of elasticity,  $E$ , illustrated by Fig. 43.13.

**Figure 43.13** Unloading and Reloading Curves

If this same material is subsequently reloaded, the *reloading curve* will follow the previous unloading curve up to the continuation of the original stress-strain curve. Therefore, the *apparent yield stress* of the reloaded specimen will be higher. This extra strength is the result of the strain hardening that has occurred.<sup>6</sup> Although the material will have a higher strength, its ductility and toughness will have been reduced.

<sup>6</sup>The additional strength is lost if the material is subsequently annealed.

## 14. COMPRESSIVE STRENGTH

*Compressive strength*,  $S_{uc}$  (i.e., ultimate strength in compression), is an important property for brittle materials such as concrete and cast iron that are primarily loaded in compression only. ( $f'_c$  is commonly used as the symbol for the compressive strength of concrete.) The compressive strengths of these materials are much greater than their tensile strengths, whereas the compressive strengths for ductile materials, such as steel, are the same as their tensile yield strengths.

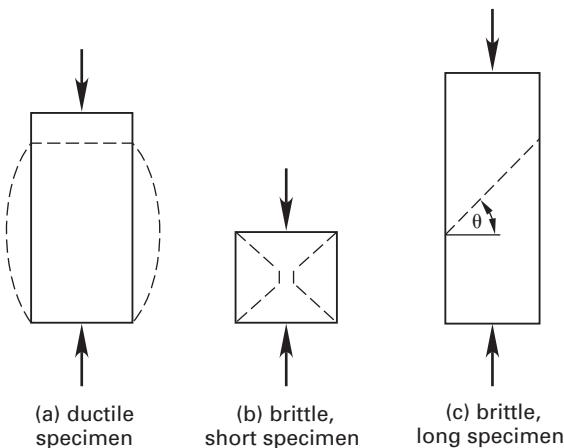

Within the linear (elastic) region, Hooke's law is valid for compression of both brittle and ductile materials.

The failure mechanism for ductile materials is plastic deformation alone. Such materials do not rupture in compression. Therefore, a ductile material can support a load long after the material is distorted beyond a useful shape.

The failure mechanism for brittle materials is shear along an inclined plane. The characteristic plane and hourglass failures for brittle materials are shown in Fig. 43.14.<sup>7</sup> Theoretically, only cohesion contributes to compressive strength, and the *angle of rupture* (i.e., the incline angle),  $\theta$ , should be  $45^\circ$ . In real materials, however, internal friction also contributes strength. The angles of rupture for cast iron, concrete, brick, and so on vary roughly between  $50^\circ$  and  $60^\circ$ . If the *angle of internal friction*,  $\phi$ , is known for the material, the angle of rupture can be calculated exactly from *Mohr's theory of rupture*.

$$\theta = 45^\circ + \frac{\phi}{2} \quad 43.20$$

Figure 43.14 Compressive Failures

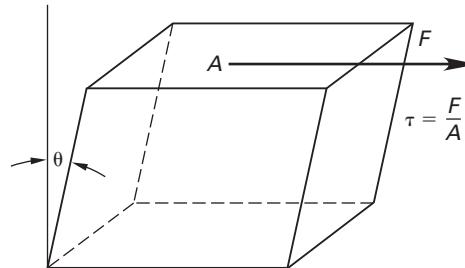

<sup>7</sup>The *hourglass failure* appears when the material is too short for a complete failure surface to develop.

## 15. TORSION TEST

Figure 43.15 illustrates a simple cube loaded by a shear stress,  $\tau$ . The volume of the cube does not decrease when loaded, but the shape changes. The *shear strain* is the angle,  $\theta$ , expressed in radians. The shear strain is proportional to the shear stress, analogous to Hooke's law for tensile loading.  $G$  is the *shear modulus*, also known as the *modulus of shear*, *modulus of elasticity in shear*, and *modulus of rigidity*.

$$\tau = G\theta \quad 43.21$$

Figure 43.15 Cube Loaded in Shear

The shear modulus can be calculated from the modulus of elasticity and Poisson's ratio and can be derived from the results of a tensile test. (See Table 43.5.)

$$G = \frac{E}{2(1+\nu)} \quad 43.22$$

Table 43.5 Approximate Values of Shear Modulus

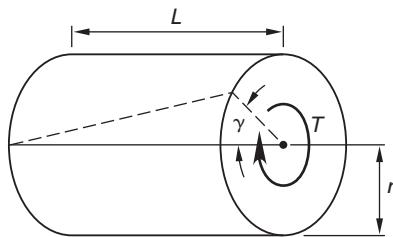

material	lbf/in <sup>2</sup>	GPa
aluminum	$3.8 \times 10^6$	26
brass	$5.5 \times 10^6$	38
copper	$6.2 \times 10^6$	43
cast iron	$8.0 \times 10^6$	55
magnesium	$2.4 \times 10^6$	17
steel	$11.5 \times 10^6$	79
stainless steel	$10.6 \times 10^6$	73
titanium	$6.0 \times 10^6$	41
glass	$4.2 \times 10^6$	29

(Multiply lbf/in<sup>2</sup> by  $6.895 \times 10^{-6}$  to obtain GPa.)

The shear stress can also be calculated from a torsion test, as illustrated by Fig. 43.16. Equation 43.23 relates the angle of twist (in radians) to the shear modulus.

$$\gamma = \frac{TL}{JG} = \frac{\tau L}{rG} \quad [\text{radians}] \quad 43.23$$

The *shear strength*,  $S_s$  or  $S_{ys}$ , of a material is the maximum shear stress that the material can support without yielding in shear. (The ultimate shear strength,  $S_{us}$ , is rarely encountered.) For ductile materials, *maximum shear stress theory* predicts the shear strength as one-half of the tensile yield strength. A more accurate relationship is derived from the *distortion energy theory* (also known as *von Mises theory*).

**Figure 43.16 Uniform Bar in Torsion**

$$S_{ys} = \frac{S_{yt}}{2} \quad [\text{maximum shear stress theory}] \quad 43.24$$

$$S_{ys} = \frac{S_{yt}}{\sqrt{3}} = 0.577 S_{yt} \quad [\text{distortion energy theory}] \quad 43.25$$

## 16. RELATIONSHIP BETWEEN THE ELASTIC CONSTANTS

The elastic constants (modulus of elasticity, shear modulus, bulk modulus, and Poisson's ratio) are related in elastic materials. Table 43.6 lists the common relationships.

## 17. FATIGUE TESTING

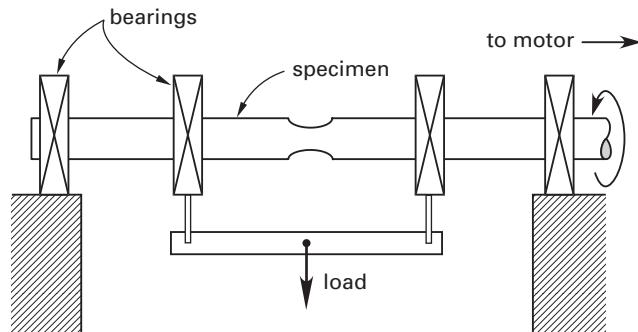

A material can fail after repeated stress loadings even if the stress level never exceeds the ultimate strength, a condition known as *fatigue failure*.

The behavior of a material under repeated loadings is evaluated by a fatigue test. A specimen is loaded repeatedly to a specific stress amplitude,  $S$ , and the number of applications of that stress required to cause failure,  $N$ , is counted. Rotating beam tests that load the specimen in bending are more common than alternating deflection and push-pull tests but are limited to round specimens.<sup>8</sup> (See Fig. 43.17.)

This procedure is repeated for different stresses, using eight to fifteen specimens. The results of these tests are graphed, resulting in an *S-N curve* (i.e., stress-number of cycles), also known as a *Wöhler curve*, which is shown in Fig. 43.18.

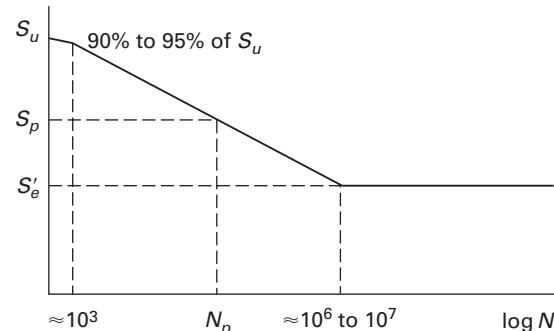

For an alternating stress test, the stress plotted on the *S-N* curve can be the maximum, minimum, or mean value. The choice depends on the method of testing as well as the intended application. The maximum stress should be used in rotating beam tests, since the mean stress is zero. For cyclic, one-dimensional bending, the maximum and mean stresses are commonly used.

<sup>8</sup>In the design of ductile steel buildings, the static case is assumed up to 20,000 cycles. However, in critical applications (such as nuclear steam vessels, turbines, and so on) that experience temperature swings, fatigue failure can occur with a smaller number of cycles due to *cyclic strain*, not due to *cyclic stress*.

**Figure 43.17 Rotating Beam Test**

For a particular stress level, say  $S_p$  in Fig. 43.18, the number of cycles required to cause failure,  $N_p$ , is the *fatigue life*.  $S_p$  is the *fatigue strength* corresponding to  $N_p$ .

For steel in bending subjected to fewer than approximately  $10^3$  loadings, the fatigue strength starts at the ultimate strength and drops to 90–95% of the ultimate strength at  $10^3$  cycles.<sup>9</sup> (Although *low-cycle fatigue* theory has its own peculiarities, a part experiencing a small number of cycles can usually be designed or analyzed for static loading.) The curve is linear between  $10^3$  and  $10^6$  cycles if a logarithmic  $N$ -scale is used. Beyond  $10^6$  to  $10^7$  cycles, there is no further decrease in strength.

**Figure 43.18 Typical S-N Curve for Steel**

Therefore, below a certain stress level, called the *endurance limit* or *endurance strength*,  $S'_e$ , the material will withstand an almost infinite number of loadings without experiencing failure.<sup>10</sup> This is characteristic of steel and titanium. Therefore, if a dynamically loaded part is to have an infinite life, the stress must be kept below the endurance limit. Appendix 43.A presents endurance limits for common steel, aluminum, and magnesium alloys. The ratio  $S'_e/S_u$  is known as the *endurance ratio* or *fatigue ratio*. For carbon steel, the endurance ratio is approximately 0.4 for pearlitic, 0.60 for ferritic, and 0.25 for martensitic microstructures. For martensitic alloy steels, it is approximately 0.35.

<sup>9</sup>Steel in tension has a lower fatigue life at  $10^3$  cycles, approximately 72–75% of  $S_u$ .

<sup>10</sup>Most endurance tests use some form of sinusoidal loading. However, the fatigue and endurance strengths do not depend much on the shape of the loading curve. Only the maximum amplitude of the stress is relevant. Therefore, the endurance limit can be used with other types of loading (sawtooth, square wave, random, etc.).

**Table 43.6** Relationships Between Elastic Constants

elastic constants	in terms of				
	$E, \nu$	$E, G$	$B, \nu$	$B, G$	$E, B$
$E$	—	—	$3(1 - 2\nu)B$	$\frac{9BG}{3B + G}$	—
$\nu$	—	$\frac{E}{2G} - 1$	—	$\frac{3B - 2G}{2(3B + G)}$	$\frac{3B - E}{6B}$
$G$	$\frac{E}{2(1 + \nu)}$	—	$\frac{3(1 - 2\nu)B}{2(1 + \nu)}$	—	$\frac{3EB}{9B - E}$
$B$	$\frac{E}{3(1 - 2\nu)}$	$\frac{GE}{3(3G - E)}$	—	—	—

For steel whose microstructure is unknown, the endurance strength is given approximately by Eq. 43.26.<sup>11</sup>

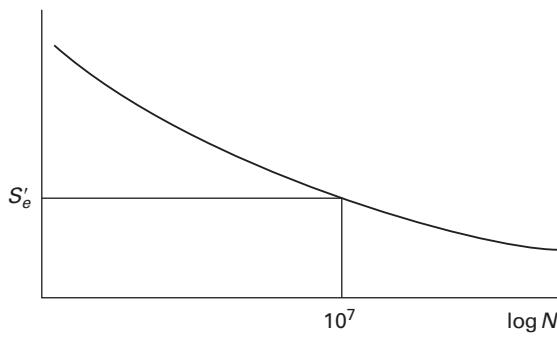

$$S'_{e,\text{steel}} = \begin{cases} 0.5S_u & [S_u < 200,000 \text{ lbf/in}^2] \\ & [S_u < 1.4 \text{ GPa}] \\ = 100,000 \text{ lbf/in}^2 & [S_u > 200,000 \text{ lbf/in}^2] \\ (700 \text{ MPa}) & [S_u > 1.4 \text{ GPa}] \end{cases} \quad 43.26$$

For cast iron, the endurance ratio is lower.

$$S'_{e,\text{cast iron}} = 0.4S_u \quad 43.27$$

Steel and titanium are the most important engineering materials that have well-defined endurance limits. Many nonferrous metals and alloys, such as aluminum, magnesium, and copper alloys, do not have well-defined endurance limits. (See Fig. 43.19.) The strength continues to decrease with cyclic loading and never levels off. In such cases, the endurance limit is taken as the stress that causes failure at  $10^7$  loadings (less typically, at  $5 \times 10^7$ ,  $10^8$ , or  $5 \times 10^8$  loadings). Alternatively, the endurance strength is approximated by Eq. 43.28.

$$S'_{e,\text{aluminum}} = \begin{cases} 0.3S_u & [\text{cast}] \\ 0.4S_u & [\text{wrought}] \end{cases} \quad 43.28$$

**Figure 43.19** Typical S-N Curve for Aluminum

The yield strength is an irrelevant factor in cyclic loading. Fatigue failures are fracture failures; they are not yielding failures. They start with microscopic cracks at the material surface. Some of the cracks are present initially; others form when repeated cold working reduces the ductility in strain-hardened areas. These cracks grow minutely with each loading. Since cracks start at the location of surface defects, the endurance limit is increased by proper treatment of the surface. Such treatments include polishing, surface hardening, shot peening, and filleting joints.

The endurance limit is not a true property of the material since the other significant influences, particularly surface finish, are never eliminated. However, representative values of  $S'_e$  obtained from ground and polished specimens provide a baseline to which other factors can be applied to account for the effects of surface finish, temperature, stress concentration, notch sensitivity, size, environment, and desired reliability. These other influences are accounted for by fatigue strength reduction (derating) factors,  $k_i$ , which are used to calculate a working endurance strength,  $S_e$ , for the material. (See Fig. 43.20.)

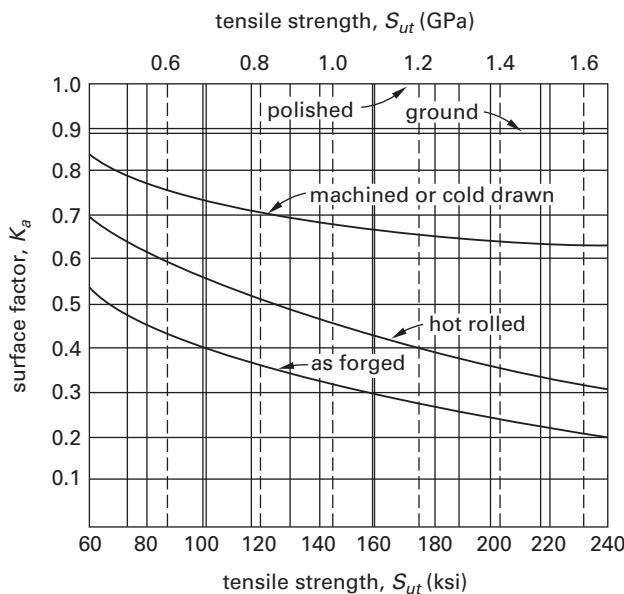

$$S_e = \prod k_i S'_e \quad 43.29$$

Since a rough surface significantly decreases the endurance strength of a specimen, it is not surprising that notches (and other features that produce stress concentration) do so as well. In some cases, the theoretical tensile stress concentration factor,  $K_t$ , due to notches and other features can be determined theoretically or experimentally. The ratio of the fatigue strength of a polished specimen to the fatigue strength of a notched specimen at the same number of cycles is known as the fatigue notch factor,  $K_f$ , also known as the fatigue stress concentration factor. The fatigue notch sensitivity,  $q$ , is a measure of the degree of agreement between the stress concentration factor and the fatigue notch factor.

$$q = \frac{K_f - 1}{K_t - 1} \quad [K_f > 1] \quad 43.30$$

<sup>11</sup>The coefficient in Eq. 43.26 actually varies between 0.25 and 0.6. However, 0.5 is commonly quoted.

## 18. TESTING OF PLASTICS

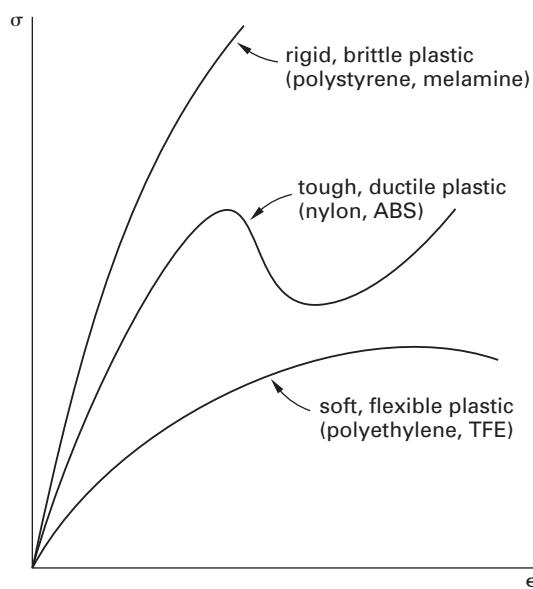

With reasonable variations, mechanical properties of plastics are evaluated using the same methods as for metals.<sup>12</sup> Although temperature is an important factor in the testing of plastics, tests for tensile strength, endurance, hardness, toughness, and creep rate are similar or the same as for metals. Figure 43.21 illustrates typical tensile test results.<sup>13</sup> Appendix 43.C presents mechanical properties of thermoplastic resins and composites.

Unlike metals, which follow Hooke's law, plastics are non-Hookean. (They may be Hookean for a short-duration loading.) The modulus of elasticity, for example, changes with stress level, temperature, time, and chemical environment. A plastic that appears to be satisfactory under one set of conditions can fail quickly under slightly different conditions. Therefore, properties of plastics determined from testing (and from tables) should be used only to compare similar materials, not to predict long-term behavior. Plastic tests are used to determine material specifications, not performance specifications.

<sup>12</sup>For example, plastic specimens for tensile testing can be produced by injection molding as well as by machining from compression-molded plaques, rather than by machining from bar stock.

<sup>13</sup>Plastics are sensitive to the rate of loading. Figure 43.21 illustrates tensile performance based on a 2 in/min loading rate. However, for a fast loading rate (such as 2 in/sec), most plastics would exhibit brittle performance. On the other hand, given a slow loading rate (such as 2 in/mo), most would behave as a soft and flexible plastic. Therefore, with different rates of loading, all three types of stress-strain performance shown in Fig. 43.21 can be obtained from the same plastic.

**Figure 43.21** Typical Tensile Test Performance for Plastics (loaded at 2 in/min)

On a short-term basis, plastics behave elastically. They distort when loaded and spring back when unloaded. Under prolonged loading, however, creep (cold flow) becomes significant. When loading is removed, there is some instantaneous recovery, some delayed recovery, and some permanent deformation. The recovery might be complete if the load is removed within 10 hours, but if the loading is longer (e.g., 100 hours), recovery may be only partial. Because of this behavior, plastics are subjected to various other tests.

Additional tests used to determine the mechanical properties of plastics include deflection temperature, long-term (e.g., 3000 hours) tensile creep, creep rupture, and *stress-relaxation* (long-duration, constant-strain tensile testing at elevated temperatures).<sup>14</sup> Because some plastics deteriorate when exposed to light, plasma, or chemicals, performance under these conditions can be evaluated, as can be the insulating and dielectric properties.

The *creep modulus* (also known as *apparent modulus*), determined from tensile creep testing, is the instantaneous ratio of stress to creep strain. The creep modulus decreases with time. The *deflection temperature* test indicates the dimensional stability of a plastic at high temperatures. A plastic bar is loaded laterally (as a beam) to a known stress level, and the temperature of the bar is gradually increased. The temperature at which the deflection reaches 0.010 in (0.254 mm) is taken as the *thermal deflection temperature* (TDT). The *Vicat softening point*, primarily used with polyethylenes, is the temperature at which a loaded standard needle penetrates 1 mm when the temperature is uniformly increased at a standard rate.

<sup>14</sup>Plastic pipes have their own special tests (e.g., ASTM D1598, D1785, and D2444).

## 19. NONDESTRUCTIVE TESTING

*Nondestructive testing* (NDT) or *nondestructive evaluation* (NDE) is used when it is impractical or uneconomical to perform destructive sampling on manufactured products and their parts. Typical applications of NDT are inspection of helicopter blades, cast aluminum wheels, and welds in nuclear pressure vessels. Some procedures are particularly useful in providing quality monitoring on a continuous, real-time basis. In addition to visual processes, the main types of nondestructive testing are magnetic particle, eddy current, liquid penetrant, ultrasonic imaging, acoustic emission, and infrared testing, as well as radiography.

The *visual-optical* process differs from normal visual inspection in the use of optical scanning systems, borescopes, magnifiers, and holographic equipment. Flaws are identified as changes in light intensity (reflected, transmitted, or refracted), color changes, polarization changes, or phase changes. This method is limited to the identification of surface flaws or interior flaws in transparent materials.

*Liquid penetrant testing* is based on a fluorescent dye being drawn by capillary action into surface defects. A developer substance is commonly used to aid in visual inspection. This method can be used with any nonporous material, including metals, plastics, and glazed ceramics. It is capable of finding cracks, porosities, pits, seams, and laps.

Liquid penetrant tests are simple, can be used with complex shapes, and can be performed on site. Workpieces must be clean and nonporous. However, only small surface defects are detectable.

*Magnetic particle testing* takes advantage of the attraction of ferromagnetic powders (e.g., the *Magnaflux*<sup>TM</sup> process) and fluorescent particles (e.g., the *Magnaglow*<sup>TM</sup> process) to leakage flux at surface flaws in magnetic materials. The particles accumulate and become visible at such flaws when an intense magnetic field is set up in a workpiece.

This method can locate most surface flaws (such as cracks, laps, and seams) and, in some special cases, subsurface flaws. The procedure is fast and simple to interpret. However, workpieces must be ferromagnetic and clean. Following the test, demagnetization may be required. A high-current power source is required.

*Eddy current testing* uses alternating current from a test coil to induce eddy currents in electrically conducting, metallic objects. Flaws and other material properties affect the current flow. The change in current is monitored by a detection circuit or on a meter or screen. This method can be used to locate defects of many types, including cracks, voids, inclusions, and weld defects, as well as to find changes in composition, structure, hardness, and porosity. Intimate contact between

the material and the test coil is not required. Operation can be continuous, automatic, and monitored electronically. Sensitivity is easily adjusted. Therefore, this method is ideal for unattended continuous processing. Many variables, however, can affect the current flow, and only electrically conducting materials can be tested with this method.

With *infrared testing*, infrared radiation emitted from objects can be detected and correlated with quality. Any discontinuities that interrupt heat flow, such as flaws, voids, and inclusions, can be detected.

Infrared testing requires access to only one side and is highly sensitive. It is applicable to complex shapes and assemblies of dissimilar components but is relatively slow. The detection can be performed electronically. Results are affected by variations in material size, coatings, and colors, and hot spots can be hidden by cool surface layers.

In *ultrasound imaging testing (ultrasonics)*, mechanical vibrations in the 0.1–50 MHz range are induced by pressing a piezoelectric transducer against a workpiece.<sup>15</sup> The transmitted waves are normally reflected back, but the waves are scattered by interior defects. The results are interpreted by reading a screen or meter. The method can be used for metals, plastics, glass, rubber, graphite, and concrete. It is excellent for detecting internal defects such as inclusions, cracks, porosities, laminations, and changes in material structure.

Ultrasound testing is extremely flexible. It can be automated and is very fast. Results can be recorded or interpreted electronically. Penetration through thick steel layers is possible. Direct contact (or immersion in a fluid) is required, but only one surface needs to be accessible. Rough surfaces and complex shapes may cause difficulties, however. A related method, *acoustic emission monitoring*, is used to test pressurized systems.

*Radiography* (i.e., *nuclear sensing*) uses neutron, X-ray, gamma-ray (e.g., Ce-137), and isotope (e.g., Co-60) sources. (When neutrons are used, the method is known as *neutron radiography* or *neutron gaging*.) The intensity of emitted radiation is changed when the rays pass through defects, and the intensity changes are monitored on a fluoroscope or recorded on film. This method can be used to detect internal defects, changes in material structure, thickness, and the absence of internal workpieces. It is also used to check liquid levels in filled containers.

Up to 30 in (0.75 m) of steel can be penetrated by X-ray sources. Gamma sources, which are more portable and lower in cost than X-ray sources, can be used with steel up to 10 in (0.25 m).

<sup>15</sup>Theoretically, any frequency can be used. However, as frequency goes up, the detail available increases, while the penetration decreases. Biomedical applications operate below 8 MHz, and industrial NDT uses 2–10 MHz waves.

Radiography requires access to both sides of the workpiece. Radiography involves some health risk, and there may be government standards associated with its use. Electrical power and cooling water may be required in large installations. Shielding and possibly film processing are also required, making this the most expensive form of nondestructive testing.

There are two types of *holographic NDT methods*. *Acoustic holography* is a form of ultrasonic testing that passes an ultrasonic beam through the workpiece (or through a medium such as water surrounding the workpiece) and measures the displacement of the workpiece (or medium). With suitable processing, a three-dimensional hologram is formed that can be visually inspected.

In one form of *optical holography*, a hologram of the unloaded workpiece is imposed on the actual workpiece. If the workpiece is then loaded (stressed), the observed changes (e.g., deflections) from the holographic image will be nonuniform when discontinuities and defects are present.

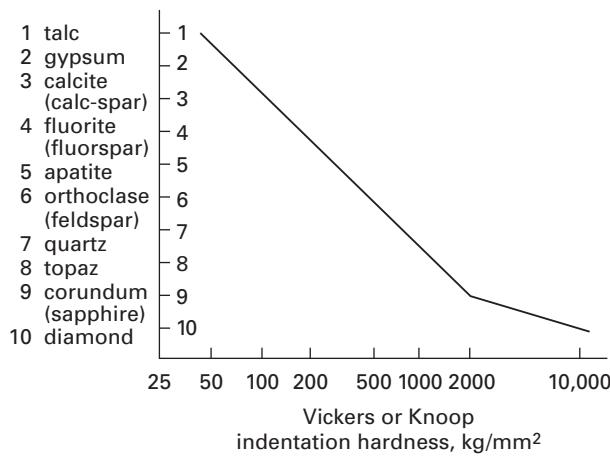

## 20. HARDNESS TESTING

Hardness tests measure the capacity of a surface to resist deformation. (See Table 43.7.) The main use of hardness testing is to verify heat treatments, an important factor in product service life. Through empirical correlations, it is also possible to predict the ultimate strength and toughness of some materials.

The *scratch hardness test*, also known as the *Mohs test*, compares the hardness of the material to that of minerals. Minerals of increasing hardness are used to scratch the sample. The resulting *Mohs scale* hardness can be used or correlated to other hardness scales, as shown in Fig. 43.22.

The *file hardness test* is a combination of the cutting and scratch tests. Files of known hardness are drawn

**Figure 43.22** Mohs Hardness Scale

across the sample. The file ceases to cut the material when the material and file hardnesses are the same.

The *Brinell hardness test* is used primarily with iron and steel castings, although it can be used with softer materials. (See Table 43.8.) The *Brinell hardness number*, BHN (or HB or H<sub>B</sub>), is determined by pressing a hardened steel ball into the surface of a specimen. The diameter of the resulting depression is correlated to the hardness. The standard ball is 10 mm in diameter and loads are 500 kg and 3000 kg for soft and hard materials, respectively.

The Brinell hardness number is the load per unit contact area. If a load,  $P$  (in kilograms), is applied through a steel ball of diameter,  $D$  (in millimeters), and produces a depression of diameter,  $d$  (in millimeters), and depth,  $t$  (in millimeters), the Brinell hardness number can be calculated from Eq. 43.31.

$$\begin{aligned} \text{BHN} &= \frac{P}{A_{\text{contact}}} = \frac{P}{\pi D t} \\ &= \frac{2P}{\pi D(D - \sqrt{D^2 - d^2})} \end{aligned} \quad 43.31$$

For heat-treated plain-carbon and medium-alloy steels, the ultimate tensile strength can be approximately calculated from the steel's Brinell hardness number.

$$S_{u,\text{MPa}} \approx 3.45(\text{BHN}) \quad [\text{SI}] \quad 43.32(a)$$

$$S_{u,\text{lbf/in}^2} \approx 500(\text{BHN}) \quad [\text{U.S.}] \quad 43.32(b)$$

The *Rockwell hardness test* is similar to the Brinell test. A steel ball or diamond spherconical penetrator (known as a *brale indenter*) is pressed into the material. The machine applies an initial load (60 kgf, 100 kgf, or 150 kgf) that sets the penetrator below surface imperfections.<sup>16</sup> Then, a significant load is applied. The Rockwell hardness,  $R$  (or HR or H<sub>R</sub>), is determined from the depth of penetration and is read directly from a dial.

Although a number of Rockwell scales (A through G) exist, the B and C scales are commonly used for steel. The *Rockwell B scale* is used with a steel ball for mild steel and high-strength aluminum. The *Rockwell C scale* is used with the brale indenter for hard steels having ultimate tensile strengths up to 300 ksi (2 GPa). The *Rockwell A scale* has a wide range and can be used with both soft materials (such as annealed brass) and hard materials (such as cemented carbides).

Other penetration hardness tests include the *Meyer*, *Vickers*, *Meyer-Vickers*, and *Knoop* tests, as described in Table 43.7.

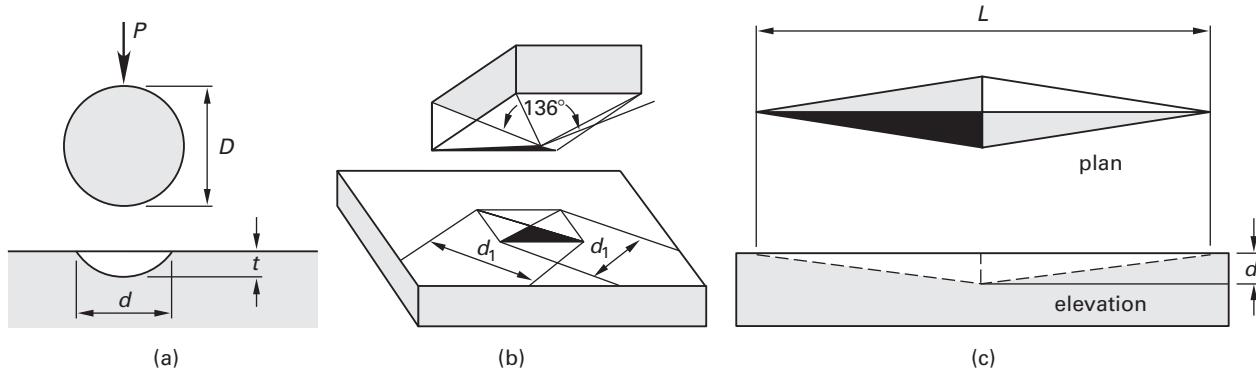

<sup>16</sup>Other Rockwell tests use 15 kgf, 30 kgf, and 45 kgf. The use of kgf units is traditional, and even modern test equipment is calibrated in kgf. Multiply kgf by 9.80665 to get newtons.

**Table 43.7** Hardness Penetration Tests

test	penetrator	diagram	measured dimension	hardness <sup>a</sup>
Brinell	sphere	(a)	diameter, $d$	$BHN = \frac{2P}{\pi D(D - \sqrt{D^2 - d^2})}$
Rockwell <sup>b</sup>	sphere or penetrator	(b)	depth, $t$	$R = C_1 - C_2$
Vickers	square pyramid	(b)	mean diagonal, $d_1$	$VHN = \frac{1.854P}{d_1^2}$
Meyer	sphere	(a)	diameter, $d$	$MHN = \frac{4P}{\pi d^2}$
Meyer-Vickers	square pyramid	(b)	mean diagonal, $d_1$	$M_V = \frac{2P}{d_1^2}$
Knoop	asymmetrical pyramid	(c)	long diagonal, $L$	$K = \frac{14.2P}{L^2}$

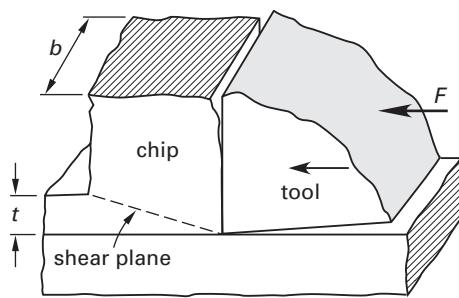

<sup>a</sup>All forces,  $P$ , in kgf. All length and depth measurements in mm.

<sup>b</sup> $C_1$  and  $C_2$  are constants that depend on the scale.

**Cutting hardness** is a measure of the force per unit area to cut a chip at low speed. (See Fig. 43.23.)

$$\text{cutting hardness} = \frac{F}{bt} \quad 43.33$$

**Figure 43.23** Cutting Hardness

All of the preceding hardness tests are *destructive tests* because they mar the material surface. However, *ultrasonic tests* and various *rebound tests* (e.g., the *Shore hardness test* and the *scleroscopic hardness test*) are *nondestructive tests*. In a rebound test, a standard object, usually a diamond-tipped hammer, is dropped

from a standard height onto the sample. The height of the rebound is measured and correlated to other hardness scales.

The various hardness tests do not measure identical properties of the material, so correlations between the various scales are not exact. For steel, the Brinell and Vickers hardness numbers are approximately the same below values of 320 Brinell. Also, the Brinell hardness is approximately ten times the Rockwell C hardness,  $R_C$ , for  $R_C > 20$ . Table 43.8 is an accepted correlation between several of the scales for steel. The table should not be used for other materials.

## 21. TOUGHNESS TESTING

During World War II, the United States experienced spectacular failures in approximately 25% of its Liberty ships and T-2 tankers. The mild steel plates of these ships were connected by welds that lost their ductility and became brittle in winter temperatures. Some of the ships actually broke into two sections. Such *brittle failures* are most likely to occur when three conditions are met: (a) triaxial stress, (b) low temperature, and (c) rapid loading.

**Toughness** is a measure of the material's ability to yield and absorb highly localized and rapidly applied stresses.

**Table 43.8** Correlations Between Hardness Scales for Steel

*Notch toughness* is evaluated by measuring the *impact energy* that causes a notched sample to fail.<sup>17</sup>

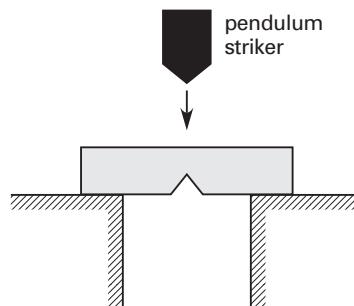

In the *Charpy test* (see Fig. 43.24), popular in the United States, a standardized beam specimen is given a 45° notch. The specimen is then centered on simple supports with the notch down. A falling pendulum striker hits the center of the specimen. This test is performed several times with different heights and different specimens until a sample fractures.

The kinetic energy expended at impact, equal to the initial potential energy less the rebound or follow-through height of the pendulum striker, is calculated from measured heights. It is designated  $C_V$  and is expressed in either foot-pounds (ft-lbf) or joules (J).<sup>18</sup> The energy required to cause failure is a measure of toughness.

At 70°F (21°C), the energy required to cause failure ranges from 45 ft-lbf (60 J) for carbon steels to approximately 110 ft-lbf (150 J) for chromium-manganese

<sup>17</sup>Without a notch, the specimen would experience uniaxial stress (tension and compression) at impact. The notch allows triaxial stresses to develop. Most materials become more brittle under triaxial stresses than under uniaxial stresses.

<sup>18</sup>The energy may also be expressed per unit cross section of specimen area.

**Figure 43.24** Charpy Test

steels. As temperature is reduced, however, the toughness decreases. In BCC metals, such as steel, at a low enough temperature the toughness decreases sharply. The transition from high-energy ductile failures to low-energy brittle failures begins at the *fracture transition plastic (FTP)* temperature.

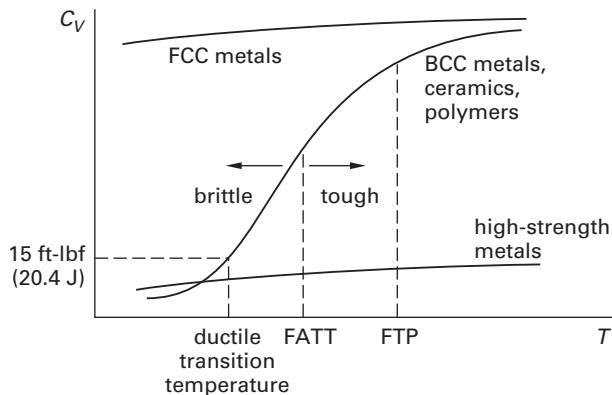

Since the transition occurs over a wide temperature range, the *transition temperature* (also known as the *ductile-brittle transition temperature*, DBTT) is taken as the temperature at which an impact of 15 ft-lbf (20.4 J) will cause failure. (15 ft-lbf is used for low-carbon ship steels. Other values may be used with other materials.) This occurs at approximately 30°F (-1°C) for low-carbon steel. Table 43.9 gives ductile transition temperatures for some forms of steel.

**Table 43.9** Approximate Ductile Transition Temperatures

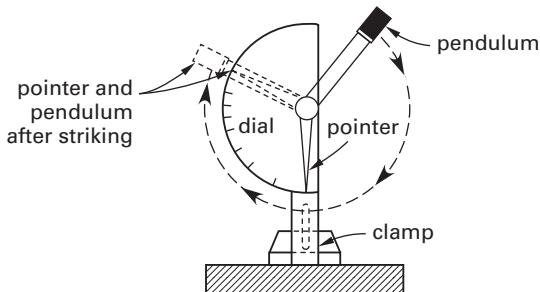

type of steel	ductile transition temperature (°F (°C))
carbon steel	30° (-1°)
high-strength, low-alloy steel	0° to 30° (-16° to -1°)
heat-treated, high-strength, carbon steel	-25° (-32°)
heat-treated, construction alloy steel	-40° to -80° (-40° to -62°)

The appearance of the fractured surface is also used to evaluate the transition temperature. The fracture can be fibrous (from shear fracture) or granular (from cleavage fracture), or a mixture of both. The fracture planes are studied and the percentages of ductile failure plotted against temperature. The temperature at which the failure is 50% fibrous and 50% granular is known as the *fracture appearance transition temperature*, FATT.

Not all materials have a ductile-brittle transition. Aluminum, copper, other FCC metals, and most HCP metals do not lose their toughness abruptly. Figure 43.25 illustrates the failure energy curves for several different types of materials.

**Figure 43.25** Failure Energy versus Temperature

Another toughness test is the *Izod test*. This is illustrated in Fig. 43.26 and is similar to the Charpy test in its use of a notched specimen. The height to which a swinging pendulum follows through after causing the specimen to fail determines the energy of failure.

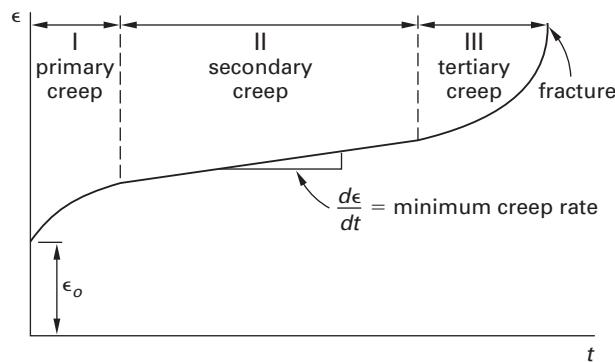

**Figure 43.26** Izod Test

## 22. CREEP TEST

*Creep* or *creep strain* is the continuous yielding of a material under constant stress. For metals, creep is negligible at low temperatures (i.e., less than half of the absolute melting temperature), although the usefulness of nonreinforced plastics as structural materials is seriously limited by creep at room temperature.

During a *creep test*, a low tensile load of constant magnitude is applied to a specimen, and the strain is measured as a function of time. The *creep strength* is the stress that results in a specific creep rate, usually 0.001% or 0.0001% per hour. The *rupture strength*, determined from a *stress-rupture test*, is the stress that results in a failure after a given amount of time, usually 100, 1000, or 10,000 hours.

If strain is plotted as a function of time, three different curvatures will be apparent following the initial elastic extension.<sup>19</sup> (See Fig. 43.27.) During the first stage, the

**Figure 43.27** Stages of Creep

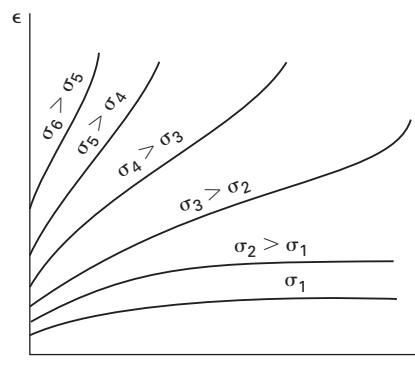

creep rate ( $d\epsilon/dt$ ) decreases since strain hardening (dislocation generation and interaction with grain boundaries and other barriers) is occurring at a greater rate than annealing (annihilation of dislocations, climb, cross-slip, and some recrystallization). This is known as *primary creep*.

During the second stage, the creep rate is constant, with strain hardening and annealing occurring at the same rate. This is known as *secondary creep* or *cold flow*. During the third stage, the specimen begins to neck down, and rupture eventually occurs. This region is known as *tertiary creep*.

The secondary creep rate is lower than the primary and tertiary creep rates. The secondary creep rate, represented by the slope (on a log-log scale) of the line during the second stage, is temperature and stress dependent. This slope increases at higher temperatures and stresses. The creep rate curve can be represented by the following empirical equation, known as *Andrade's equation*.

$$\epsilon = \epsilon_0(1 + \beta t^{1/3}) e^{kt} \quad 43.34$$

Dislocation climb (glide and creep) is the primary creep mechanism, although diffusion creep and grain boundary sliding also contribute to creep on a microscopic level. On a larger scale, the mechanisms of creep involve slip, subgrain formation, and grain-boundary sliding. (See Fig. 43.28.)

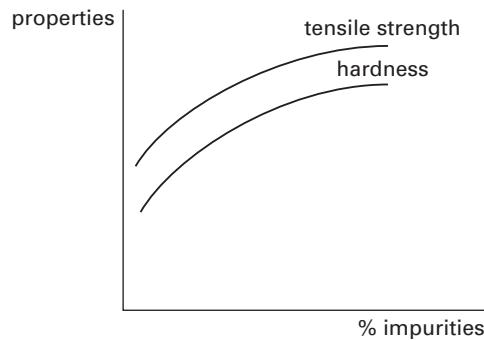

**Figure 43.28** Effect of Stress on Creep Rates

<sup>19</sup>In Great Britain, the initial elastic elongation,  $\epsilon_0$ , is considered the first stage. Therefore, creep has four stages in British nomenclature.

### 23. EFFECTS OF IMPURITIES AND STRAIN ON MECHANICAL PROPERTIES

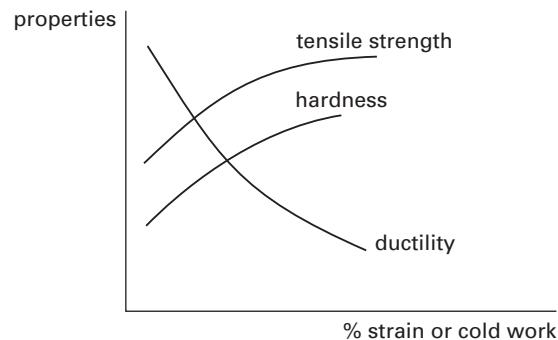

Anything that restricts the movement of dislocations will increase the strength of metals and reduce ductility. Alloying materials, impurity atoms, imperfections, and other dislocations produce stronger materials. This is illustrated in Fig. 43.29.

**Figure 43.29** Effect of Impurities on Mechanical Properties

Additional dislocations are generated by the plastic deformation (i.e., cold working) of metals, and these dislocations can strain-harden the metal. Figure 43.30 shows the effect of strain-hardening on mechanical properties.

## 1. BASIC CONCEPTS

*Strength of materials* (known also as *mechanics of materials*) deals with the elastic behavior of loaded engineering materials.<sup>1</sup>

Stress is force per unit area,  $F/A$ . Typical units of stress are lbf/in<sup>2</sup>, ksi (thousands of pounds per square inch), and MPa. Although there are many names given to stress, there are only two primary types, differing in the orientation of the loaded area. With *normal stress*,  $\sigma$ , the area is normal to the force carried. With *shear stress*,  $\tau$ , the area is parallel to the force. (See Fig. 44.1.)

Figure 44.1 Normal and Shear Stress

*Strain*,  $\epsilon$ , is elongation expressed on a fractional or percentage basis. It may be listed as having units of in/in, mm/mm, percent, or no units at all. A strain in one direction will be accompanied by strains in orthogonal directions in accordance with Poisson's ratio. *Dilation* is the sum of the strains in the three coordinate directions.

$$\text{dilation} = \epsilon_x + \epsilon_y + \epsilon_z \quad 44.1$$

## 2. HOOKE'S LAW

*Hooke's law* is a simple mathematical statement of the relationship between elastic stress and strain: Stress is proportional to strain. (See Fig. 44.2.) For normal

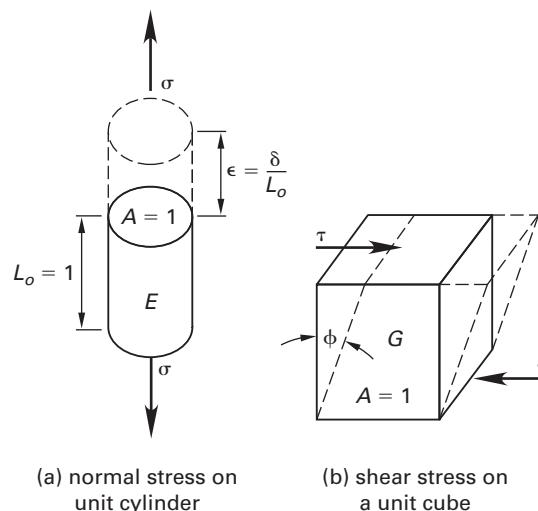

stress, the constant of proportionality is the *modulus of elasticity* (*Young's modulus*),  $E$ .

$$\sigma = E\epsilon \quad 44.2$$

For shear stress, the constant of proportionality is the *shear modulus*,  $G$ .

$$\tau = G\phi \quad 44.3$$

Figure 44.2 Application of Hooke's Law

## 3. ELASTIC DEFORMATION

Since stress is  $F/A$  and strain is  $\delta/L_o$ , Hooke's law can be rearranged in form to give the elongation of an axially loaded member with a uniform cross section experiencing normal stress. Tension loading is considered positive; compressive loading is negative.

$$\delta = L_o\epsilon = \frac{\delta}{L_o} = \frac{L_oF}{EA} \quad 44.4$$

The actual length of a member under loading is given by Eq. 44.5. The algebraic sign of the deformation must be observed.

$$L = L_o + \delta \quad 44.5$$

## 4. TOTAL STRAIN ENERGY

The energy stored in a loaded member is equal to the work required to deform the member. Below the proportionality limit, the total *strain energy* for a member loaded in tension or compression is given by Eq. 44.6.

$$U = \frac{1}{2}F\delta = \frac{F^2L_o}{2AE} = \frac{\sigma^2L_oA}{2E} \quad 44.6$$

<sup>1</sup>Plastic behavior and ultimate strength design are not covered in this chapter.

## 5. STIFFNESS AND RIGIDITY

*Stiffness* is the amount of force required to cause a unit of deformation (displacement) and is often referred to as a *spring constant*. Typical units are pounds per inch and newtons per meter. The stiffness of a spring or other structure can be calculated from the deformation equation by solving for  $F/\delta$ . Equation 44.7 is valid for tensile and compressive normal stresses. For torsion and bending, the stiffness equation will depend on how the deflection is calculated.

$$k = \frac{F}{\delta} \quad [\text{general form}] \quad 44.7(a)$$

$$k = \frac{AE}{L_o} \quad [\text{normal stress form}] \quad 44.7(b)$$

When more than one spring or resisting member share the load, the relative stiffnesses are known as *rigidities*. Rigidities have no units, and the individual rigidity values have no significance. (See Fig. 44.3.) A ratio of two rigidities, however, indicates how much stiffer one member is compared to another. Equation 44.8 is one method of calculating rigidity of member  $j$  in a multi-member structure. (Since rigidities are relative numbers, they can be multiplied by the least common denominator to obtain integer values.)

$$R_j = \frac{k_j}{\sum_i k_i} \quad 44.8$$

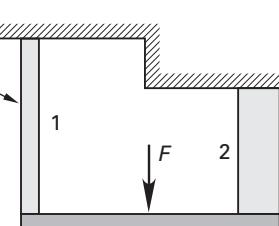

Figure 44.3 Stiffness and Rigidity

$$k_1 = \frac{A_1 E_1}{L_1} = 25 \times 10^3 \text{ lbf/in}$$

$$k_2 = \frac{A_2 E_2}{L_2} = 75 \times 10^3 \text{ lbf/in}$$

$$R_1 = 1.0$$

$$R_2 = 3.0$$

*Rigidity* is proportional to the reciprocal of deflection. (See Table 44.1.) *Flexural rigidity* is the reciprocal of deflection in members that are acted upon by a moment (i.e., are in bending), although that term may also be used to refer to the product,  $EI$ , of the modulus of elasticity and the moment of inertia.

Table 44.1 Deflection and Stiffness for Various Systems  
(due to bending moment alone)

	$\frac{wL^4}{384EI}$	$\frac{384EI}{L^3}$

## 6. THERMAL DEFORMATION

If the temperature of an object is changed, the object will experience length, area, and volume changes. The magnitude of these changes will depend on the

coefficient of linear expansion,  $\alpha$ , which is widely tabulated for solids. (See Table 44.2.) The coefficient of volumetric expansion,  $\beta$ , can be calculated from the coefficient of linear expansion.

$$\Delta L = \alpha L_o (T_2 - T_1) \quad 44.9$$

$$\Delta A = \gamma A_o (T_2 - T_1) \quad 44.10$$

$$\gamma \approx 2\alpha \quad 44.11$$

$$\Delta V = \beta V_o (T_2 - T_1) \quad 44.12$$

$$\beta \approx 3\alpha \quad 44.13$$

**Table 44.2** Average Coefficients of Linear Thermal Expansion  
(multiply all values by  $10^{-6}$ )

substance	1/°F	1/°C
aluminum alloy	12.8	23.0
brass	10.0	18.0
cast iron	5.6	10.1
chromium	3.8	6.8
concrete	6.7	12.0
copper	8.9	16.0
glass (plate)	4.9	8.9
glass (Pyrex™)	1.8	3.2
invar	0.39	0.7
lead	15.6	28.0
magnesium alloy	14.5	26.1
marble	6.5	11.7
platinum	5.0	9.0
quartz, fused	0.2	0.4
steel	6.5	11.7
tin	14.9	26.9
titanium alloy	4.9	8.8
tungsten	2.4	4.4
zinc	14.6	26.3

(Multiply 1/°F by 9/5 to obtain 1/°C.)

(Multiply 1/°C by 5/9 to obtain 1/°F.)

It is a common misconception that a hole in a plate will decrease in size when the plate is heated (because the surrounding material “squeezes in” on the hole). However, changes in temperature affect all dimensions the same way. In this case, the circumference of the hole is a linear dimension that follows Eq. 44.9. As the circumference increases, the hole area also increases. (See Fig. 44.4.)

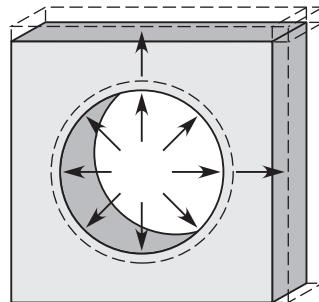

If Eq. 44.9 is rearranged, an expression for the *thermal strain* is obtained.

$$\epsilon_{th} = \frac{\Delta L}{L_o} = \alpha(T_2 - T_1) \quad 44.14$$

Thermal strain is handled in the same manner as strain due to an applied load. For example, if a bar is heated but is not allowed to expand, the stress can be calculated from the thermal strain and Hooke’s law.

$$\sigma_{th} = E\epsilon_{th} \quad 44.15$$

**Figure 44.4** Thermal Expansion of an Area

Low values of the coefficient of expansion, such as with Pyrex™ glassware, result in low thermally induced stresses and high insensitivity to temperature extremes. Differences in the coefficients of expansion of two materials are used in *bimetallic elements*, such as thermostatic springs and strips.

### Example 44.1

A replacement steel railroad rail ( $L = 20.0$  m,  $A = 60 \times 10^{-4}$  m $^2$ ) was installed when its temperature was 5°C. The rail was installed tightly in the line, without an allowance for expansion. If the rail ends are constrained by adjacent rails and if the spikes prevent buckling, what is the compressive force in the rail at 25°C?

#### Solution

From Table 44.2, the coefficient of linear expansion for steel is  $11.7 \times 10^{-6}$  1/°C. From Eq. 44.14, the thermal strain is

$$\begin{aligned}\epsilon_{th} &= \alpha(T_2 - T_1) = \left(11.7 \times 10^{-6} \frac{1}{^{\circ}\text{C}}\right)(25^{\circ}\text{C} - 5^{\circ}\text{C}) \\ &= 2.34 \times 10^{-4} \text{ m/m}\end{aligned}$$

The modulus of elasticity of steel is  $20 \times 10^{10}$  N/m $^2$  ( $20 \times 10^4$  MPa). The compressive stress is given by Hooke’s law. Use Eq. 44.15.

$$\begin{aligned}\sigma_{th} &= E\epsilon_{th} = \left(20 \times 10^{10} \frac{\text{N}}{\text{m}^2}\right)\left(2.34 \times 10^{-4} \frac{\text{m}}{\text{m}}\right) \\ &= 4.68 \times 10^7 \text{ N/m}^2\end{aligned}$$

The compressive force is

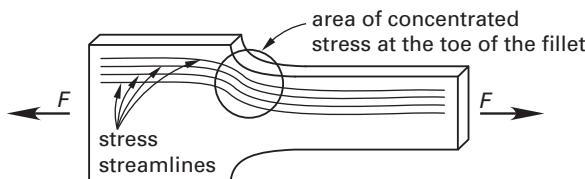

$$\begin{aligned}F &= \sigma_{th}A = \left(4.68 \times 10^7 \frac{\text{N}}{\text{m}^2}\right)(60 \times 10^{-4} \text{ m}^2) \\ &= 281\,000 \text{ N}\end{aligned}$$

## 7. STRESS CONCENTRATIONS

A *geometric stress concentration* occurs whenever there is a discontinuity or nonuniformity in an object. Examples of nonuniform shapes are stepped shafts, plates with holes and notches, and shafts with keyways. It is

convenient to think of stress as lines of force following streamlines within an object. (See Fig. 44.5.) There will be a stress concentration wherever local geometry forces the streamlines closer together.

**Figure 44.5** Streamline Analogy to Stress Concentrations

Stress values determined by simplistic  $F/A$ ,  $Mc/I$ , or  $Tr/J$  calculations will be greatly understated. *Stress concentration factors (stress risers)* are correction factors used to account for the nonuniform stress distributions. The symbol  $K$  is often used, but this is not universal. The actual stress is determined as the product of the stress concentration factor,  $K$ , and the *nominal stress*,  $\sigma_0$ . Values of the stress concentration factor are almost always greater than 1.0 and can run as high as 3.0 and above. (See App. 44.B.) The exact value for a given application must be determined from extensive experimentation or from published tabulations of standard configurations.

$$\sigma' = K\sigma_0 \quad 44.16$$

Stress concentration factors are normally not applied to members with multiple redundancy, for static loading of ductile materials, or where local yielding around the discontinuity reduces the stress. For example, there will be many locations of stress concentration in a lap rivet connection. However, the stresses are kept low by design, and stress concentrations are disregarded.

Stress concentration factors are not applicable to every point on an object; they apply only to the point of maximum stress. For example, with filleted shafts, the maximum stress occurs at the toe of the fillet. Therefore, the stress concentration factor should be applied to the stress calculated from the smaller section's properties. For objects with holes or notches, it is important to know if the nominal stress to which the factor is applied is calculated from an area that includes or excludes the holes or notches.

In addition to geometric stress concentrations, there are also *fatigue stress concentrations*. The *fatigue stress concentration factor* is the ratio of the fatigue strength without a stress concentration to the fatigue stress with a stress concentration. Fatigue stress concentration factors depend on the material, material strength, and geometry of the stress concentration (i.e., radius of the notch). Fatigue stress concentration factors can be less than the geometric factors from which they are computed.

## 8. COMBINED STRESSES (BIAXIAL LOADING)

Loading is rarely confined to a single direction. Many practical cases have different normal and shear stresses on two or more perpendicular planes. Sometimes, one of the stresses may be small enough to be disregarded, reducing the analysis to one dimension. In other cases, however, the shear and normal stresses must be combined to determine the maximum stresses acting on the material.

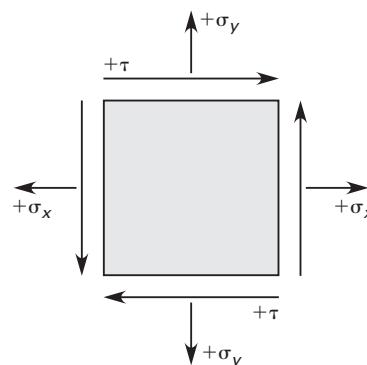

For any point in a loaded specimen, a plane can be found where the shear stress is zero. The normal stresses associated with this plane are known as the *principal stresses*, which are the maximum and minimum stresses acting at that point in any direction.

For two-dimensional (biaxial) loading (i.e., two normal stresses combined with a shearing stress), the normal and shear stresses on a plane whose normal line is inclined an angle  $\theta$  from the horizontal can be found from Eq. 44.17 and Eq. 44.18. Proper sign convention must be adhered to when using the combined stress equations. The positive senses of shear and normal stresses are shown in Fig. 44.6. As is usually the case, tensile normal stresses are positive; compressive normal stresses are negative. In two dimensions, shear stresses are designated as clockwise (positive) or counterclockwise (negative).<sup>2</sup>

$$\sigma_\theta = \frac{1}{2}(\sigma_x + \sigma_y) + \frac{1}{2}(\sigma_x - \sigma_y) \cos 2\theta + \tau \sin 2\theta \quad 44.17$$

$$\tau_\theta = -\frac{1}{2}(\sigma_x - \sigma_y) \sin 2\theta + \tau \cos 2\theta \quad 44.18$$

**Figure 44.6** Sign Convention for Combined Stress

At first glance, the orientation of the shear stresses may seem confusing. However, the arrangement of stresses shown produces equilibrium in the  $x$ - and  $y$ -directions without causing rotation. Other than a mirror image or a trivial rotation of the arrangement shown in Fig. 44.6,

<sup>2</sup>Some sources refer to the shear stress as  $\tau_{xy}$ ; others use the symbol  $\tau_z$ . When working in two dimensions only, the subscripts  $xy$  and  $z$  are unnecessary and confusing conventions.

no other arrangement of shear stresses will produce equilibrium.

The maximum and minimum values (as  $\theta$  is varied) of the normal stress,  $\sigma_\theta$ , are the *principal stresses*, which can be found by differentiating Eq. 44.17 with respect to  $\theta$ , setting the derivative equal to zero, and substituting  $\theta$  back into Eq. 44.17. Equation 44.19 is derived in this manner. A similar procedure is used to derive the *extreme shear stresses* (i.e., maximum and minimum shear stresses) in Eq. 44.20 from Eq. 44.18. (The term *principal stress* implies a normal stress, never a shear stress.)

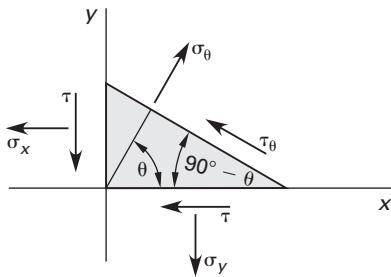

$$\sigma_1, \sigma_2 = \frac{1}{2}(\sigma_x + \sigma_y) \pm \tau_1 \quad 44.19$$

$$\tau_1, \tau_2 = \pm \frac{1}{2}\sqrt{(\sigma_x - \sigma_y)^2 + (2\tau)^2} \quad 44.20$$

The angles of the planes on which the normal stresses are minimum and maximum are given by Eq. 44.21. (See Fig. 44.7.)  $\theta$  is measured from the  $x$ -axis, clockwise if negative and counterclockwise if positive. Equation 44.21 will yield two angles,  $90^\circ$  apart. These angles can be substituted back into Eq. 44.17 and Eq. 44.18 to determine which angle corresponds to the minimum normal stress and which angle corresponds to the maximum normal stress.<sup>3</sup>

$$\theta_{\sigma_1, \sigma_2} = \frac{1}{2}\arctan\left(\frac{2\tau}{\sigma_x - \sigma_y}\right) \quad 44.21$$

**Figure 44.7** Stresses on an Inclined Plane

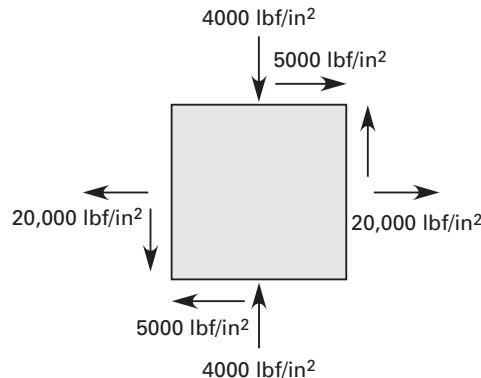

The angles of the planes on which the shear stresses are minimum and maximum are given by Eq. 44.22. These planes will be  $90^\circ$  apart and will be rotated  $45^\circ$  from the planes of principal normal stresses. As with Eq. 44.21,  $\theta$  is measured from the  $x$ -axis, clockwise if negative and counterclockwise if positive. Generally, the sign of a shear stress on an inclined plane will be unimportant.

$$\theta_{\tau_1, \tau_2} = \frac{1}{2}\arctan\left(\frac{\sigma_x - \sigma_y}{-2\tau}\right) \quad 44.22$$

<sup>3</sup>Alternatively, the following procedure can be used to determine the direction of the principal planes. Let  $\sigma_x$  be the algebraically larger of the two given normal stresses. The angle between the direction of  $\sigma_x$  and the direction of  $\sigma_1$ , the algebraically larger principal stress, will always be less than  $45^\circ$ .

### Example 44.2

- (a) Find the maximum normal and shear stresses on the object shown. (b) Determine the angle of the plane of principal normal stresses.

### Solution

- (a) Find the principal shear stresses first. The applied  $4000 \text{ lbf/in}^2$  compressive stress is negative. Equation 44.20 can be used directly.

$$\begin{aligned} \tau_1 &= \frac{1}{2}\sqrt{(\sigma_x - \sigma_y)^2 + (2\tau)^2} \\ &= \frac{1}{2}\sqrt{\left(20,000 \frac{\text{lbf}}{\text{in}^2} - \left(-4000 \frac{\text{lbf}}{\text{in}^2}\right)\right)^2 \\ &\quad + \left((2)\left(5000 \frac{\text{lbf}}{\text{in}^2}\right)\right)^2} \\ &= 13,000 \text{ lbf/in}^2 \end{aligned}$$

From Eq. 44.19, the maximum normal stress is

$$\begin{aligned} \sigma_1 &= \frac{1}{2}(\sigma_x + \sigma_y) + \tau_1 \\ &= \left(\frac{1}{2}\right)\left(20,000 \frac{\text{lbf}}{\text{in}^2} + \left(-4000 \frac{\text{lbf}}{\text{in}^2}\right)\right) + 13,000 \frac{\text{lbf}}{\text{in}^2} \\ &= 21,000 \text{ lbf/in}^2 \quad [\text{tension}] \end{aligned}$$

- (b) The angle of the principal normal stresses is given by Eq. 44.21.

$$\begin{aligned} \theta &= \frac{1}{2}\arctan\left(\frac{2\tau}{\sigma_x - \sigma_y}\right) \\ &= \frac{1}{2}\arctan\left(\frac{(2)\left(5000 \frac{\text{lbf}}{\text{in}^2}\right)}{20,000 \frac{\text{lbf}}{\text{in}^2} - \left(-4000 \frac{\text{lbf}}{\text{in}^2}\right)}\right) \\ &= \left(\frac{1}{2}\right)(22.6^\circ, 202.6^\circ) \\ &= 11.3^\circ, 101.3^\circ \end{aligned}$$

It is not obvious which angle produces which normal stress. One of the angles can be substituted back into Eq. 44.17 for  $\sigma_\theta$ .

$$\begin{aligned}\sigma_{11.3^\circ} &= \frac{1}{2}(\sigma_x + \sigma_y) + \frac{1}{2}(\sigma_x - \sigma_y)\cos 2\theta + \tau \sin 2\theta \\ &= \left(\frac{1}{2}\right) \left(20,000 \frac{\text{lbf}}{\text{in}^2} + \left(-4000 \frac{\text{lbf}}{\text{in}^2}\right)\right) \\ &\quad + \left(\frac{1}{2}\right) \left(20,000 \frac{\text{lbf}}{\text{in}^2} - \left(-4000 \frac{\text{lbf}}{\text{in}^2}\right)\right) \\ &\quad \times \cos((2)(11.3^\circ)) \\ &\quad + \left(5000 \frac{\text{lbf}}{\text{in}^2}\right) \sin((2)(11.3^\circ)) \\ &= 21,000 \frac{\text{lbf}}{\text{in}^2}\end{aligned}$$

The  $11.3^\circ$  angle corresponds to the maximum normal stress of  $21,000 \text{ lbf/in}^2$ .

## 9. MOHR'S CIRCLE FOR STRESS

Mohr's circle can be constructed to graphically determine the principal stresses. (See Fig. 44.8.)

*step 1:* Determine the applied stresses:  $\sigma_x$ ,  $\sigma_y$ , and  $\tau$ . (Tensile normal stresses are positive; compressive normal stresses are negative. Clockwise shear stresses are positive; counterclockwise shear stresses are negative.)

*step 2:* Draw a set of  $\sigma$ - $\tau$  axes.

*step 3:* Plot the center of the circle, point **c**, by calculating  $\sigma_c = \frac{1}{2}(\sigma_x + \sigma_y)$ .

*step 4:* Plot the point  $\mathbf{p}_1 = (\sigma_x, -\tau)$ . (Alternatively, plot  $\mathbf{p}'_1$  at  $(\sigma_y, +\tau)$ .)

*step 5:* Draw a line from point  $\mathbf{p}_1$  through center **c** and extend it an equal distance beyond the  $\sigma$ -axis. This is the diameter of the circle.

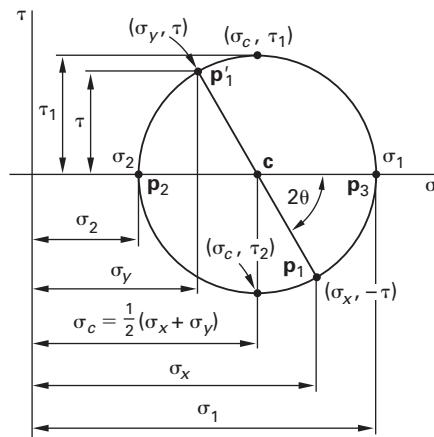

*step 6:* Using the center **c** and point  $\mathbf{p}_1$ , draw the circle. An alternative method is to draw a circle of radius  $r$  about point **c**.

$$r = \frac{1}{2}\sqrt{(\sigma_x - \sigma_y)^2 + (2\tau)^2} \quad 44.23$$

*step 7:* Point  $\mathbf{p}_2$  defines the smaller principal stress,  $\sigma_2$ . Point  $\mathbf{p}_3$  defines the larger principal stress,  $\sigma_1$ .

*step 8:* Determine the angle  $\theta$  as half of the angle  $2\theta$  on the circle. This angle corresponds to the larger principal stress,  $\sigma_1$ . On Mohr's circle, angle  $2\theta$  is measured counterclockwise from the  $\mathbf{p}_1$ - $\mathbf{p}'_1$  line to the horizontal axis.

Figure 44.8 Mohr's Circle for Stress

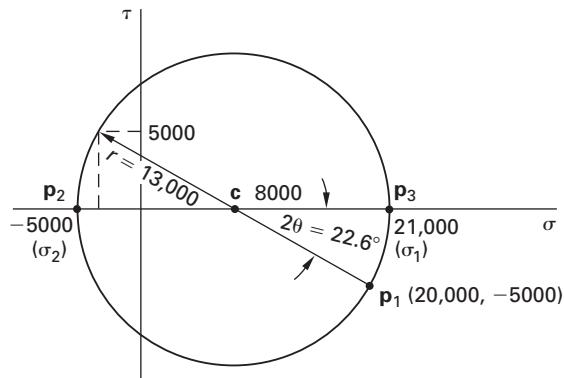

### Example 44.3

Construct Mohr's circle for Ex. 44.2.

*Solution*

$$\begin{aligned}\sigma_c &= \frac{1}{2}(\sigma_x + \sigma_y) \\ &= \left(\frac{1}{2}\right) \left(20,000 \frac{\text{lbf}}{\text{in}^2} + \left(-4000 \frac{\text{lbf}}{\text{in}^2}\right)\right) \\ &= 8000 \frac{\text{lbf}}{\text{in}^2}\end{aligned}$$

$$\begin{aligned}r &= \frac{1}{2}\sqrt{(\sigma_x - \sigma_y)^2 + (2\tau)^2} \\ &= \frac{1}{2}\sqrt{\left(20,000 \frac{\text{lbf}}{\text{in}^2} - \left(-4000 \frac{\text{lbf}}{\text{in}^2}\right)\right)^2 \\ &\quad + \left((2)\left(5000 \frac{\text{lbf}}{\text{in}^2}\right)\right)^2} \\ &= 13,000 \frac{\text{lbf}}{\text{in}^2}\end{aligned}$$

## 10. IMPACT LOADING

If a load is applied to a structure suddenly, the structure's response will be composed of two parts: a transient response (which decays to zero) and a steady-state response. (These two parts are also known as the *dynamic* and *static responses*, respectively.) It is not unusual for the transient loading to be larger than the steady-state response.

Although a *dynamic analysis* of the structure is preferred, the procedure is lengthy and complex. Therefore, arbitrary multiplicative factors may be applied to the steady-state stress to determine the maximum transient. For example, if a load is applied quickly as compared to the natural period of vibration of the structure (e.g., the classic definition of an *impact load*), a dynamic factor of 2.0 might be used. Actual dynamic factors should be determined or validated by testing.

The energy-conservation method (i.e., the work-energy principle) can be used to determine the maximum stress due to a falling mass. The total change in potential energy of the mass from the change in elevation and the deflection,  $\delta$ , is equated to the appropriate expression for total strain energy. (See Sec. 44.4.)

## 11. SHEAR AND MOMENT

*Shear* at a point is the sum of all vertical forces acting on an object. It has units of pounds, kips, tons, newtons, and so on. Shear is not the same as shear stress, since the area of the object is not considered.

A typical application is shear at a point on a beam,  $V$ , defined as the sum of all vertical forces between the point and one of the ends.<sup>4</sup> The direction (i.e., to the left or right of the point) in which the summation proceeds is not important. Since the values of shear will differ only in sign for summations to the left and right ends, the direction that results in the fewest calculations should be selected.

$$V = \sum_{\text{point to one end}} F_i \quad 44.24$$

Shear is taken as positive when there is a net upward force to the left of a point and negative when there is a net downward force between the point and the left end.

*Moment* at a point is the total bending moment acting on an object. In the case of a beam, the moment,  $M$ , will be the algebraic sum of all moments and couples located between the investigation point and one of the beam ends. As with shear, the number of calculations required

<sup>4</sup>The conditions of equilibrium require that the sum of all vertical forces on a beam be zero. However, the *shear* can be nonzero because only a portion of the beam is included in the analysis. Since that portion extends to the beam end in one direction only, the shear is sometimes called *resisting shear* or *one-way shear*.

to calculate the moment can be minimized by careful choice of the beam end.<sup>5</sup>

$$M = \sum_{\text{point to one end}} F_i d_i + \sum_{\text{point to one end}} C_i \quad 44.25$$

Moment is taken as positive when the upper surface of the beam is in compression and the lower surface is in tension. Since the beam ends will usually be higher than the midpoint, it is commonly said that "a positive moment will make the beam smile."

## 12. SHEAR AND BENDING MOMENT DIAGRAMS

The value of the shear and moment,  $V$  and  $M$ , will depend on the location along the beam. Both shear and moment can be described mathematically for simple loadings, but the formulas are likely to become discontinuous as the loadings become more complex. It is much more convenient to describe the shear and moment functions graphically. Graphs of shear and moment as functions of position along the beam are known as *shear* and *moment diagrams*. Drawing these diagrams does not require knowing the shape or area of the beam.

The following guidelines and conventions should be observed when constructing a *shear diagram*.

- The shear at any point is equal to the sum of the loads and reactions from the point to the left end.
- The magnitude of the shear at any point is equal to the slope of the moment line at that point.

$$V = \frac{dM}{dx} \quad 44.26$$

- Loads and reactions acting upward are positive.
- The shear diagram is straight and sloping over uniformly distributed loads.
- The shear diagram is straight and horizontal between concentrated loads.
- The shear is a vertical line and is undefined at points of concentrated loads.

The following guidelines and conventions should be observed when constructing a *bending moment diagram*.

<sup>5</sup>The conditions of equilibrium require that the sum of all moments on a beam be zero. However, the *moment* can be nonzero because only a portion of the beam is included in the analysis. Since that portion extends to the beam end in one direction only, the moment is sometimes called *bending moment*, *flexural moment*, *resisting moment*, or *one-way moment*.

By convention, the moment diagram is drawn on the compression side of the beam.

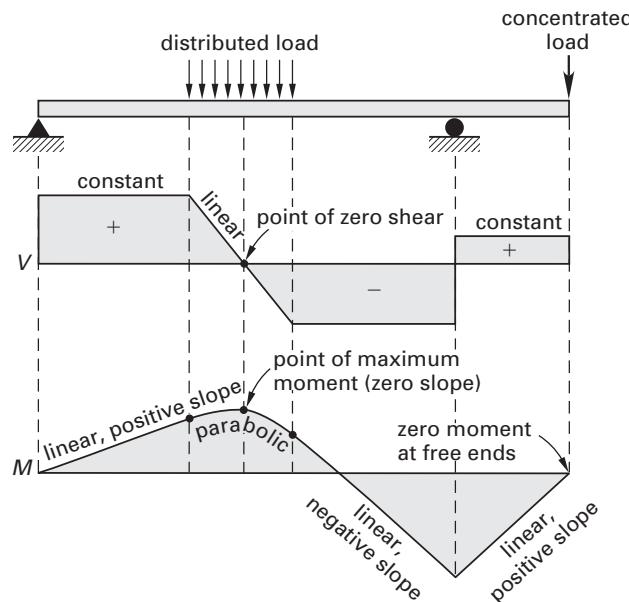

- The moment at any point is equal to the sum of the moments and couples from the point to the left end.<sup>6</sup>
- Clockwise moments about the point are positive.
- The magnitude of the moment at any point is equal to the area under the shear line up to that point. This is equivalent to the integral of the shear function.

$$M = \int V dx \quad 44.27$$

- The *maximum moment* occurs where the shear is zero.
- The moment diagram is straight and sloping between concentrated loads.
- The moment diagram is curved (parabolic upward) over uniformly distributed loads.

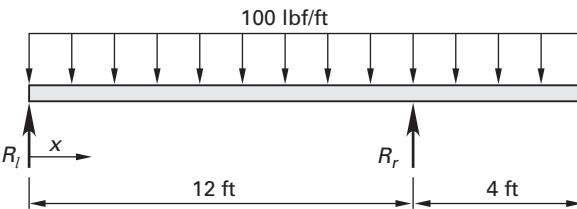

These principles are illustrated in Fig. 44.9.

**Figure 44.9** Drawing Shear and Moment Diagrams

#### Example 44.4

Draw the shear and bending moment diagrams for the following beam.

#### Solution

First, determine the reactions. Take moments about the left end. The uniform load of  $100x$  can be assumed to be concentrated at  $L/2$ .

$$R_r = \frac{\frac{1}{2}wL^2}{x} = \frac{\left(\frac{1}{2}\right)(16 \text{ ft})(16 \text{ ft})\left(100 \frac{\text{lbf}}{\text{ft}}\right)}{12 \text{ ft}} = 1066.7 \text{ lbf}$$

$$R_l = (16 \text{ ft})\left(100 \frac{\text{lbf}}{\text{ft}}\right) - R_r = 533.3 \text{ lbf}$$

The shear diagram starts at +533.3 at the left reaction but decreases linearly at the rate of 100 lbf/ft between the two reactions. Measuring  $x$  from the left end, the shear line goes through zero at

$$x = \frac{533.3 \text{ lbf}}{100 \frac{\text{lbf}}{\text{ft}}} = 5.333 \text{ ft}$$

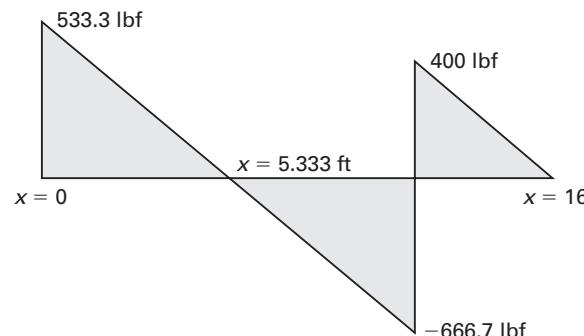

The shear just to the left of the right reaction is

$$533.3 \text{ lbf} - (12 \text{ ft})\left(100 \frac{\text{lbf}}{\text{ft}}\right) = -666.7 \text{ lbf}$$

The shear just to the right of the right reaction is

$$-666.7 \text{ lbf} + R_r = +400 \text{ lbf}$$

To the right of the right reaction, the shear diagram decreases to zero at the same constant rate: 100 lbf/ft. This is sufficient information to draw the shear diagram.

The bending moment at a distance  $x$  to the right of the left end has two parts. The left reaction of 533.3 lbf acts with moment arm  $x$ . The moment between the two reactions is

$$M_x = 533.3x - 100x\left(\frac{x}{2}\right)$$

<sup>6</sup>If the beam is cantilevered with its built-in end at the left, the fixed-end moment will be unknown. In that case, the moment must be calculated to the right end of the beam.

This equation describes a parabolic section (curved upward) with a peak at  $x = 5.333$  ft, where the shear is zero. The maximum moment is

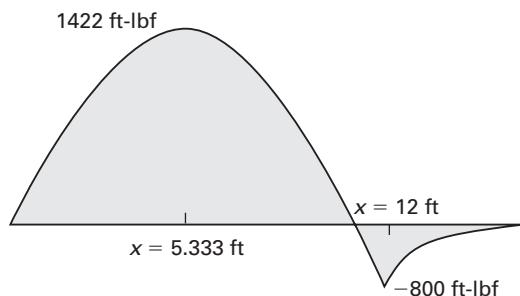

$$M_{x=5.333 \text{ ft}} = (533.3 \text{ lbf})(5.333 \text{ ft}) - \left(50 \frac{\text{lbf}}{\text{ft}}\right)(5.333 \text{ ft})^2 \\ = 1422.0 \text{ ft-lbf}$$

The moment at the right reaction (where  $x = 12$  ft) is

$$M_{x=12 \text{ ft}} = (533.3 \text{ lbf})(12 \text{ ft}) - \left(50 \frac{\text{lbf}}{\text{ft}}\right)(12 \text{ ft})^2 \\ = -800 \text{ ft-lbf}$$

The right end is a free end, so the moment is zero. The moment between the right reaction and the right end could be calculated by summing moments to the left end, but it is more convenient to sum moments to the right end. Measuring  $x$  from the right end, the moment is derived only from the uniform load.

$$M = 100x\left(\frac{x}{2}\right) = 50x^2$$

This is sufficient information to draw the moment diagram. Once the maximum moment is located, no attempt is made to determine the exact curvature. The point where  $M = 0$  is of limited interest, and no attempt is made to determine the exact location.

Notice that the cross-sectional area of the beam was not needed in this example.

### 13. SHEAR STRESS IN BEAMS

*Shear stress* is generally not the limiting factor in most designs. However, it can control the design (or be limited by code) in wood, masonry, and concrete beams and in thin tubes.

The average shear stress experienced at a point along the length of a beam depends on the shear,  $V$ , at that point and the area,  $A$ , of the beam. The shear can be found from the shear diagram.

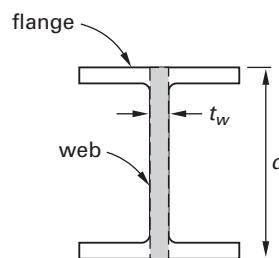

$$\tau = \frac{V}{A} \quad 44.28$$

In most cases, the entire area,  $A$ , of the beam is used in calculating the average shear stress. However, in flanged beam calculations it is assumed that only the web

carries the average shear stress.<sup>7</sup> (See Fig. 44.10.) The flanges are not included in shear stress calculations.

$$\tau = \frac{V}{t_w d} \quad 44.29$$

Figure 44.10 Web of a Flanged Beam

Shear stress is also induced in a beam due to flexure (i.e., bending). Figure 44.6 shows that for biaxial loading, identical shear stresses exist simultaneously in all four directions. One set of parallel shears (a couple) counteracts the rotational moment from the other set of parallel shears. The horizontal shear exists even when the loading is vertical (e.g., when a horizontal beam is loaded by a vertical force). For that reason, the term *horizontal shear* is sometimes used to distinguish it from the applied shear load.

The exact value of the horizontal shear stress is dependent on the location,  $y_1$ , within the depth of the beam. The shear stress distribution is given by Eq. 44.30. The shear stress is zero at the top and bottom surfaces of the beam and is usually maximum at the neutral axis (i.e., the center).

$$\tau_{y_1} = \frac{Q V}{I b} \quad 44.30$$

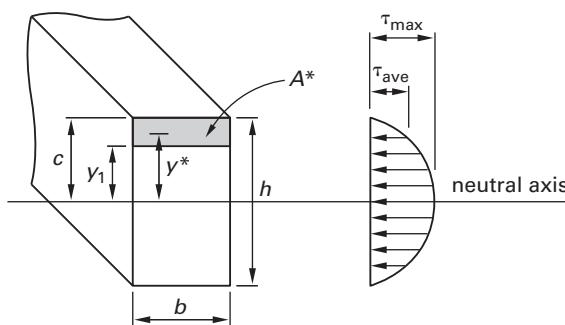

In Eq. 44.30,  $V$  is the vertical shear at the point along the length of the beam where the shear stress is wanted.  $I$  is the beam's centroidal moment of inertia, and  $b$  is the width of the beam at the depth  $y_1$  within the beam where the shear stress is wanted.  $Q$  is the *statical moment* of the area, as defined by Eq. 44.31.

$$Q = \int_{y_1}^c y \, dA \quad 44.31$$

For rectangular beams,  $dA = b \, dy$ . Then, the statical moment of the area  $A^*$  above layer  $y_1$  is equal to the product of the area and the distance from the centroidal axis to the centroid of the area. (See Fig. 44.11.)

$$Q = y^* A^* \quad 44.32$$

<sup>7</sup>This is more than an assumption; it is a fact. There are several reasons the flanges do not contribute to shear resistance, including a non-uniform shear stress distribution in the flanges. This nonuniformity is too complex to be analyzed by elementary methods.

**Figure 44.11** Shear Stress Distribution Within a Rectangular Beam

Equation 44.33 calculates the maximum shear stress in a rectangular beam. It is 50% higher than the average shear stress.

$$\tau_{\max, \text{rectangular}} = \frac{3V}{2A} = \frac{3V}{2bh} \quad 44.33$$

For a beam with a circular cross section, the maximum shear stress is

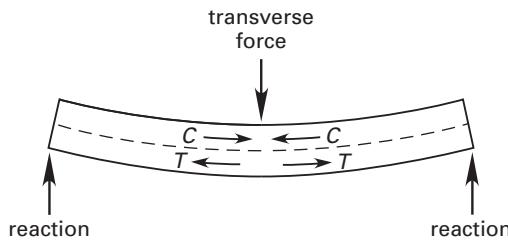

$$\tau_{\max, \text{circular}} = \frac{4V}{3A} = \frac{4V}{3\pi r^2} \quad 44.34$$

For a hollow cylinder used as a beam, the maximum shear stress occurs at the plane of the neutral axis and is

$$\tau_{\max, \text{hollow cylinder}} = \frac{2V}{A} \quad 44.35$$

## 14. BENDING STRESS IN BEAMS

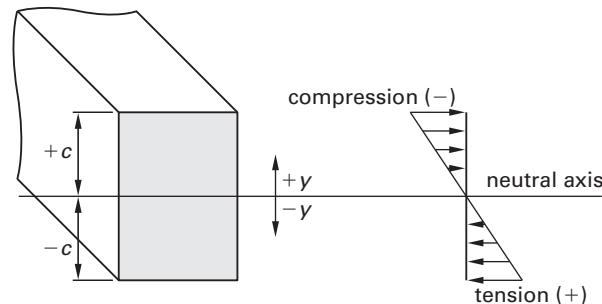

Normal stress occurs in a bending beam, as shown in Fig. 44.12, where the beam is acted upon by a *transverse force*. Although it is a normal stress, the term *bending stress* or *flexural stress* is used to indicate the cause of the stress. The lower surface of the beam experiences tensile stress (which causes lengthening). The upper surface of the beam experiences compressive stress (which causes shortening). There is no normal stress along a horizontal plane passing through the centroid of the cross section, a plane known as the *neutral plane* or the *neutral axis*.

**Figure 44.12** Normal Stress Due to Bending

Bending stress varies with location (depth) within the beam. It is zero at the neutral axis and increases linearly

with distance from the neutral axis, as predicted by Eq. 44.36. (See Fig. 44.13.)

$$\sigma_b = -\frac{My}{I_c} \quad 44.36$$

**Figure 44.13** Bending Stress Distribution in a Beam

In Eq. 44.36, *M* is the *bending moment*. *I<sub>c</sub>* is the centroidal moment of inertia of the beam's cross section. The negative sign in Eq. 44.36, required by the convention that compression is negative, is commonly omitted.

Since the maximum stress will govern the design, *y* can be set equal to *c* to obtain the *extreme fiber stress*. *c* is the distance from the neutral axis to the *extreme fiber* (i.e., the top or bottom surface most distant from the neutral axis).

$$\sigma_{b,\max} = \frac{Mc}{I_c} \quad 44.37$$

Equation 44.37 shows that the maximum bending stress will occur where the moment along the length of the beam is maximum. The region immediately adjacent to the point of maximum bending moment is called the *dangerous section* of the beam. The dangerous section can be found from a bending moment or shear diagram.

For any given beam cross section, *I<sub>c</sub>* and *c* are fixed. Therefore, these two terms can be combined into the *section modulus*, *S*.<sup>8</sup>

$$\sigma_{b,\max} = \frac{M}{S} \quad 44.38$$

$$S = \frac{I_c}{c} \quad 44.39$$

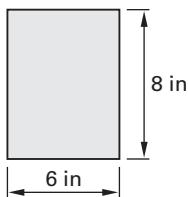

Since *c* = *h*/2, the section modulus of a rectangular *b* × *h* section (*I<sub>c</sub>* = *bh*<sup>3</sup>/12) is

$$S_{\text{rectangular}} = \frac{bh^2}{6} \quad 44.40$$

<sup>8</sup>The symbol *Z* is also commonly used for the section modulus, particularly when referring to the plastic section modulus.

**Example 44.5**

The beam in Ex. 44.4 has a 6 in  $\times$  8 in cross section. What are the maximum shear and bending stresses in the beam?

**Solution**

The maximum shear (taken from the shear diagram) is 666.7 lbf. (The negative sign can be disregarded.) From Eq. 44.33, the maximum shear stress in a rectangular beam is

$$\tau_{\max} = \frac{3V}{2A} = \frac{(3)(666.7 \text{ lbf})}{(2)(6 \text{ in})(8 \text{ in})} = 20.8 \text{ lbf/in}^2$$

The centroidal moment of inertia is

$$I_c = \frac{bh^3}{12} = \frac{(6 \text{ in})(8 \text{ in})^3}{12} = 256 \text{ in}^4$$

The maximum bending moment (from the bending moment diagram) is 1422 ft-lbf. From Eq. 44.37, the maximum bending stress is

$$\sigma_{b,\max} = \frac{Mc}{I_c} = \frac{(1422 \text{ ft-lbf})\left(12 \frac{\text{in}}{\text{ft}}\right)(4 \text{ in})}{256 \text{ in}^4} = 266.6 \text{ lbf/in}^2$$

## 15. STRAIN ENERGY DUE TO BENDING MOMENT

The elastic strain energy due to a bending moment stored in a beam is

$$U = \frac{1}{2EI} \int M^2(x) dx \quad 44.41$$

The use of Eq. 44.41 is illustrated by Ex. 44.10.

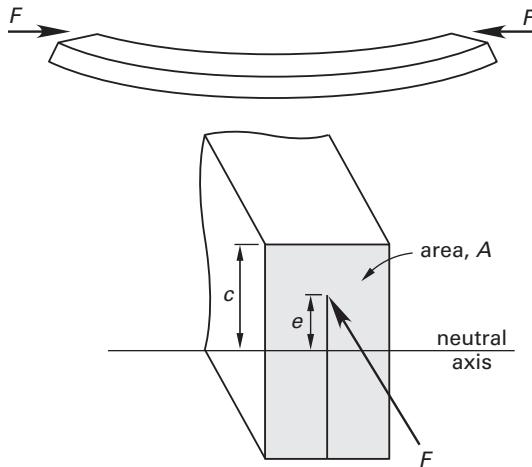

## 16. ECCENTRIC LOADING OF AXIAL MEMBERS

If a load is applied through the centroid of a tension or compression member's cross section, the loading is said to be *axial loading* or *concentric loading*. *Eccentric loading* occurs when the load is not applied through the centroid.

If an axial member is loaded eccentrically, it will bend and experience bending stress in the same manner as a

beam. Since the member experiences both axial stress and bending stress, it is known as a *beam-column*. In Fig. 44.14,  $e$  is known as the *eccentricity*.

**Figure 44.14** Eccentric Loading of an Axial Member

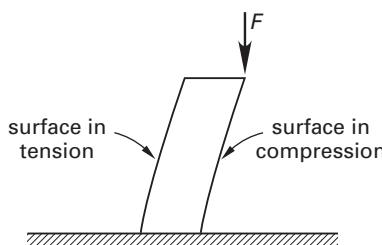

Both the axial stress and bending stress are normal stresses oriented in the same direction; therefore, simple addition can be used to combine them. Combined stress theory is not applicable. By convention,  $F$  is negative if the force compresses the member, which is shown in Fig. 44.14.

$$\sigma_{\max,\min} = \frac{F}{A} \pm \frac{Mc}{I_c} \quad 44.42$$

$$\sigma_{\max,\min} = \frac{F}{A} \pm \frac{Fec}{I_c} \quad 44.43$$

If a pier or column (primarily designed as a compression member) is loaded with an eccentric compressive load, part of the section can still be placed in tension. (See Fig. 44.15.) Tension will exist when the  $Mc/I_c$  term in Eq. 44.42 is larger than the  $F/A$  term. It is particularly important to eliminate or severely limit tensile stresses in unreinforced concrete and masonry piers, since these materials cannot support tension.

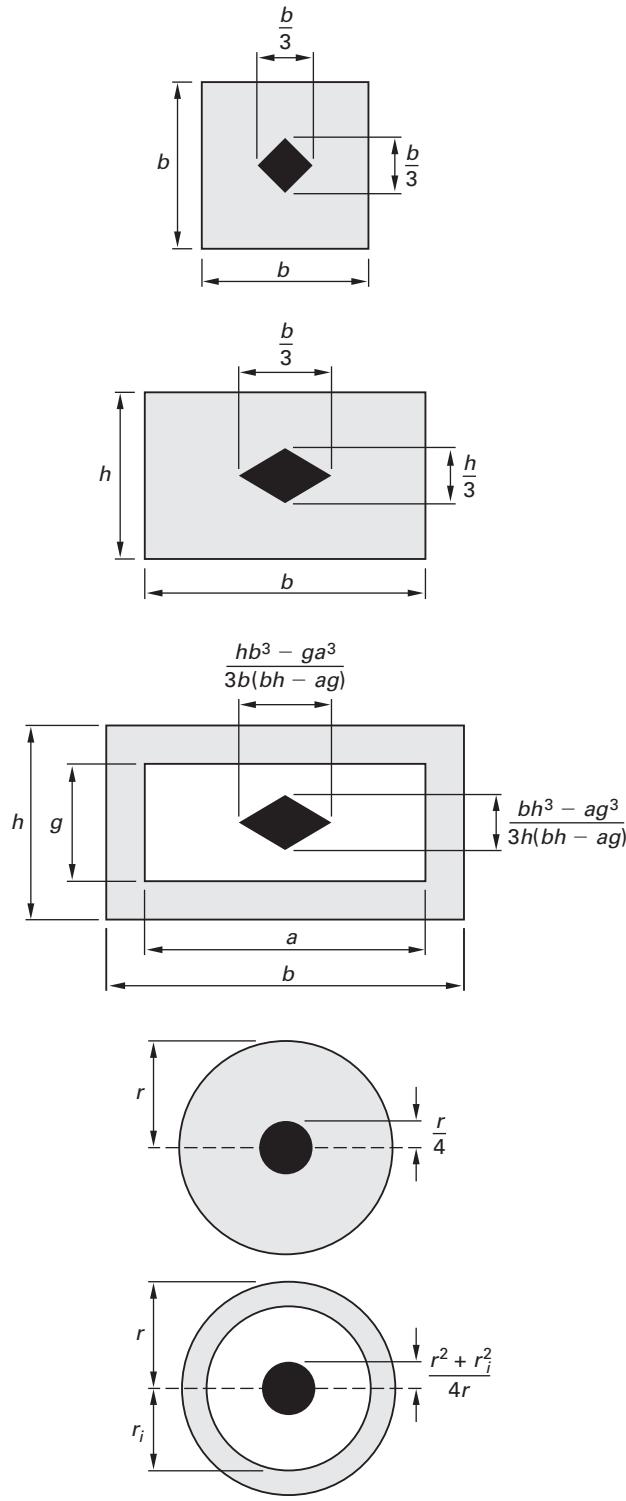

**Figure 44.15** Tension in a Pier

Regardless of the magnitude of the load, there will be no tension as long as the eccentricity is low. In a rectangular member, the load must be kept within a

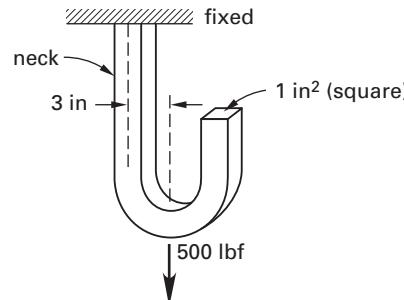

rhombus-shaped area formed from the middle thirds of the centroidal axes. This area is known as the *core*, *kern*, or *kernel*. Figure 44.16 illustrates the kerns for other cross sections.

**Figure 44.16** Kerns of Common Cross Sections

### Example 44.6

A built-in hook with a cross section of 1 in  $\times$  1 in carries a load of 500 lbf, but the load is not in line with the centroidal axis of the hook's neck. What are the minimum and maximum stresses in the neck? Is the neck in tension everywhere?

#### Solution

The centroidal moment of inertia of a 1 in  $\times$  1 in section is

$$I_c = \frac{bh^3}{12} = \frac{(1 \text{ in})(1 \text{ in})^3}{12} = 0.0833 \text{ in}^4$$

The hook is eccentrically loaded with an eccentricity of 3 in. From Eq. 44.43, the total stress is the sum of the direct axial tension and the bending stress. As the hook bends to reduce the eccentricity, the inner face of the neck will experience a tensile bending stress. The outer face of the neck will experience a compressive bending stress.

$$\begin{aligned}\sigma_{\max,\min} &= \frac{F}{A} \pm \frac{F_{ec}}{I_c} \\ &= \frac{500 \text{ lbf}}{1 \text{ in}^2} \pm \frac{(500 \text{ lbf})(3 \text{ in})(0.5 \text{ in})}{0.0833 \text{ in}^4} \\ &= 500 \frac{\text{lbf}}{\text{in}^2} \pm 9000 \frac{\text{lbf}}{\text{in}^2} \\ &= +9500 \text{ lbf/in}^2, -8500 \text{ lbf/in}^2\end{aligned}$$

The 500 lbf/in<sup>2</sup> direct stress is tensile, and the inner face experiences a total tensile stress of 9500 lbf/in<sup>2</sup>. However, the compressive bending stress of 9000 lbf/in<sup>2</sup> counteracts the direct tensile stress, resulting in an 8500 lbf/in<sup>2</sup> compressive stress at the outer face of the neck.

### 17. BEAM DEFLECTION: DOUBLE INTEGRATION METHOD

The deflection and the slope of a loaded beam are related to the moment and shear by Eq. 44.44 through Eq. 44.48.

$$y = \text{deflection} \quad 44.44$$

$$y' = \frac{dy}{dx} = \text{slope} \quad 44.45$$

$$y'' = \frac{d^2y}{dx^2} = \frac{M(x)}{EI} \quad 44.46$$

$$y''' = \frac{d^3y}{dx^3} = \frac{V(x)}{EI} \quad 44.47$$

If the *moment function*,  $M(x)$ , is known for a section of the beam, the deflection at any point can be found from Eq. 44.48.

$$y = \frac{1}{EI} \int \left( \int M(x) dx \right) dx \quad 44.48$$

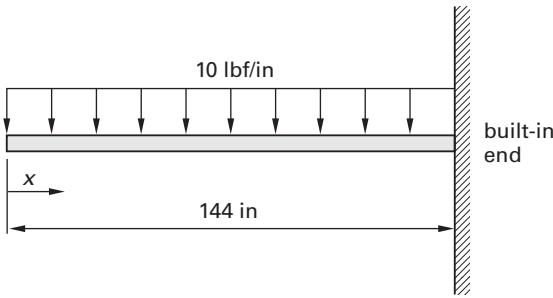

In order to find the deflection, constants must be introduced during the integration process. For some simple configurations, these constants can be found from Table 44.3.

**Table 44.3** Beam Boundary Conditions

end condition	$y$	$y'$	$y''$	$V$	$M$
simple support	0				0
built-in support	0	0			
free end			0	0	0
hinge					0

### Example 44.7

Find the tip deflection of the beam shown.  $EI$  is  $5 \times 10^{10}$  lbf-in $^2$  everywhere.

*Solution*

The moment at any point  $x$  from the left end of the beam is

$$M(x) = -10x\left(\frac{1}{2}x\right) = -5x^2$$

This is negative by the left-hand rule convention. From Eq. 44.46,

$$y'' = \frac{M(x)}{EI}$$

$$EIy'' = M(x) = -5x^2$$

$$EIy' = \int -5x^2 dx = -\frac{5}{3}x^3 + C_1$$

Since  $y' = 0$  at a built-in support (from Table 44.3) and  $x = 144$  in at the built-in support,

$$0 = \left(-\frac{5}{3}\right)(144)^3 + C_1$$

$$C_1 = 4.98 \times 10^6$$

$$\begin{aligned} EIy &= \int \left(-\frac{5}{3}x^3 + 4.98 \times 10^6\right) dx \\ &= -\frac{5}{12}x^4 + (4.98 \times 10^6)x + C_2 \end{aligned}$$

Again,  $y = 0$  at  $x = 144$  in, so  $C_2 = -5.38 \times 10^8$  lbf-in $^3$ . Therefore, the deflection as a function of  $x$  is

$$y = \frac{1}{EI} \left( -\frac{5}{12}x^4 + (4.98 \times 10^6)x - 5.38 \times 10^8 \right)$$

At the tip  $x = 0$ , so the deflection is

$$y_{\text{tip}} = \frac{-5.38 \times 10^8 \text{ lbf-in}^3}{5 \times 10^{10} \text{ lbf-in}^2} = -0.0108 \text{ in}$$

### 18. BEAM DEFLECTION: MOMENT AREA METHOD

The moment area method is a semigraphical technique that is applicable whenever slopes of deflection beams are not too great. This method is based on the following two theorems.

- *Theorem I:* The angle between tangents at any two points on the *elastic line* of a beam is equal to the area of the moment diagram between the two points divided by  $EI$ .

$$\phi = \int \frac{M(x)dx}{EI} \quad 44.49$$

- *Theorem II:* One point's deflection away from the tangent of another point is equal to the *statical moment* of the bending moment between those two points divided by  $EI$ .

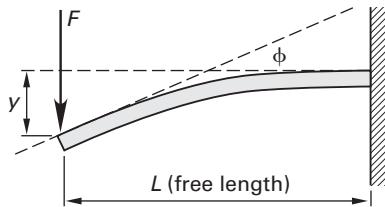

$$y = \int \frac{xM(x)dx}{EI} \quad 44.50$$

If  $EI$  is constant, the statical moment  $\int xM(x)dx$  can be calculated as the product of the total moment diagram area times the horizontal distance from the point whose deflection is wanted to the centroid of the moment diagram.

If the moment diagram has positive and negative parts (areas above and below the zero line), the statical moment should be taken as the sum of two products, one for each part of the moment diagram.

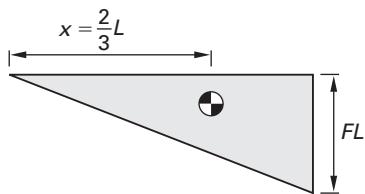

### Example 44.8

Find the deflection,  $y$ , and the angle,  $\phi$ , at the free end of the cantilever beam shown. Neglect the beam weight.

*Solution*

The deflection angle,  $\phi$ , is the angle between the tangents at the free and built-in ends (Theorem I). The moment diagram is

The area of the moment diagram is

$$\int M(x) dx = \frac{1}{2}(FL)(L) = \frac{1}{2}FL^2$$

From Eq. 44.49,

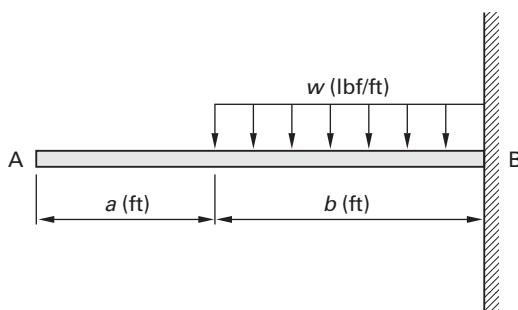

$$\phi = \int \frac{M(x) dx}{EI} = \frac{FL^2}{2EI}$$

The centroid of the moment diagram is located at  $x = \frac{2}{3}L$ . From Eq. 44.50,

$$y = \int \frac{xM(x) dx}{EI} = \left( \frac{FL^2}{2EI} \right) \left( \frac{2}{3}L \right) = \frac{FL^3}{3EI}$$

#### Example 44.9

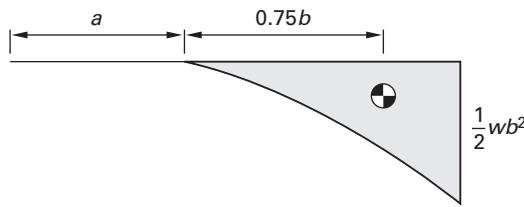

Find the deflection of the free end of the cantilever beam shown. Neglect the beam weight.

*Solution*

The distance from point A (where the deflection is wanted) to the centroid is  $a + 0.75b$ . The area of the moment diagram is  $wb^3/6$ . From Eq. 44.50,

$$y = \int \frac{xM(x) dx}{EI} = \left( \frac{wb^3}{6EI} \right) (a + 0.75b)$$

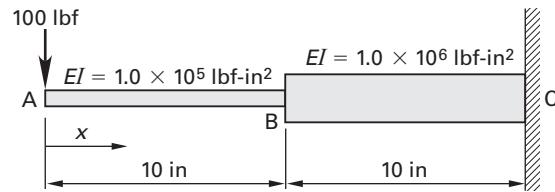

#### 19. BEAM DEFLECTION: STRAIN ENERGY METHOD

The deflection at a point of load application can be found by the strain energy method. This method uses the work-energy principle and equates the external work to the total internal strain energy. Since work is a force moving through a distance (which in this case is the deflection), Eq. 44.51 holds true.

$$\frac{1}{2}Fy = \sum U \quad 44.51$$

#### Example 44.10

Find the deflection at the tip of the stepped beam shown.

*Solution*

In section AB,  $M(x) = 100x$  in-lbf.

From Eq. 44.41,

$$\begin{aligned} U &= \frac{1}{2EI} \int M^2(x) dx \\ &= \frac{1}{(2)(1 \times 10^5 \text{ lbf-in}^2)} \int_{0 \text{ in}}^{10 \text{ in}} (100x)^2 \\ &= 16.67 \text{ in-lbf} \end{aligned}$$

In section BC,  $M = 100x$ .

$$U = \frac{1}{(2)(1 \times 10^6 \text{ lbf-in}^2)} \int_{10 \text{ in}}^{20 \text{ in}} (100x)^2 = 11.67 \text{ in-lbf}$$

Equating the internal work,  $U$ , and the external work,

$$\begin{aligned} \sum U &= W \\ 16.67 \text{ in-lbf} + 11.67 \text{ in-lbf} &= \left(\frac{1}{2}\right)(100 \text{ lbf})y \\ y &= 0.567 \text{ in} \end{aligned}$$

## 20. BEAM DEFLECTION: CONJUGATE BEAM METHOD

The *conjugate beam method* changes a deflection problem into one of drawing moment diagrams. The method has the advantage of being able to handle beams of varying cross sections (e.g., stepped beams) and materials. It has the disadvantage of not easily being able to handle beams with two built-in ends. The following steps constitute the conjugate beam method.

*step 1:* Draw the moment diagram for the beam as it is actually loaded.

*step 2:* Construct the  $M/EI$  diagram by dividing the value of  $M$  at every point along the beam by  $EI$  at that point. If the beam has a constant cross section,  $EI$  will be constant, and the  $M/EI$  diagram will have the same shape as the moment diagram. However, if the beam cross section varies with  $x$ ,  $I$  will change. In that case, the  $M/EI$  diagram will not look the same as the moment diagram.

*step 3:* Draw a conjugate beam of the same length as the original beam. The material and the cross-sectional area of this conjugate beam are not relevant.

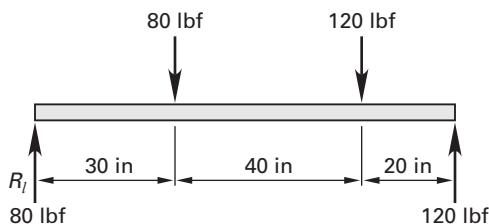

- (a) If the actual beam is simply supported at its ends, the conjugate beam will be simply supported at its ends.
- (b) If the actual beam is simply supported away from its ends, the conjugate beam has hinges at the support points.
- (c) If the actual beam has free ends, the conjugate beam has built-in ends.
- (d) If the actual beam has built-in ends, the conjugate beam has free ends.

*step 4:* Load the conjugate beam with the  $M/EI$  diagram. Find the conjugate reactions by methods of statics. Use the superscript \* to indicate conjugate parameters.

*step 5:* Find the conjugate moment at the point where the deflection is wanted. The deflection is numerically equal to the moment as calculated from the conjugate beam forces.

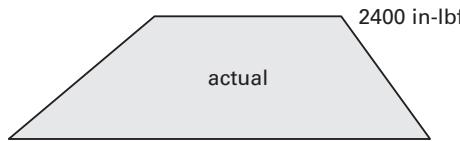

### Example 44.11

Find the deflections at the two load points.  $EI$  has a constant value of  $2.356 \times 10^7 \text{ lbf-in}^2$ .

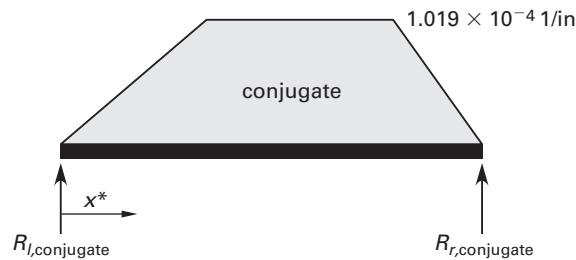

### Solution

Applying step 1, the moment diagram for the actual beam is

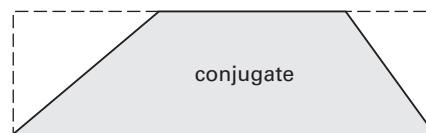

Applying steps 2, 3, and 4, since the beam cross section is constant, the conjugate load has the same shape as the original moment diagram. The peak load on the conjugate beam is

$$\frac{M}{EI} = \frac{2400 \text{ in-lbf}}{2.356 \times 10^7 \text{ lbf-in}^2} = 1.019 \times 10^{-4} \text{ 1/in}$$

The conjugate reaction,  $R_{l,\text{conjugate}}$ , is found by the following method. The loading diagram is assumed to be made up of a rectangular load and two negative triangular loads. The area of the rectangular load (which has a centroid at  $x_{\text{conjugate}} = 45 \text{ in}$ ) is taken as  $(90 \text{ in})(1.019 \times 10^{-4} \text{ 1/in}) = 9.171 \times 10^{-3}$ .

Similarly, the area of the left triangle (which has a centroid at  $x_{\text{conjugate}} = 10 \text{ in}$ ) is  $(0.5)(30 \text{ in})(1.019 \times 10^{-4} \text{ 1/in}) = 1.529 \times 10^{-3}$ . The area of the right triangle (which has a centroid at  $x_{\text{conjugate}} = 83.33 \text{ in}$ ) is taken as  $(0.5)(20 \text{ in})(1.019 \times 10^{-4} \text{ 1/in}) = 1.019 \times 10^{-3}$ .

$$\begin{aligned} \sum M_l^* &= (90 \text{ in})R_{r,\text{conjugate}} \\ &\quad + (1.019 \times 10^{-3})(83.3 \text{ in}) \\ &\quad + (1.529 \times 10^{-3})(10 \text{ in}) \\ &\quad - (9.171 \times 10^{-3})(45 \text{ in}) \\ &= 0 \end{aligned}$$

$$R_{r,\text{conjugate}} = 3.472 \times 10^{-3}$$

Then,

$$\begin{aligned} R_{l,\text{conjugate}} &= (9.171 - 1.019 - 1.529 - 3.472) \times 10^{-3} \\ &= 3.151 \times 10^{-3} \end{aligned}$$

In step 5, the conjugate moment at  $x_{\text{conjugate}} = 30 \text{ in}$  is the deflection of the actual beam at that point.

$$\begin{aligned} M_{\text{conjugate}} &= (3.151 \times 10^{-3})(30 \text{ in}) \\ &\quad + (1.529 \times 10^{-3})(30 \text{ in} - 10 \text{ in}) \\ &\quad - (9.171 \times 10^{-3})\left(\frac{30 \text{ in}}{90 \text{ in}}\right)(15 \text{ in}) \\ &= 7.926 \times 10^{-2} \text{ in} \end{aligned}$$

The conjugate moment (the deflection) at the right-most load is

$$\begin{aligned} M_{\text{conjugate}} &= (3.472 \times 10^{-3})(20 \text{ in}) \\ &\quad + (1.019 \times 10^{-3})(13.3 \text{ in}) \\ &\quad - (9.171 \times 10^{-3})\left(\frac{20 \text{ in}}{90 \text{ in}}\right)(10 \text{ in}) \\ &= 6.261 \times 10^{-2} \text{ in} \end{aligned}$$

## 21. BEAM DEFLECTION: SUPERPOSITION

When multiple loads act simultaneously on a beam, all of the loads contribute to deflection. The principle of *superposition* permits the deflections at a point to be calculated as the sum of the deflections from each individual load acting singly.<sup>9</sup> This principle is valid as long as none of the deflections is excessive and all stresses are kept less than the yield point of the beam material.

## 22. BEAM DEFLECTION: TABLE LOOKUP METHOD

Appendix 44.A is a compilation of the most commonly used beam deflection formulas. These formulas should never need to be derived and should be used whenever possible. They are particularly useful in calculating deflections due to multiple loads using the principle of superposition.

The actual deflection of very *wide beams* (i.e., those whose widths are larger than approximately 8 or 10 times the thickness) is less than that predicted by the equations in App. 44.A for elastic behavior. (This is particularly true for leaf springs.) The large width prevents lateral expansion and contraction of the beam material, reducing the deflection. For wide beams, the calculated deflection should be reduced by multiplying by  $(1 - \nu^2)$ .

## 23. INFLECTION POINTS

The *inflection point* (also known as a *point of contraflexure*) on a horizontal beam in elastic bending occurs where the curvature changes from concave up to

<sup>9</sup>The principle of superposition is not limited to deflections. It can also be used to calculate the shear and moment at a point and to draw the shear and moment diagrams.

concave down, or vice versa. There are three ways of determining the inflection point.

1. If the elastic deflection equation,  $y(x)$ , is known, the inflection point can be found from differentiation (i.e., by determining the value of  $x$  for which  $y''(x) = M(x) = 0$ ).
2. From Eq. 44.46,  $y''(x) = M(x)/EI$ .  $y''(x)$  is also the reciprocal of the *radius of curvature*,  $\rho$ , of the beam.

$$y''(x) = \frac{1}{\rho(x)} = \frac{M(x)}{EI} \quad 44.52$$

Since the flexural rigidity,  $EI$ , is always positive, the radius of curvature,  $\rho(x)$ , changes sign when the moment equation,  $M(x)$ , changes sign.

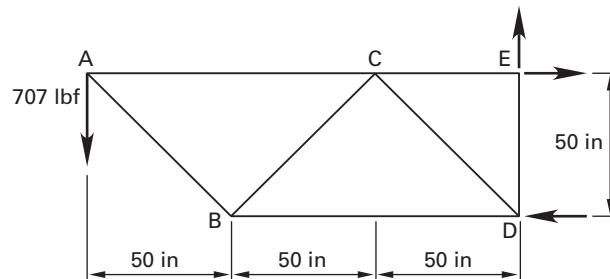

3. If a shear diagram is known, the inflection point can sometimes be found by noting the point at which the positive and negative shear areas on either side of the point balance.

## 24. TRUSS DEFLECTION: STRAIN ENERGY METHOD

The deflection of a truss at the point of a single load application can be found by the *strain energy method* if all member forces are known. This method is illustrated by Ex. 44.12.

### Example 44.12

Find the vertical deflection of point A under the external load of 707 lbf.  $AE = 10^6 \text{ lbf}$  for all members. The internal forces have already been determined.

### Solution

The length of member AB is  $\sqrt{(50 \text{ in})^2 + (50 \text{ in})^2} = 70.7 \text{ in}$ . From Eq. 44.6, the internal strain energy in member AB is

$$U = \frac{F^2 L_o}{2AE} = \frac{(-1000 \text{ lbf})^2 (70.7 \text{ in})}{(2)(10^6 \text{ lbf})} = 35.4 \text{ in-lbf}$$

Similarly, the energy in all members can be determined.

member	$L$ (in)	$F$ (lbf)	$U$ (in-lbf)
AB	70.7	-1000	+35.4
BC	70.7	+1000	+35.4
AC	100	+707	+25.0
BD	100	-1414	+100.0
CD	70.7	-1000	+35.4
CE	50	+2121	+112.5
DE	50	+707	+12.5
			356.2

The work done by a constant force,  $F$ , moving through a distance,  $y$ , is  $Fy$ . In this case, the force increases with  $y$ . The average force is  $\frac{1}{2}F$ . The external work is  $W_{\text{ext}} = (\frac{1}{2})(707 \text{ lbf})y$ , so

$$(\frac{1}{2})(707 \text{ lbf})y = 356.2 \text{ in-lbf}$$

$$y = 1 \text{ in}$$

## 25. TRUSS DEFLECTION: VIRTUAL WORK METHOD

The *virtual work method* (also known as the *unit load method*) is an extension of the strain energy method. It can be used to determine the deflection of any point on a truss.

*step 1:* Draw the truss twice.

*step 2:* On the first truss, place all the actual loads.

*step 3:* Find the forces,  $S$ , due to the actual applied loads in all the members.

*step 4:* On the second truss, place a dummy one-unit load,  $f$ , in the direction of the desired displacement.

*step 5:* Find the forces,  $u$ , due to the one-unit dummy load in all members.

*step 6:* Find the desired displacement from Eq. 44.53. The summation is over all truss members that have nonzero forces in *both* trusses.

$$f\delta = \sum \frac{SuL}{AE} \quad [f=1] \quad 44.53$$

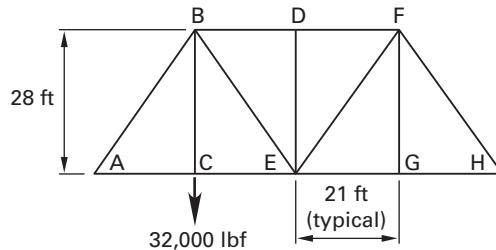

### Example 44.13

What is the horizontal deflection of joint F on the truss shown? Use  $E = 3 \times 10^7 \text{ lbf/in}^2$ . Joint A is restrained horizontally. Member lengths and areas are listed in the accompanying table.

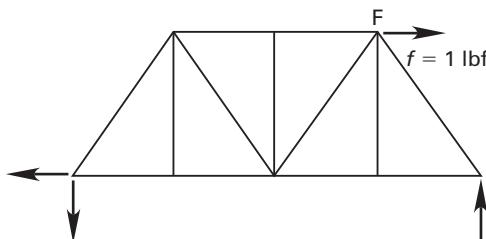

*Solution*

Applying steps 1 and 2, use the truss as drawn.

Applying step 3, the forces in all the truss members are summarized in step 5.

Applying step 4, draw the truss and load it with a unit horizontal force at point F.

Applying step 5, find the forces,  $u$ , in all members of the second truss. These are summarized in the following table. Notice the sign convention: + for tension and - for compression.

member	$S$ (lbf)	$u$ (lbf)	$L$ (ft)	$A$ (in $^2$ )	$\frac{SuL}{AE}$ (ft-lbf)
AB	-30,000	5/12	35	17.5	$-8.33 \times 10^{-4}$
CB	32,000	0	28	14	0
EB	-10,000	-5/12	35	17.5	$2.78 \times 10^{-4}$
ED	0	0	28	14	0
EF	10,000	5/12	35	17.5	$2.78 \times 10^{-4}$
GF	0	0	28	14	0
HF	-10,000	-5/12	35	17.5	$2.78 \times 10^{-4}$
BD	-12,000	1/2	21	10.5	$-4.00 \times 10^{-4}$
DF	-12,000	1/2	21	10.5	$-4.00 \times 10^{-4}$
AC	18,000	3/4	21	10.5	$9.00 \times 10^{-4}$
CE	18,000	3/4	21	10.5	$9.00 \times 10^{-4}$
EG	6000	1/4	21	10.5	$1.00 \times 10^{-4}$
GH	6000	1/4	21	10.5	$1.00 \times 10^{-4}$
					$12.01 \times 10^{-4}$

Applying step 6, the deflection is conveniently calculated by summing the last column in the table. Since  $12.01 \times 10^{-4}$  is positive, the deflection is in the direction of the dummy unit load. In this case, the deflection is to the right.

## 26. MODES OF BEAM FAILURE

Beams can fail in different ways, including excessive deflection, local buckling, lateral buckling, and rotation.

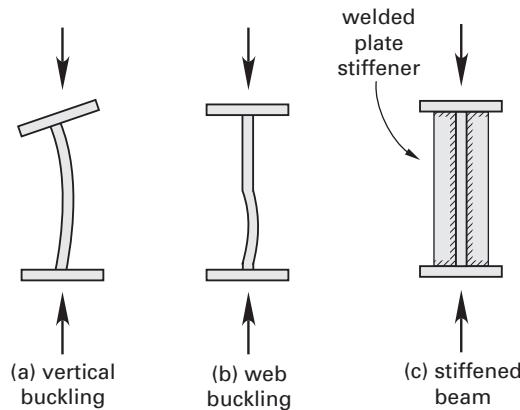

Excessive deflection occurs when a beam bends more than a permitted amount.<sup>10</sup> The deflection is elastic

<sup>10</sup>Building codes specify maximum permitted deflections in terms of beam length.

and no yielding occurs. For this reason, the failure mechanism is sometimes called *elastic failure*. Although the beam does not yield, the excessive deflection may cause cracks in plaster and sheetrock, misalignment of doors and windows, and occupant concern and reduction of confidence in the structure.

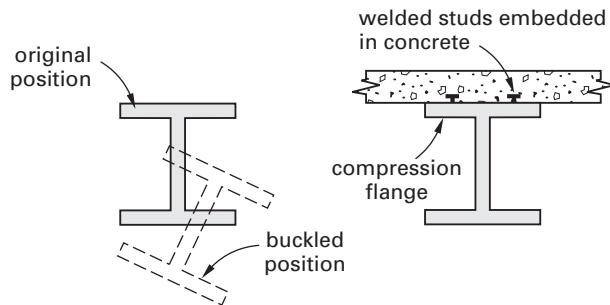

*Local buckling* is an overload condition that occurs near large concentrated loads. Such locations include where a column frames into a supporting girder or a reaction point. *Vertical buckling* and *web crippling*, two types of local buckling, can be eliminated by use of *stiffeners*. Such stiffeners can be referred to as *intermediate stiffeners*, *bearing stiffeners*, *web stiffeners*, or *flange stiffeners*, depending on the location and technique of stiffening. (See Fig. 44.17.)

Figure 44.17 Local Buckling and Stiffeners

*Lateral buckling*, such as illustrated in Fig. 44.18, occurs when a long, unsupported member rolls out of its normal plane. To prevent lateral buckling, either the beam's compression flange must be supported continuously or at frequent intervals along its length, or the beam must be restrained against twisting about its longitudinal axis.

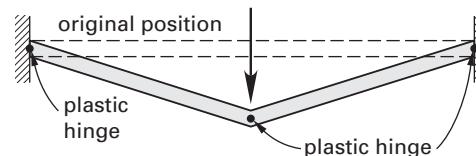

Figure 44.18 Lateral Buckling and Flange Support

*Rotation* is an inelastic (plastic) failure of the beam. When the bending stress at a point exceeds the strength

of the beam material, the material yields, as shown in Fig. 44.19. As the beam yields, its slope changes. Since the beam appears to be rotating at a hinge at the yield point, the term *plastic hinge* is used to describe the failure mechanism.

Figure 44.19 Beam Failure by Rotation

## 27. CURVED BEAMS

Many members (e.g., hooks, chain links, clamps, and machine frames) have curved main axes. The distribution of bending stress in a curved beam is nonlinear. Compared to a straight beam, the stress at the inner radius is higher because the inner radius fibers are shorter. Conversely, the stress at the outer radius is lower because the outer radius fibers are longer. Also, the neutral axis is shifted from the center inward toward the center of curvature.

Since the process of finding the neutral axis and calculating the stress amplification is complex, tables and graphs are used for quick estimates and manual computations. The forms of these computational aids vary, but the straight-beam stress is generally multiplied by factors,  $K$ , to obtain the stresses at the extreme faces. The factor values depend on the beam cross section and radius of curvature.

$$\sigma_{\text{curved}} = K \sigma_{\text{straight}} = \frac{K M c}{I} \quad 44.54$$

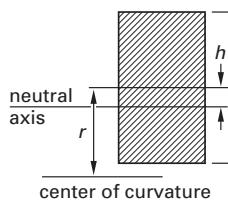

Table 44.4 is typical of compilations for round and rectangular beams. Factors  $K_A$  and  $K_B$  are the multipliers for the inner (high stress) and outer (low stress) faces, respectively. The ratio  $h/r$  is the fractional distance that the neutral axis shifts inward toward the radius of curvature.

## 28. COMPOSITE STRUCTURES

A *composite structure* is one in which two or more different materials are used. Each material carries part of an applied load. Examples of composite structures include steel-reinforced concrete and steel-plated timber beams.

Most simple composite structures can be analyzed using the *method of consistent deformations*, also known as the *area transformation method*. This method assumes that the strains are the same in both materials at the interface between them. Although the strains are the

**Table 44.4** Curved Beam Correction Factors

solid rectangular section	$r/c$	$K_A$	$K_B$	$h/r$
	1.2	2.89	0.57	0.305
	1.4	2.13	0.63	0.204
	1.6	1.79	0.67	0.149
	1.8	1.63	0.70	0.112
	2.0	1.52	0.73	0.090
	3.0	1.30	0.81	0.041
	4.0	1.20	0.85	0.021
	6.0	1.12	0.90	0.0093
	8.0	1.09	0.92	0.0052
	10.0	1.07	0.94	0.0033
	1.2	3.41	0.54	0.224
	1.4	2.40	0.60	0.151
	1.6	1.96	0.65	0.108
	1.8	1.75	0.68	0.084
	2.0	1.62	0.71	0.069
	3.0	1.33	0.79	0.03
	4.0	1.23	0.84	0.016
	6.0	1.14	0.89	0.007
	8.0	1.10	0.91	0.0039
	10.0	1.08	0.93	0.0025

same, the stresses in the two adjacent materials are not equal, since stresses are proportional to the moduli of elasticity.

The following steps comprise an analysis method based on area transformation.

*step 1:* Determine the modulus of elasticity for each of the materials used in the structure.

*step 2:* For each of the materials used, calculate the *modular ratio*,  $n$ .

$$n = \frac{E}{E_{\text{weakest}}} \quad 44.55$$

$E_{\text{weakest}}$  is the smallest modulus of elasticity of any of the materials used in the composite structure. For two materials that experience the same strains (i.e., are perfectly bonded),  $n$  is also the ratio of stresses.

*step 3:* For all of the materials except the weakest, multiply the actual material stress area by  $n$ . Consider this expanded (*transformed*) area to have the same composition as the weakest material.

*step 4:* If the structure is a tension or compression member, the distribution or placement of the transformed area is not important. Just assume that the transformed areas carry the axial load. For beams in bending, the transformed area can add to the width of the beam, but it cannot change

the depth of the beam or the thickness of the reinforcement.

*step 5:* For compression or tension members, calculate the stresses in the weakest and stronger materials.

$$\sigma_{\text{weakest}} = \frac{F}{A_t} \quad 44.56$$

$$\sigma_{\text{stronger}} = \frac{nF}{A_t} \quad 44.57$$

*step 6:* For flexural (bending) members, find the centroid of the transformed beam, and complete steps 7 through 9.

*step 7:* Find the centroidal moment of inertia of the transformed beam  $I_{c,t}$ .

*step 8:* Find  $V_{\text{max}}$  and  $M_{\text{max}}$  by inspection or from the shear and moment diagrams.

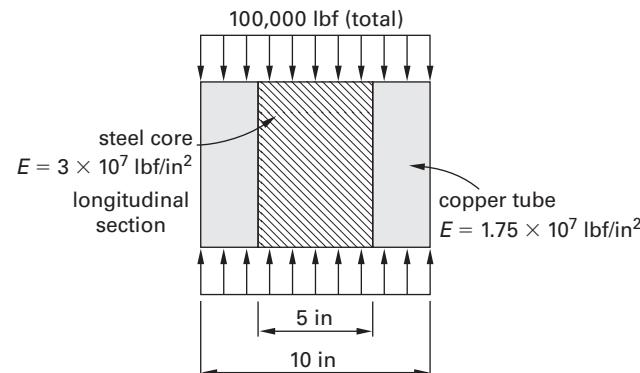

*step 9:* Calculate the stresses in the weakest and stronger materials.

$$\sigma_{\text{weakest}} = \frac{Mc_{\text{weakest}}}{I_{c,t}} \quad 44.58$$

$$\sigma_{\text{stronger}} = \frac{nMc_{\text{stronger}}}{I_{c,t}} \quad 44.59$$

#### Example 44.14

A short circular steel core is surrounded by a copper tube. The assemblage supports an axial compressive load of 100,000 lbf. The core and tube are well bonded, and the load is applied uniformly. Find the compressive stress in the inner steel core and the outer copper tube.

#### Solution

The moduli of elasticity are given in the illustration. From step 2, the modular ratio is

$$n = \frac{E_{\text{steel}}}{E_{\text{copper}}} = \frac{3 \times 10^7 \text{ lbf/in}^2}{1.75 \times 10^7 \text{ lbf/in}^2} = 1.714$$

The actual cross-sectional area of the steel is

$$\begin{aligned} A_{\text{steel}} &= \frac{\pi}{4} d^2 = \left(\frac{\pi}{4}\right)(5 \text{ in})^2 \\ &= 19.63 \text{ in}^2 \end{aligned}$$

The actual cross-sectional area of the copper is

$$\begin{aligned} A_{\text{copper}} &= \frac{\pi}{4} (d_o^2 - d_i^2) = \left(\frac{\pi}{4}\right)\left((10 \text{ in})^2 - (5 \text{ in})^2\right) \\ &= 58.90 \text{ in}^2 \end{aligned}$$

The steel is the stronger material. Its area must be expanded to an equivalent area of copper. From step 3, the total transformed area is

$$\begin{aligned} A_t &= A_{\text{copper}} + nA_{\text{steel}} = 58.90 \text{ in}^2 + (1.714)(19.63 \text{ in}^2) \\ &= 92.55 \text{ in}^2 \end{aligned}$$

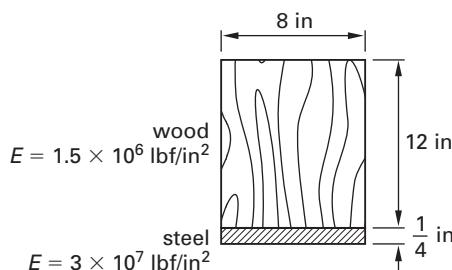

Since the two pieces are well bonded and the load is applied uniformly, both pieces experience identical strains. From step 5, the compressive stresses are

$$\begin{aligned} \sigma_{\text{copper}} &= \frac{F}{A_t} = \frac{-100,000 \text{ lbf}}{92.55 \text{ in}^2} \\ &= -1080 \text{ lbf/in}^2 \quad [\text{compression}] \end{aligned}$$

$$\begin{aligned} \sigma_{\text{steel}} &= \frac{nF}{A_t} = n\sigma_{\text{copper}} = (1.714)\left(-1080 \frac{\text{lbf}}{\text{in}^2}\right) \\ &= -1851 \text{ lbf/in}^2 \end{aligned}$$

### Example 44.15

At a particular point along the length of a steel-reinforced wood beam, the moment is 40,000 ft-lbf. Assume the steel reinforcement is lag-bolted to the wood at regular intervals along the beam. What are the maximum bending stresses in the wood and steel?

*Solution*

The moduli of elasticity are given in the illustration. From step 2, the modular ratio is

$$n = \frac{E_{\text{steel}}}{E_{\text{wood}}} = \frac{3 \times 10^7 \frac{\text{lbf}}{\text{in}^2}}{1.5 \times 10^6 \frac{\text{lbf}}{\text{in}^2}} = 20$$

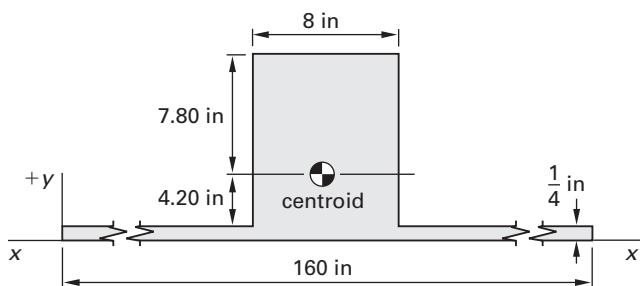

The actual cross-sectional area of the steel is

$$A_{\text{steel}} = (0.25 \text{ in})(8 \text{ in}) = 2 \text{ in}^2$$

The steel is the stronger material. Its area must be expanded to an equivalent area of wood. Since the depth of the beam and reinforcement cannot be increased (step 4), the width must increase. The width of the transformed steel plate is

$$b' = nb = (20)(8 \text{ in}) = 160 \text{ in}$$

The centroid of the transformed section is 4.45 in from the horizontal axis. The centroidal moment of inertia of the transformed section is  $I_{c,t} = 2211.5 \text{ in}^4$ . (The calculations for centroidal location and moment of inertia are not presented here.)

Since the steel plate is bolted to the wood at regular intervals, both pieces experience the same strain. From step 9, the stresses in the wood and steel are

$$\begin{aligned} \sigma_{\text{max,wood}} &= \frac{Mc_{\text{wood}}}{I_{c,t}} \\ &= \frac{(40,000 \text{ ft-lbf})(12 \frac{\text{in}}{\text{ft}})(7.8 \text{ in})}{2211.5 \text{ in}^4} \\ &= 1693 \text{ lbf/in}^2 \end{aligned}$$

$$\begin{aligned} \sigma_{\text{max,steel}} &= \frac{nMc_{\text{steel}}}{I_{c,t}} \\ &= \frac{(20)(40,000 \text{ ft-lbf})(12 \frac{\text{in}}{\text{ft}})(4.45 \text{ in})}{2211.5 \text{ in}^4} \\ &= 19,317 \text{ lbf/in}^2 \end{aligned}$$

## 1. ALLOWABLE STRESS DESIGN

Once an actual stress has been determined, it can be compared to the *allowable stress*. In engineering design, the term “allowable” always means that a factor of safety has been applied to the governing material strength.

$$\text{allowable stress} = \frac{\text{material strength}}{\text{factor of safety}} \quad 45.1$$

For ductile materials, the material strength used is the yield strength. For steel, the factor of safety ranges from 1.5 to 2.5, depending on the type of steel and the application. Higher factors of safety are seldom necessary in normal, noncritical applications, due to steel’s predictable and reliable performance.

$$\sigma_a = \frac{S_y}{\text{FS}} \quad [\text{ductile}] \quad 45.2$$

For brittle materials, the material strength used is the ultimate strength. Since brittle failure is sudden and unpredictable, the factor of safety is high (e.g., in the 6 to 10 range).

$$\sigma_a = \frac{S_u}{\text{FS}} \quad [\text{brittle}] \quad 45.3$$

If an actual stress is less than the allowable stress, the design is considered acceptable. This is the principle of the *allowable stress design method*, also known as the *working stress design method*.

$$\sigma_{\text{actual}} \leq \sigma_a \quad 45.4$$

## 2. ULTIMATE STRENGTH DESIGN

The allowable stress method has been replaced in most structural work by the *ultimate strength design method*, also known as the *load factor design method*, *plastic design method*, or just *strength design method*. This design method does not use allowable stresses at all. Rather, the member is designed so that its actual *nominal strength* exceeds the required ultimate strength.<sup>1</sup>

The *ultimate strength* (i.e., the required strength) of a member is calculated from the actual *service loads* and multiplicative factors known as *overload factors* or *load factors*. Usually, a distinction is made between dead loads and live loads.<sup>2</sup> For example, the required ultimate moment-carrying capacity in a concrete beam designed according to ACI 318 would be<sup>3</sup>

$$M_u = 1.2M_{\text{dead load}} + 1.6M_{\text{live load}} \quad 45.5$$

The *nominal strength* (i.e., the actual ultimate strength) of a member is calculated from the dimensions and materials. A *capacity reduction factor*,  $\phi$ , of 0.70 to 0.90 is included in the calculation to account for typical workmanship and increase required strength. The moment criteria for an acceptable design is

$$M_n \geq \frac{M_u}{\phi} \quad 45.6$$

## 3. SLENDER COLUMNS

Very short compression members are known as *piers*. Long compression members are known as *columns*. Failure in piers occurs when the applied stress exceeds the yield strength of the material. However, very long columns fail by sideways *buckling* long before the compressive stress reaches the yield strength. Buckling failure is sudden, often without significant initial sideways bending. The load at which a column fails is known as the *critical load* or *Euler load*.

The *Euler load* is the theoretical maximum load that an initially straight column can support without buckling. For columns with frictionless or pinned ends, this load is given by Eq. 45.7.  $r$  is the *radius of gyration*.

$$F_e = \frac{\pi^2 EI}{L^2} = \frac{\pi^2 EA}{\left(\frac{L}{r}\right)^2} \quad 45.7$$

The corresponding column stress is given by Eq. 45.8. In order to use Euler’s theory, this stress cannot exceed

<sup>1</sup>It is a characteristic of the ultimate strength design method that the term “strength” actually means load, shear, or moment. Strength seldom, if ever, refers to stress. Thus, the nominal strength of a member might be the load (in pounds, kips, newtons, etc.) or moment (in ft-lbf, ft-kips, or N-m) that the member supports at plastic failure.

<sup>2</sup>*Dead load* is an inert, inactive load, primarily due to the structure’s own weight. *Live load* is the weight of all nonpermanent objects, including people and furniture, in the structure.

<sup>3</sup>ACI 318 has been adopted as the source of concrete design rules in the United States.

half of the compressive yield strength of the column material.

$$\sigma_e = \frac{F_e}{A} = \frac{\pi^2 E}{\left(\frac{L}{r}\right)^2} \quad [\sigma_e < \frac{1}{2} S_y] \quad 45.8$$

The quantity  $L/r$  is known as the *slenderness ratio*. Long columns have high slenderness ratios. The smallest slenderness ratio for which Eq. 45.8 is valid, found by setting  $\sigma_e = S_y$ , is the *critical slenderness ratio*. Typical critical slenderness ratios range from 80 to 120. The critical slenderness ratio becomes smaller as the compressive yield strength increases.

$L$  is the longest unbraced column length. If a column is braced against buckling at some point between its two ends, the column is known as a *braced column*, and  $L$  will be less than the full column height. Columns with rectangular cross sections have two radii of gyration,  $r_x$  and  $r_y$ , and so will have two slenderness ratios. The largest slenderness ratio will govern the design.

Columns do not always have frictionless or pinned ends. Often, a column will be fixed ("clamped," "built in," etc.) at its top and base. In such cases, the *effective length*,  $L'$ , must be used in place of  $L$  in Eq. 45.7 and Eq. 45.8.

$$L' = K L \quad 45.9$$

Equation 45.8 becomes Eq. 45.10.

$$\sigma_e = \frac{F_e}{A} = \frac{\pi^2 E}{\left(\frac{L'}{r}\right)^2} \quad [\sigma_e < \frac{1}{2} S_y] \quad 45.10$$

$K$  is the *end restraint coefficient*, which varies from 0.5 to 2.0 according to Table 45.1. For most real columns, the design values of  $K$  should be used since infinite stiffness of the supporting structure is not achievable.

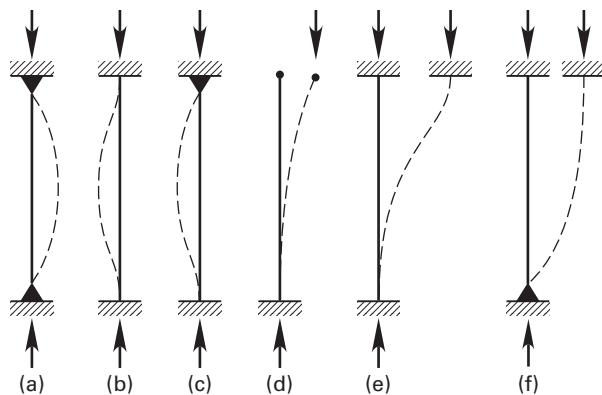

*Euler's curve* for columns, line BCD in Fig. 45.1, is generated by plotting the *Euler stress* versus the slenderness ratio. (See Eq. 45.8.) Since the material's compressive yield strength cannot be exceeded, a horizontal line, AC, is added to limit applications to the region below. Theoretically, members with slenderness ratios less than  $(SR)_C$  could be treated as pure compression members. However, this is not done in practice.

Defects in materials, errors in manufacturing, inability to achieve theoretical end conditions, and eccentricities frequently combine to cause column failures in the region around point C. This region is excluded by designers.

**Table 45.1** Theoretical End Restraint Coefficients,  $K$

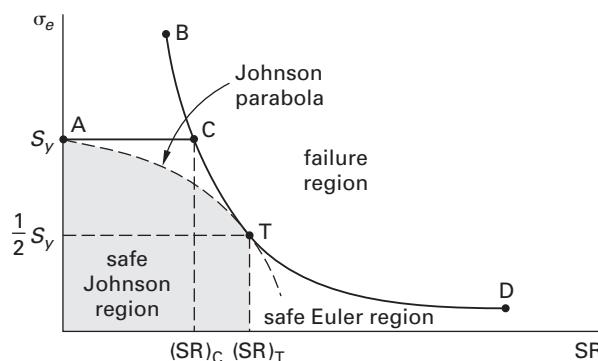

illus.	end conditions	ideal	recommended for design

**Figure 45.1** Euler's Curve

The empirical *Johnson procedure* used to exclude the failure area is to draw a parabolic curve from point A through a tangent point T on the Euler curve at a stress of  $\frac{1}{2} S_y$ . The corresponding value of the slenderness ratio is

$$(SR)_T = \sqrt{\frac{2\pi^2 E}{S_y}} \quad 45.11$$

**Example 45.1**

A steel member is used as an 8.5 ft long column. The ends are pinned. What is the maximum allowable compressive stress in order to have a factor of safety of 3.0? Use the following data for the column.

$$E = 2.9 \times 10^7 \text{ lbf/in}^2$$

$$S_y = 36,000 \text{ lbf/in}^2$$

$$r = 0.569 \text{ in}$$

*Solution*

First, check the slenderness ratio to see if this is a long column.

$$\begin{aligned} (\text{SR})_T &= \sqrt{\frac{2\pi^2 E}{S_y}} = \sqrt{\frac{2\pi^2 (2.9 \times 10^7 \text{ lbf/in}^2)}{36,000 \text{ lbf/in}^2}} \\ &= 126.1 \end{aligned}$$

$K = 1$  since the ends are pinned, and  $L' = L$ .

$$\frac{L}{r} = \frac{(8.5 \text{ ft})(12 \text{ in})}{0.569 \text{ in}} = 179.3 \quad [>126.1, \text{ so OK}]$$

From Eq. 45.8, the Euler stress is

$$\begin{aligned} \sigma_e &= \frac{\pi^2 E}{\left(\frac{L}{r}\right)^2} = \frac{\pi^2 (2.9 \times 10^7 \text{ lbf/in}^2)}{(179.3)^2} \\ &= 8903 \text{ lbf/in}^2 \end{aligned}$$

Since  $8903 \text{ lbf/in}^2$  is less than half of the yield strength of  $36,000 \text{ lbf/in}^2$ , the Euler formula is valid. The allowable working stress is

$$\begin{aligned} \sigma_a &= \frac{\sigma_e}{\text{FS}} = \frac{8903 \text{ lbf}}{3} \\ &= 2968 \text{ lbf/in}^2 \end{aligned}$$

**4. INTERMEDIATE COLUMNS**

Columns with slenderness ratios less than the critical slenderness ratio, but that are too long to be short piers, are known as *intermediate columns*. The *parabolic formula* (also known as the *J.B. Johnson formula*) is used to describe the parabolic line between points A and T on Fig. 45.1. The critical stress is given by Eq. 45.12, where  $a$  and  $b$  are curve-fit constants.

$$\sigma_{\text{cr}} = \frac{F_{\text{cr}}}{A} = a - b\left(\frac{KL}{r}\right)^2 \quad 45.12$$

It is commonly assumed that the stress at point A is  $S_y$  and the stress at point T is  $\frac{1}{2}S_y$ . In that case, the parabolic formula becomes

$$\sigma_{\text{cr}} = S_y - \left(\frac{1}{E}\right) \left(\frac{S_y}{2\pi}\right)^2 \left(\frac{KL}{r}\right)^2 \quad 45.13$$

**5. ECCENTRICALLY LOADED COLUMNS**

Accidental eccentricities are introduced during the course of normal manufacturing, so the load on real columns is rarely axial. The *secant formula* is one of the methods available for determining the critical column stress and critical load with eccentric loading.<sup>4</sup>

$$\begin{aligned} \sigma_{\text{max}} &= \sigma_{\text{ave}}(1 + \text{amplification factor}) \\ &= \left(\frac{F}{A}\right) \left(1 + \left(\frac{ec}{r^2}\right) \sec\left(\frac{\pi}{2} \sqrt{\frac{F}{F_e}}\right)\right) \\ &= \left(\frac{F}{A}\right) \left(1 + \left(\frac{ec}{r^2}\right) \sec\left(\frac{L}{2r} \sqrt{\frac{F}{AE}}\right)\right) \\ &= \left(\frac{F}{A}\right) \left(1 + \left(\frac{ec}{r^2}\right) \sec\phi\right) \end{aligned} \quad 45.14$$

$$\phi = \frac{1}{2} \left(\frac{L}{r}\right) \sqrt{\frac{F}{AE}} \quad 45.15$$

For a given *eccentricity*,  $e$ , or eccentricity ratio,  $ec/r^2$ , and an assumed value of the buckling load,  $F$ , Eq. 45.15 is solved by trial and error for the slenderness ratio,  $L/r$ . Equation 45.14 and Eq. 45.15 converge quickly to the known  $L/r$  ratio when assumed values of  $F$  are substituted. ( $L/r$  is smaller when  $F$  is larger.)

**6. THIN-WALLED CYLINDRICAL TANKS**

In general, tanks under internal pressure experience circumferential, longitudinal, and radial stresses. If the wall thickness is small, the radial stress component is negligible and can be disregarded. A cylindrical tank is a *thin-walled tank* if its wall thickness-to-internal diameter ratio is less than approximately 0.1.<sup>5</sup>

$$\frac{t}{d_i} = \frac{t}{2r_i} < 0.1 \quad [\text{thin-walled}] \quad 45.16$$

The *hoop stress*,  $\sigma_h$ , also known as *circumferential stress* and *tangential stress*, for a cylindrical thin-walled tank under internal pressure is derived from the free-body

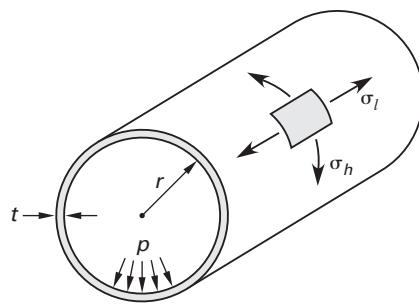

<sup>4</sup>The design of timber, steel, and reinforced concrete building columns is very code intensive. None of the theoretical methods presented in this section is acceptable for building design.

<sup>5</sup>There is overlap in the thin-wall/thick-wall criterion. The limiting ratios between thin- and thick-walled cylinders are matters of the accuracy desired. Lamé's solution can always be used for both thick- and thin-walled cylinders.

diagram of a cylinder half.<sup>6</sup> (See Fig. 45.2.) Since the cylinder is assumed to be thin-walled, it is not important which radius (e.g., inner, mean, or outer) is used in Eq. 45.17. By common convention, the inner radius is used in theoretical and academic analyses. However, certain codes and standards (e.g., 49 CFR Part 195.106, ASME B31.3, B31.4, and B31.8) require use of the outer radius with their code-specific equations.

$$\sigma_h = \frac{pr}{t} \quad 45.17$$

**Figure 45.2** Stresses in a Thin-Walled Tank

The axial forces on the ends of the cylindrical tank produce a stress, known as the *longitudinal stress* or *long stress*,  $\sigma_l$ , directed along the tank's longitudinal axis.

$$\sigma_l = \frac{pr}{2t} \quad 45.18$$

Unless the tank is subject to torsion, there is no external shear stress. Accordingly, the hoop and long stresses are the principal normal stresses. They do not combine into larger stresses. Their effect should be evaluated according to the appropriate failure theory. The maximum in-plane shear stress is  $pr/4t$ , while the maximum out-of-plane shear stress (corresponding to a  $45^\circ$  rotation of the plane stress element about the longitudinal axis) is  $pr/2t$ .

The increase in length due to pressurization is easily determined from the longitudinal strain.

$$\Delta L = L\epsilon_l = L \left( \frac{\sigma_l - \nu\sigma_h}{E} \right) \quad 45.19$$

The increase in circumference (from which the radial increase can also be determined) due to pressurization is

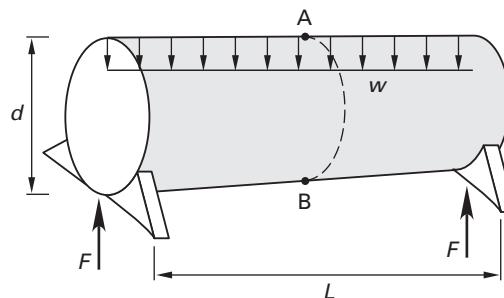

$$\Delta C = C\epsilon_h = \pi d_o \left( \frac{\sigma_h - \nu\sigma_l}{E} \right) \quad 45.20$$

### Example 45.2

A thin-walled pressurized tank is supported at both ends, as shown. Points A and B are located midway between the supports and at the upper and lower

<sup>6</sup>There is no simple way, including the more exact Lamé's solution, of evaluating theoretical stresses in thin-walled cylinders under external pressure, since failure is by collapse, not yielding. However, empirical equations exist for predicting the *collapsing pressure*.

surfaces, respectively. Evaluate the maximum stresses on the tank.

### Solution

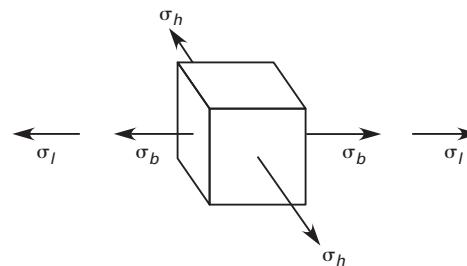

Since the tank is thin-walled, the radial stress is essentially zero. The hoop and longitudinal stresses are given by Eq. 45.17 and Eq. 45.18, respectively. Point A also experiences a bending stress due to the weight of the tank and contents. The bending stress is

$$\sigma_b = \frac{Mc}{I}$$

$$c = \frac{d}{2} = r$$

$$M = \frac{FL}{2} = \frac{wL^2}{8}$$

$$I = \frac{\pi}{4}(r_o^4 - r_i^4) \approx \pi r^3 t$$

The bending stress is compressive at point A and tensile at point B. At point B, the bending stress has the same sign (tensile) as the longitudinal stress, and these two stresses add to each other. There is no torsional stress, so the resultant normal stresses are the principal stresses.

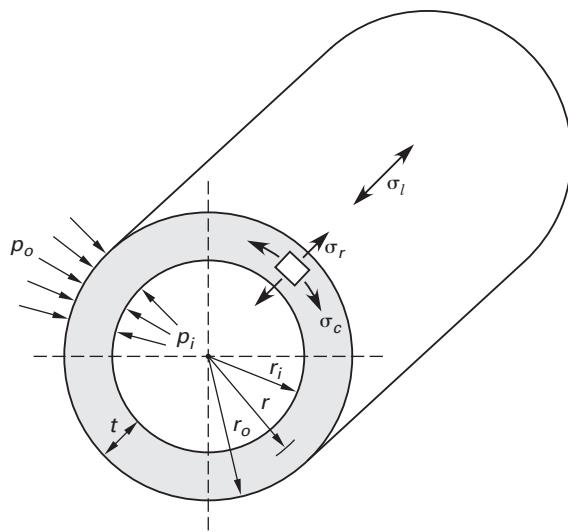

$$\sigma_1 = \sigma_h$$

$$\sigma_2 = \sigma_l + \sigma_b$$

### 7. THICK-WALLED CYLINDERS

A thick-walled cylinder has a wall thickness-to-radius ratio greater than 0.2 (i.e., a wall thickness-to-diameter ratio greater than 0.1). Figure 45.3 illustrates a thick-walled tank under either internal or external pressure.

In thick-walled tanks, radial stress is significant and cannot be disregarded. In *Lamé's solution*, a thick-walled cylinder is assumed to be made up of thin laminar rings.

**Figure 45.3** Thick-Walled Cylinder

This method shows that the radial and circumferential stresses vary with location within the tank wall. (The term *circumferential stress* is preferred over *hoop stress* when dealing with thick-walled cylinders.) Compressive stresses are negative.

$$\sigma_c = \frac{r_i^2 p_i - r_o^2 p_o + \frac{(p_i - p_o) r_i^2 r_o^2}{r^2}}{r_o^2 - r_i^2} \quad 45.21$$

$$\sigma_r = \frac{r_i^2 p_i - r_o^2 p_o - \frac{(p_i - p_o) r_i^2 r_o^2}{r^2}}{r_o^2 - r_i^2} \quad 45.22$$

$$\sigma_l = \frac{p_i r_i^2}{r_o^2 - r_i^2} \quad \left[ \begin{array}{l} p_o \text{ does not act} \\ \text{longitudinally on the ends} \end{array} \right] \quad 45.23$$

At every point in the cylinder, the circumferential, radial, and long stresses are the principal stresses. Unless an external torsional shear stress is added, it is not necessary to use the combined stress equations. Failure theories can be applied directly.

The cases of main interest are those of internal or external pressure only. The stress equations for these cases are summarized in Table 45.2. The maximum shear and normal stresses occur at the inner surface for both internal and external pressure.

The *diametral strain* (which is the same as the *circumferential* and *radial strains*) is given by Eq. 45.24. Radial stresses are always compressive (and negative), and algebraic signs must be observed with Eq. 45.24. Since the circumferential and radial stresses depend on location

**Table 45.2** Stresses in Thick-Walled Cylinders\*

stress	external pressure, \$p\$	internal pressure, \$p\$
\$\sigma_{c,o}\$	\$\frac{(r_o^2 + r_i^2)p_o}{r_o^2 - r_i^2}\$	\$\frac{2r_i^2 p_i}{r_o^2 - r_i^2}\$
\$\sigma_{r,o}\$	\$-p_o\$	0
\$\sigma_{c,i}\$	\$\frac{-2r_o^2 p_o}{r_o^2 - r_i^2}\$	\$\frac{(r_o^2 + r_i^2)p_i}{r_o^2 - r_i^2}\$
\$\sigma_{r,i}\$	0	\$-p_i\$
\$\tau_{\max}\$	\$\frac{1}{2}\sigma_{c,i}\$	\$\frac{1}{2}(\sigma_{c,i} + p_i)\$

\*This table can be used with thin-walled cylinders. However, in most cases it will not be necessary to do so.

within the wall thickness, the strain can be evaluated at inner, outer, and any intermediate locations within the wall.

$$\epsilon = \frac{\Delta d}{d} = \frac{\Delta C}{C} = \frac{\Delta r}{r} = \frac{\sigma_c - \nu(\sigma_r + \sigma_l)}{E} \quad 45.24$$

## 8. THIN-WALLED SPHERICAL TANKS

There is no unique axis in a spherical tank or in the spherical ends of a cylindrical tank. The hoop and long stresses are identical.

$$\sigma = \frac{pr}{2t} \quad 45.25$$

## 9. INTERFERENCE FITS

When assembling two pieces, interference fitting is often more economical than pinning, keying, or splining. The assembly operation can be performed in a hydraulic press, either with both pieces at room temperature or after heating the outer piece and cooling the inner piece. The former case is known as a *press fit* or *interference fit*; the latter as a *shrink fit*.

If two cylinders are pressed together, the pressure acting between them will expand the outer cylinder (placing it into tension) and will compress the inner cylinder. The *interference*, \$I\$, is the difference in dimensions between the two cylinders. *Diametral interference* and *radial interference* are both used.<sup>7</sup>

$$\begin{aligned} I_{\text{diametral}} &= 2I_{\text{radial}} = d_{o,\text{inner}} - d_{i,\text{outer}} \\ &= |\Delta d_{o,\text{inner}}| + |\Delta d_{i,\text{outer}}| \end{aligned} \quad 45.26$$

<sup>7</sup>Theoretically, the interference can be given to either the inner or outer cylinder, or it can be shared by both cylinders. However, in the case of a surface-hardened shaft with a standard diameter, all of the interference is usually given to the disk. Otherwise, it may be necessary to machine the shaft and remove some of the hardened surface.

If the two cylinders have the same length, the thick-wall cylinder equations can be used. The materials used for the two cylinders do not need to be the same. Since there is no longitudinal stress from an interference fit and since the radial stress is negative, the strain from Eq. 45.24 is

$$\epsilon = \frac{\Delta d}{d} = \frac{\Delta C}{C} = \frac{\Delta r}{r} = \frac{\sigma_c - \nu\sigma_r}{E} \quad 45.27$$

Equation 45.28 applies to the general case where both cylinders are hollow and have different moduli of elasticity and Poisson's ratios. The outer cylinder is designated as the *hub*; the inner cylinder is designated as the *shaft*. If the shaft is solid, use  $r_{i,\text{shaft}} = 0$  in Eq. 45.28.

$$\begin{aligned} I_{\text{diametral}} &= 2I_{\text{radial}} \\ &= \left( \frac{2pr_{o,\text{shaft}}}{E_{\text{hub}}} \right) \left( \frac{r_{o,\text{hub}}^2 + r_{o,\text{shaft}}^2}{r_{o,\text{hub}}^2 - r_{o,\text{shaft}}^2} + \nu_{\text{hub}} \right) \\ &\quad + \left( \frac{2pr_{o,\text{shaft}}}{E_{\text{shaft}}} \right) \left( \frac{r_{o,\text{shaft}}^2 + r_{i,\text{shaft}}^2}{r_{o,\text{shaft}}^2 - r_{i,\text{shaft}}^2} - \nu_{\text{shaft}} \right) \end{aligned} \quad 45.28$$

In the special case where the shaft is solid and is made from the same material as the hub, the diametral interference is given by Eq. 45.29.

$$\begin{aligned} I_{\text{diametral}} &= 2I_{\text{radial}} \\ &= \left( \frac{4pr_{\text{shaft}}}{E} \right) \left( \frac{1}{1 - \left( \frac{r_{\text{shaft}}}{r_{o,\text{hub}}} \right)^2} \right) \end{aligned} \quad 45.29$$

The maximum assembly force required to overcome friction during a press-fitting operation is given by Eq. 45.30. This relationship is approximate because the coefficient of friction is not known with certainty, and the assembly force affects the pressure,  $p$ , through Poisson's ratio. The coefficient of friction is highly variable. Values in the range of 0.03–0.33 have been reported. In the absence of experimental data, it is reasonable to use 0.12 for lightly oiled connections and 0.15 for dry assemblies.

$$F_{\max} = fN = 2\pi fpr_{o,\text{shaft}} L_{\text{interface}} \quad 45.30$$

The maximum torque that the press-fitted hub can withstand or transmit is given by Eq. 45.31. This can be greater or less than the shaft's torsional shear capacity. Both values should be calculated.

$$T_{\max} = 2\pi fpr_{o,\text{shaft}}^2 L_{\text{interface}} \quad 45.31$$

Most interference fits are designed to keep the contact pressure or the stress below a given value. Designs of interference fits limited by strength generally use the

distortion energy failure criterion. That is, the maximum shear stress is compared with the shear strength determined from the failure theory.

### Example 45.3

A steel cylinder has inner and outer diameters of 1.0 in and 2.0 in, respectively. The cylinder is pressurized internally to 10,000 lbf/in<sup>2</sup>. The modulus of elasticity is  $2.9 \times 10^7$  lbf/in<sup>2</sup>, and Poisson's ratio is 0.3. What is the radial strain at the inside face?

*Solution*

The longitudinal stress is

$$\begin{aligned} \sigma_l &= \frac{F}{A} = \frac{p_i \pi r_i^2}{\pi(r_o^2 - r_i^2)} = \frac{p_i r_i^2}{r_o^2 - r_i^2} \\ &= \frac{\left( 10,000 \frac{\text{lbf}}{\text{in}^2} \right) (0.5 \text{ in})^2}{(1.0 \text{ in})^2 - (0.5 \text{ in})^2} \\ &= 3333 \text{ lbf/in}^2 \end{aligned}$$

The stresses at the inner face are found from Table 45.2.

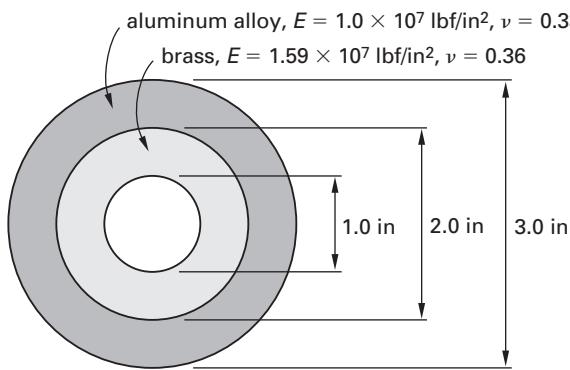

$$\begin{aligned} \sigma_{c,i} &= \frac{(r_o^2 + r_i^2)p}{r_o^2 - r_i^2} \\ &= \frac{\left( (1.0 \text{ in})^2 + (0.5 \text{ in})^2 \right) \left( 10,000 \frac{\text{lbf}}{\text{in}^2} \right)}{(1.0 \text{ in})^2 - (0.5 \text{ in})^2} \\ &= 16,667 \text{ lbf/in}^2 \\ \sigma_{r,i} &= -p = -10,000 \text{ lbf/in}^2 \end{aligned}$$

The circumferential and radial stresses increase the radial strain; the longitudinal stress decreases the radial strain. The radial strain is

$$\begin{aligned} \frac{\Delta r}{r} &= \frac{\sigma_{c,i} - \nu(\sigma_{r,i} + \sigma_l)}{E} \\ &= \frac{16,667 \frac{\text{lbf}}{\text{in}^2} - (0.3)(-10,000 \frac{\text{lbf}}{\text{in}^2} + 3333 \frac{\text{lbf}}{\text{in}^2})}{2.9 \times 10^7 \frac{\text{lbf}}{\text{in}^2}} \\ &= 6.44 \times 10^{-4} \end{aligned}$$

### Example 45.4

A hollow aluminum cylinder is pressed over a hollow brass cylinder as shown. Both cylinders are 2 in long. The interference is 0.004 in. The average coefficient of friction during assembly is 0.25. (a) What is the maximum shear stress in the brass? (b) What initial disassembly force is required to separate the two cylinders?

*Solution*

(a) Work with the aluminum outer cylinder, which is under internal pressure.

$$\sigma_{c,i} = \frac{(r_o^2 + r_i^2)p}{r_o^2 - r_i^2} = \frac{((1.5 \text{ in})^2 + (1.0 \text{ in})^2)p}{(1.5 \text{ in})^2 - (1.0 \text{ in})^2}$$

$$= 2.6p$$

$$\sigma_{r,i} = -p$$

From Eq. 45.24, the diametral strain is

$$\epsilon = \frac{\sigma_{c,i} - \nu(\sigma_{r,i} + \sigma_l)}{E} = \frac{2.6p - 0.33(-p)}{1.0 \times 10^7 \frac{\text{lbf}}{\text{in}^2}}$$

$$= 2.93 \times 10^{-7} p$$

$$\Delta d = \epsilon d = (2.93 \times 10^{-7} p)(2.0 \text{ in})$$

$$= 5.86 \times 10^{-7} p$$

Now work with the brass inner cylinder, which is under external pressure. Use Table 45.2.

$$\sigma_{c,o} = \frac{-(r_o^2 + r_i^2)p}{r_o^2 - r_i^2} = \frac{-((1.0 \text{ in})^2 + (0.5 \text{ in})^2)p}{(1.0 \text{ in})^2 - (0.5 \text{ in})^2}$$

$$= -1.667p$$

$$\sigma_{r,o} = -p$$

From Eq. 45.24, the diametral strain is

$$\epsilon = \frac{\sigma_{c,o} - \nu(\sigma_{r,o} + \sigma_l)}{E}$$

$$= \frac{-1.667p - 0.36(-p)}{1.59 \times 10^7 \frac{\text{lbf}}{\text{in}^2}}$$

$$= -0.822 \times 10^{-7} p$$

$$\Delta d = \epsilon d = (-0.822 \times 10^{-7} p)(2.0 \text{ in})$$

$$= -1.644 \times 10^{-7} p$$

The diametral interference is known to be 0.004 in. From Eq. 45.26,

$$I_{\text{diametral}} = |\Delta d_{o,\text{inner}}| + |\Delta d_{i,\text{outer}}|$$

$$0.004 \text{ in} = |5.86 \times 10^{-7} p| + |-1.644 \times 10^{-7} p|$$

$$p = 5330 \text{ lbf/in}^2$$

(Equation 45.28 could have been used to find  $p$  directly.)

From Table 45.2, the circumferential stress at the inner face of the brass (under external pressure) is

$$\sigma_{c,i} = \frac{-2r_o^2 p}{r_o^2 - r_i^2} = \frac{(-2)(1.0 \text{ in})^2 \left(5330 \frac{\text{lbf}}{\text{in}^2}\right)}{(1.0 \text{ in})^2 - (0.5 \text{ in})^2}$$

$$= -14,213 \text{ lbf/in}^2$$

Also from Table 45.2, the maximum shear stress is

$$\tau_{\max} = \frac{1}{2}\sigma_{c,i} = \left(\frac{1}{2}\right)\left(-14,213 \frac{\text{lbf}}{\text{in}^2}\right)$$

$$= -7107 \text{ lbf/in}^2$$

(b) The initial force necessary to disassemble the two cylinders is the same as the maximum assembly force. Use Eq. 45.30.

$$F_{\max} = 2\pi f p r_{\text{shaft}} L_{\text{interface}}$$

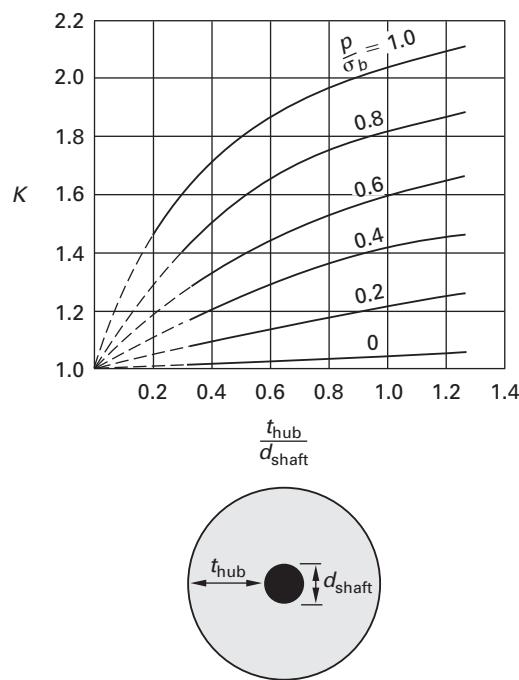

$$= (2\pi)(0.25)\left(5330 \frac{\text{lbf}}{\text{in}^2}\right)(1 \text{ in})(2 \text{ in})$$

$$= 16,745 \text{ lbf}$$

## 10. STRESS CONCENTRATIONS FOR PRESS-FITTED SHAFTS IN FLEXURE

When a shaft carrying a press-fitted hub (whose thickness is less than the shaft length) is loaded in flexure, there will be an increase in shaft bending stress in the vicinity of the inner hub edge. The fatigue life of the shaft can be seriously affected by this stress increase. The extent of the increase depends on the magnitude of the bending stress,  $\sigma_b$ , and the contact pressure,  $p$ , and can be as high as 2.0 or more.

Some designs attempt to reduce the increase in shaft stress by grooving the disk (to allow the disk to flex). Other designs rely on various treatments to increase the fatigue strength of the shaft. For an unmodified simple press-fit, the multiplicative stress concentration factor (to be applied to the bending stress calculated from  $\sigma_b = Mc/I$ ) is given by Fig. 45.4.

**Figure 45.4** Stress Concentration Factors for Press Fits

## 11. BOLTS

There are three leading specifications for bolt thread families: ANSI, ISO metric, and DIN metric.<sup>8</sup> ANSI (essentially identical to SAE, ASTM, and ISO-inch standard) is widely used in the United States. Deutches Institut für Normung (DIN) fasteners are widely available and broadly accepted.<sup>9</sup> ISO metric (the International Organization for Standardization) fasteners are used in large volume by U.S. car manufacturers. The CEN (European Committee for Standardization) standards promulgated by the European Community (EC) have essentially adopted the ISO standards.

An American National (Unified) thread is specified by the sequence of parameters S(×L)-N-F-A-(H-E), where S is the thread outside diameter (nominal size), L is the optional shank length, N is the number of threads per inch, F is the thread pitch family, A is the class (allowance), and H and E are the optional hand and engagement length designations. The letter R can be added to the thread pitch family to indicate that the thread roots are radiused (for better fatigue resistance). For example, a  $\frac{3}{8} \times 1\text{-}16\text{UNC-2A}$  bolt has a  $\frac{3}{8}$  in diameter, a 1 in

**Table 45.3** Representative American National (United) Bolt Thread Designations<sup>a</sup>

S	Size 1–12 $\frac{1}{4}$ – $\frac{9}{16}$ in in $\frac{1}{16}$ in increments $\frac{5}{8}$ – $1\frac{1}{2}$ in in $\frac{1}{8}$ in increments $1\frac{3}{4}$ –4 in in $\frac{1}{4}$ in increments
F	Thread Family UNC and NC—Unified Coarse <sup>b</sup> UNF and NF—Unified Fine <sup>b</sup> UNEF and NEF—Unified Extra Fine <sup>c</sup> 8N—8 threads per inch 12UN and 12N—12 threads per inch 16UN and 16N—16 threads per inch UN, UNS, and NS—special series
A	Allowance (A—external threads, B—internal threads) <sup>d</sup> 1A and 1B—liberal allowance for each of assembly with dirty or damaged threads 2A and 2B—normal production allowance (sufficient for plating) 3A and 3B—close tolerance work with no allowance
H	Hand blank—right-hand thread LH—left-hand thread

<sup>a</sup>In addition to fastener thread families, there are other special-use threads, such as Acme, stub, square, buttress, and worm series.

<sup>b</sup>Previously known as United States Standard or American Standard.

<sup>c</sup>The UNEF series is the same as the Society of Automotive Engineers (SAE) fine series.

<sup>d</sup>Allowance classes 2 and 3 (without the A and B designation) were used prior to industry transition to the Unified classes.

length, and 16 Unified Coarse threads per inch rolled with a class 2A accuracy.<sup>10</sup> A UNRC bolt would be identical except for radiused roots. Table 45.3 lists some (but not all) values for these parameters.

The *grade* of a bolt indicates the fastener material and is marked on the bolt cap.<sup>11</sup> In this regard, the marking depends on whether an SAE grade or ASTM designation is used. The minimum *proof load* (i.e., the maximum stress the bolt can support without acquiring a permanent set) increases with the grade. (The term *proof strength* is less common.) Table 45.4 lists how the caps of the bolts are marked to distinguish among the major grades.<sup>12</sup> If a bolt is manufactured in the United States, its cap must also show the logo or mark of the manufacturer.

A metric thread is specified by an M or MJ and a diameter and a pitch in millimeters, in that order. For example, M10 × 1.5 is a thread having a nominal major diameter of 10 mm and a pitch of 1.5 mm. The MJ series have rounded root fillets and larger minor diameters.

<sup>8</sup>Other fastener families include the Italian UNI, Swiss VSM, Japanese JIS, and United Kingdom's BS series.

<sup>9</sup>To add to the confusion, many DIN standards are identical to ISO standards, with only slight differences in the tolerance ranges. However, the standards are not interchangeable in every case.

<sup>10</sup>Threads are generally rolled, not cut, into a bolt.

<sup>11</sup>The *type* of a structural bolt should not be confused with the *grade* of a structural rivet.

<sup>12</sup>Optional markings can also be used.

Head markings on metric bolts indicate their *property class* and correspond to the approximate tensile strength in MPa divided by 100. For example, a bolt marked 8.8 would correspond to a medium carbon, quenched and tempered bolt with an approximate tensile strength of 880 MPa. (The minimum of the tensile strength range for property class 8.8 is 830 MPa.) (See Table 45.5.)

## 12. RIVET AND BOLT CONNECTIONS

Figure 45.5 illustrates a tension *lap joint* connection using rivet or bolt connectors.<sup>13</sup> Unless the plate material is very thick, the effects of eccentricity are

<sup>13</sup>Rivets are no longer used in building construction, but they are still extensively used in manufacturing.

\*Based on ANSI B1.1.

**Figure 45.5** Tension Lap Joint

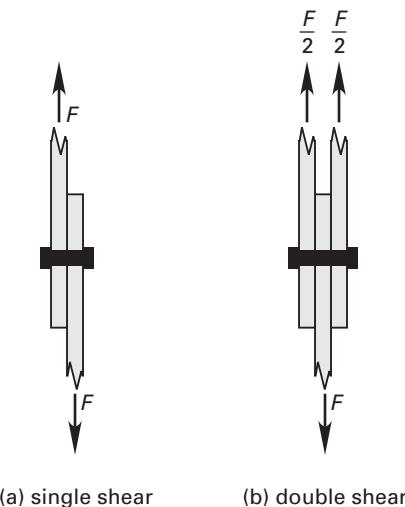

disregarded. A connection of this type can fail in shear, tension, or bearing. A common design procedure is to determine the number of connectors based on shear stress and then to check the bearing and tensile stresses.

One of the failure modes is shearing of the connectors. In the case of *single shear*, each connector supports its proportionate share of the load. In *double shear*, each connector has two shear planes, and the stress per

connector is halved.<sup>14</sup> (See Fig. 45.6.) The shear stress in a cylindrical connector is

$$\tau = \frac{F}{A} = \frac{F}{\frac{\pi d^2}{4}} \quad 45.32$$

**Figure 45.6** Single and Double Shear

The number of required connectors, as determined by shear, is

$$n = \frac{\tau}{\text{allowable shear stress}} \quad 45.33$$

The plate can fail in tension. Although the design of structural steel building members in tension is codified, theoretically, if there are  $n$  connector holes of diameter  $d$  in a line across the width,  $b$ , of the plate, the cross-sectional area in the plate remaining to resist the tension is

$$A_t = t(b - nd) \quad 45.34$$

The number of connectors across the plate width must be chosen to keep the tensile stress less than the allowable stress. The maximum tensile stress in the plate will be

$$\sigma_t = \frac{F}{A_t} \quad 45.35$$

The plate can also fail by *bearing* (i.e., crushing). The number of connectors must be chosen to keep the actual

<sup>14</sup>"Double shear" is not the same as "double rivet" or "double butt." *Double shear* means that there are two shear planes in one rivet. *Double rivet* means that there are two rivets along the force path. *Double butt* refers to the use of two backing plates (i.e., "scabs") used on either side to make a tension connection between two plates. Similarly, *single butt* refers to the use of a single backing plate to make a tension connection between two plates.

bearing stress below the allowable bearing stress. For one connector, the bearing stress in the plate is

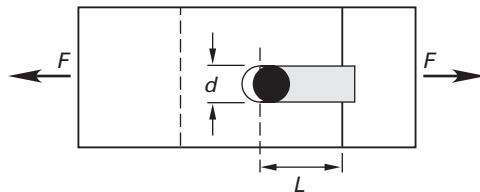

$$\sigma_p = \frac{F}{dt} \quad 45.36$$

$$n = \frac{\sigma_p}{\sigma_{a,\text{bearing}}} \quad 45.37$$

The plate can also fail by shear tear-out, as illustrated in Fig. 45.7. The shear stress is

$$\tau = \frac{F}{2A} = \frac{F}{2dL} \quad 45.38$$

**Figure 45.7** Shear Tear-Out

The *joint efficiency* is the ratio of the strength of the joint divided by the strength of a solid (i.e., unpunched or undrilled) plate.

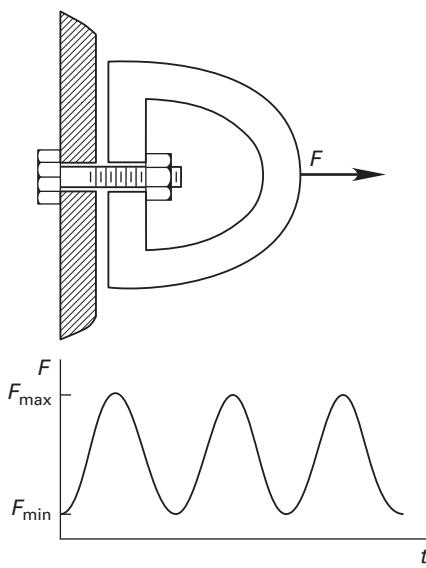

### 13. BOLT PRELOAD

Consider the ungasketed connection shown in Fig. 45.8. The load varies from  $F_{\min}$  to  $F_{\max}$ . If the bolt is initially snug but without initial tension, the force in the bolt also will vary from  $F_{\min}$  to  $F_{\max}$ . If the bolt is tightened so that there is an initial *preload force*,  $F_i$ , greater than  $F_{\max}$  in addition to the applied load, the bolt will be placed in tension and the parts held together will be in compression.<sup>15</sup> When a load is applied, the bolt tension will increase even more, but the compression in the parts will decrease.

The amount of compression in the parts will vary as the applied load varies. The clamped members will carry some of the applied load, since this varying load has to "uncompress" the clamped part as well as lengthen the bolt. The net result is the reduction of the variation of the force in the bolt. The initial tension produces a larger mean stress, but the overall result is the reduction of the alternating stress. Preloading is an effective method of reducing the alternating stress in bolted tension connections.

It is convenient to define the *spring constant*,  $k$ , of the bolt. The *grip*,  $L$ , is the thickness of the parts being connected by the bolt (not the bolt length). It is

**Figure 45.8** Bolted Tension Joint with Varying Load

common to use the nominal diameter of the bolt, disregarding the reduction due to threading.

$$k_{\text{bolt}} = \frac{F}{\Delta L} = \frac{A_{\text{bolt}} E_{\text{bolt}}}{L} \quad 45.39$$

The actual spring constant for a bolted part,  $k_{\text{part}}$ , is difficult to determine if the clamped area is not small and well defined. The only accurate way to determine the stiffness of a part in a bolted joint is through experimentation. If the clamped parts are flat plates, various theories can be used to calculate the effective load-bearing areas of the flanges, but doing so is a laborious process.

One simple rule of thumb is that the bolt force spreads out to three times the bolt-hole diameter. Of course, the hole diameter needs to be considered (i.e., needs to be subtracted) in calculating the effective force area. If the modulus of elasticity is the same for the bolt and the clamped parts, using this rule of thumb, the larger area results in the parts being eight times stiffer than the bolts.

$$k_{\text{parts}} = \frac{A_{e,\text{parts}} E_{\text{parts}}}{L} \quad 45.40$$

If the clamped parts have different moduli of elasticity, or if a gasket constitutes one of the layers compressed by the bolt, the composite spring constant can be found from Eq. 45.41.<sup>16</sup>

$$\frac{1}{k_{\text{parts,composite}}} = \frac{1}{k_1} + \frac{1}{k_2} + \frac{1}{k_3} + \dots \quad 45.41$$

<sup>15</sup>If the initial preload force is less than  $F_{\max}$ , the bolt may still carry a portion of the applied load. Equation 45.43 can be solved for the value of  $F$  that will result in a loss of compression ( $F_{\text{parts}} = 0$ ) and cause the bolt to carry the entire applied load.

<sup>16</sup>If a soft washer or gasket is used, its spring constant can control Eq. 45.41.

The bolt and the clamped parts all carry parts of the applied load,  $F_{\text{applied}}$ .  $F_i$  is the initial preload force.

$$F_{\text{bolt}} = F_i + \frac{k_{\text{bolt}} F_{\text{applied}}}{k_{\text{bolt}} + k_{\text{parts}}} \quad 45.42$$

$$F_{\text{parts}} = \frac{k_{\text{parts}} F_{\text{applied}}}{k_{\text{bolt}} + k_{\text{parts}}} - F_i \quad 45.43$$

O-ring (metal and elastomeric) seals permit metal-to-metal contact and affect the effective spring constant of the parts very little. However, the seal force tends to separate bolted parts and must be added to the applied force. The seal force can be obtained from the seal deflection and seal stiffness or from manufacturer's literature.

For static loading, recommended amounts of preloading often are specified as a percentage of the *proof load* (or *proof strength*) in psi or MPa.<sup>17</sup> For bolts, the proof load is slightly less than the yield strength. Traditionally, preload has been specified conservatively as 75% of proof for reusable connectors and 90% of proof for one-use connectors.<sup>18</sup> Connectors with some ductility can safely be used beyond the yield point, and 100% is now in widespread use.<sup>19</sup> When understood, advantages of preloading to 100% of proof load often outweigh the disadvantages.<sup>20</sup>

If the applied load varies, the forces in the bolt and parts will also vary. In that case, the preload must be determined from an analysis of the Goodman line.

Tightening of a tension bolt will induce a torsional stress in the bolt.<sup>21</sup> Where the bolt is to be locked in place, the torsional stress can be removed without greatly affecting the preload by slightly backing off the bolt. If the bolt is subject to cyclic loading, the bolt will probably slip back by itself, and it is reasonable to neglect the effects of torsion in the bolt altogether. (This is the reason that well-designed connections allow for a loss of 5–10% of the initial preload during routine use.)

Stress concentrations at the beginning of the threaded section are significant in cyclic loading.<sup>22</sup> To avoid a

<sup>17</sup>This is referred to as a "rule of thumb" specification, because a mathematical analysis is not performed to determine the best preload.

<sup>18</sup>Some U.S. military specifications call for 80% of proof load in tension fasteners and only 30% for shear fasteners. The object of keeping the stresses below yielding is to be able to reuse the bolts.

<sup>19</sup>Even under normal elastic loading of a bolt, local plastic deformation occurs in the bolt-head fillet and thread roots. Since the stress-strain curve is nearly flat at the yield point, a small amount of elongation into the plastic region does not increase the stress or tension in the bolt.

<sup>20</sup>The disadvantages are (a) field maintenance probably will not be possible, as manually running up bolts to 100% proof will result in many broken bolts; (b) bolts should not be reused, as some will have yielded; and (c) the highest-strength bolts do not exhibit much plastic elongation and ordinarily should not be run up to 100% proof load.

<sup>21</sup>An argument for the conservative 75% of proof load preload limit is that the residual torsional stress will increase the bolt stress to 90% or higher anyway, and the additional 10% needed to bring the preload up to 100% probably will not improve economic performance much.

<sup>22</sup>Stress concentrations are frequently neglected for static loading.

reduction in fatigue life, the alternating stress used in the Goodman line should be multiplied by an appropriate stress concentration factor,  $K$ . For fasteners with rolled threads, an average factor of 2.2 for SAE grades 0–2 (metric grades 3.6–5.8) is appropriate. For SAE grades 4–8 (metric grades 6.6–10.9), an average factor of 3.0 is appropriate. Stress concentration factors for the fillet under the bolt head are different, but lower than these values. Stress concentration factors for cut threads are much higher.

The stress in a bolt depends on its load-carrying area. This area is typically obtained from a table of bolt properties. In practice, except for loading near the bolt's failure load, working stresses are low, and the effects of threads usually are ignored, so the area is based on the major (nominal) diameter.

$$\sigma_{\text{bolt}} = \frac{K F}{A} \quad 45.44$$

#### 14. BOLT TORQUE TO OBTAIN PRELOAD

During assembly, the preload tension is not monitored directly. Rather, the torque required to tighten the bolt is used to determine when the proper preload has been reached. Methods of obtaining the required preload include the standard torque wrench, the *run-of-the-nut method* (e.g., turning the bolt some specific angle past snugging torque), *direct-tension indicating* (DTI) washers, and computerized automatic assembly.

The standard manual torque wrench does not provide precise, reliable preloads, since the fraction of the torque going into bolt tension is variable.<sup>23</sup> Torque-, angle-, and time-monitoring equipment, usually part of an automated assembly operation, is essential to obtaining precise preloads on a consistent basis. It automatically applies the snugging torque and specified rotation, then checks the results with torque and rotation sensors. The computer warns of out-of-spec conditions.

The *Maney formula* is a simple relationship between the initial bolt tension,  $F_i$ , and the installation torque,  $T$ . The *torque coefficient*,  $K_T$  (also known as the *bolt torque factor* and the *nut factor*) used in Eq. 45.46 depends mainly on the coefficient of friction,  $f$ . The torque coefficient for lubricated bolts generally varies from 0.15 to 0.20, and a value of 0.2 is commonly used.<sup>24</sup> With anti-seize lubrication, it can drop as low as 0.12. (The torque coefficient is not the same as the coefficient of friction.)

$$T = K_T d_{\text{bolt}} F_i \quad 45.45$$

<sup>23</sup>Even with good lubrication, about 50% of the torque goes into overcoming friction between the head and collar/flange, another 40% is lost in thread friction, and only the remaining 10% goes into tensioning the connector.

<sup>24</sup>With a coefficient of friction of 0.15, the torque coefficient is approximately 0.20 for most bolt sizes, regardless of whether the threads are coarse or fine.

$$K_T = \frac{f_c r_c}{d_{\text{bolt}}} + \left( \frac{r_t}{d_{\text{bolt}}} \right) \left( \frac{\tan \theta + f_t \sec \alpha}{1 - f_t \tan \theta \sec \alpha} \right) \quad 45.46$$

$$\tan \theta = \frac{\text{lead per revolution}}{2\pi r_t} \quad 45.47$$

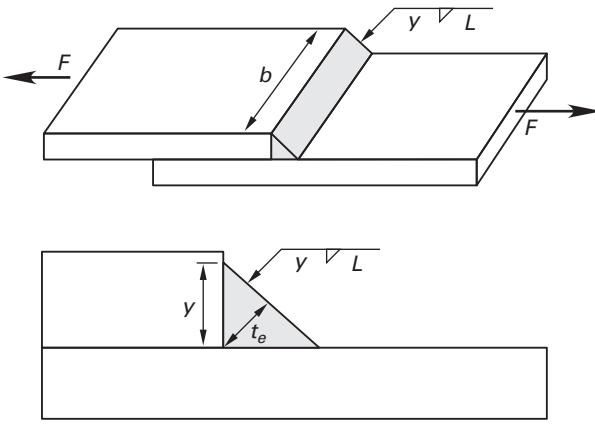

$f_c$  is the coefficient of friction at the collar (fastener bearing face).  $r_c$  is the mean collar radius (i.e., the effective radius of action of the friction forces on the bearing face).  $r_t$  is the effective radius of action of the frictional forces on the thread surfaces. Similarly,  $f_t$  is the coefficient of friction between the thread contact surfaces.  $\theta$  is the *lead angle*, also known as the *helix thread angle*.  $\alpha$  is the *thread half angle* ( $30^\circ$  for UNF threads), and  $d_{t,m}$  is the mean thread diameter.

## 15. FILLET WELDS

The common *fillet weld* is shown in Fig. 45.9. Such welds are used to connect one plate to another. The applied load,  $F$ , is assumed to be carried in shear by the *effective weld throat*. The *effective throat size*,  $t_e$ , is related to the weld size,  $y$ , by Eq. 45.48.

$$t_e = \frac{\sqrt{2}}{2} y \quad 45.48$$

Figure 45.9 Fillet Lap Weld and Symbol

Neglecting any increased stresses due to eccentricity, the shear stress in a fillet lap weld depends on the *effective throat thickness*,  $t_e$ , and is

$$\tau = \frac{F}{bt_e} \quad 45.49$$

Weld (filler) metal should have a strength equal to or greater than the base material. Properties of filler metals are readily available from their manufacturers and, for standard rated welding rods, from engineering handbooks.

## 16. CIRCULAR SHAFT DESIGN

Shear stress occurs when a shaft is placed in torsion. The shear stress at the outer surface of a bar of radius  $r$ , which is torsionally loaded by a torque,  $T$ , is

$$\tau = G\theta = \frac{Tr}{J} \quad 45.50$$

The total strain energy due to torsion is

$$U = \frac{T^2 L}{2GJ} \quad 45.51$$

$J$  is the shaft's polar moment of inertia. For a solid round shaft,

$$J = \frac{\pi r^4}{2} = \frac{\pi d^4}{32} \quad [\text{solid}] \quad 45.52$$

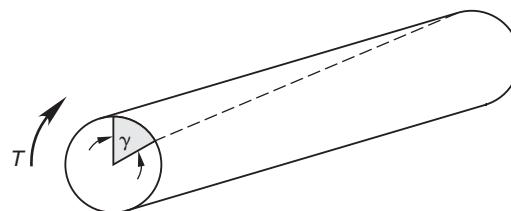

For a hollow round shaft,

$$J = \frac{\pi}{2} (r_o^4 - r_i^4) \quad [\text{hollow}] \quad 45.53$$

If a shaft of length  $L$  carries a torque  $T$ , as in Fig. 45.10, the angle of twist (in radians) will be

$$\gamma = \frac{L\theta}{r} = \frac{TL}{GJ} \quad 45.54$$

Figure 45.10 Torsional Deflection of a Circular Shaft

$G$  is the *shear modulus*. For steel, it is approximately  $11.5 \times 10^6 \text{ lbf/in}^2$  ( $8.0 \times 10^4 \text{ MPa}$ ). The shear modulus also can be calculated from the modulus of elasticity.

$$G = \frac{E}{2(1+\nu)} \quad 45.55$$

The torque,  $T$ , carried by a shaft spinning at  $n$  revolutions per minute is related to the transmitted power.

$$T_{\text{N}\cdot\text{m}} = \frac{9549 P_{\text{kW}}}{n_{\text{rpm}}} \quad [\text{SI}] \quad 45.56(a)$$

$$T_{\text{in-lbf}} = \frac{63,025 P_{\text{horsepower}}}{n_{\text{rpm}}} \quad [\text{U.S.}] \quad 45.56(b)$$

If a statically loaded shaft without axial loading experiences a bending stress,  $\sigma_x = Mc/I$  (i.e., is loaded in flexure), in addition to torsional shear

stress,  $\tau = Tr/J$ , the maximum shear stress from the combined stress theory is

$$\tau_{\max} = \sqrt{\left(\frac{\sigma_x}{2}\right)^2 + \tau^2} \quad 45.57$$

$$\tau_{\max} = \frac{16}{\pi d^3} \sqrt{M^2 + T^2} \quad 45.58$$

The equivalent normal stress from the distortion energy theory is

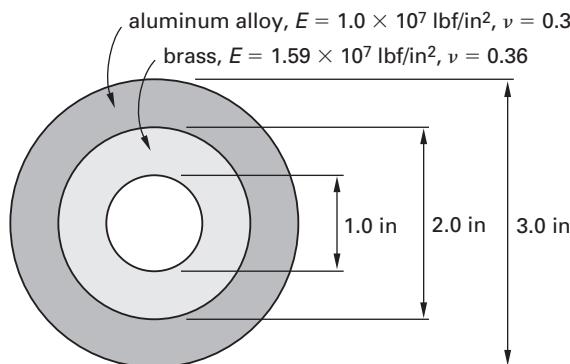

$$\sigma' = \frac{16}{\pi d^3} \sqrt{4M^2 + 3T^2} \quad 45.59$$

The diameter can be determined by setting the shear and normal stresses equal to the maximum allowable shear (as calculated from the maximum shear stress theory,  $S_y/2(\text{FS})$ , or from the distortion energy theory,  $\sqrt{3}S_y/2(\text{FS})$ , and normal stresses, respectively).

Equation 45.57 and Eq. 45.58 should not be used with dynamically loaded shafts (i.e., those that are turning). Fatigue design of shafts should be designed according to a specific code (e.g., ANSI or ASME) or should use a fatigue analysis (e.g., Goodman, Soderberg, or Gerber).

### Example 45.5

The press-fitted, aluminum alloy-brass cylinder described in Ex. 45.2 is used as a shaft. The press fit is adequate to maintain nonslipping contact between the two materials. The shaft carries a steady torque of 24,000 in-lbf. There is no bending stress. What is the maximum torsional shear stress in the (a) aluminum and (b) brass?

#### Solution

The stronger material (as determined from the shear modulus,  $G$ ) should be converted to an equivalent area of the weaker material.

From Eq. 45.55, for the aluminum,

$$G_{\text{aluminum}} = \frac{E}{2(1+\nu)} = \frac{1.0 \times 10^7 \text{ lbf/in}^2}{(2)(1+0.33)} = 3.76 \times 10^6 \text{ lbf/in}^2$$

From Eq. 45.55, for the brass,

$$G_{\text{brass}} = \frac{E}{2(1+\nu)} = \frac{1.59 \times 10^7 \text{ lbf/in}^2}{(2)(1+0.36)} = 5.85 \times 10^6 \text{ lbf/in}^2$$

Brass has the higher shear modulus. The modular shear ratio is

$$n = \frac{G_{\text{brass}}}{G_{\text{aluminum}}} = \frac{5.85 \times 10^6 \text{ lbf/in}^2}{3.76 \times 10^6 \text{ lbf/in}^2} = 1.56$$

The polar moment of inertia of the aluminum is

$$J_{\text{aluminum}} = \frac{\pi}{2} (r_o^4 - r_i^4) \\ = \left(\frac{\pi}{2}\right) ((1.5 \text{ in})^4 - (1.0 \text{ in})^4) \\ = 6.38 \text{ in}^4$$

The equivalent polar moment of inertia of the brass is

$$J_{\text{brass}} = n \left(\frac{\pi}{2}\right) (r_o^4 - r_i^4) \\ = (1.56) \left(\frac{\pi}{2}\right) ((1.0 \text{ in})^4 - (0.5 \text{ in})^4) \\ = 2.30 \text{ in}^4$$

The total equivalent polar moment of inertia is

$$J_{\text{total}} = J_{\text{aluminum}} + J_{\text{brass}} = 6.38 \text{ in}^4 + 2.30 \text{ in}^4 \\ = 8.68 \text{ in}^4$$

(a) The maximum torsional shear stress in the aluminum occurs at the outer edge. Use Eq. 45.50.

$$\tau = \frac{Tr}{J} = \frac{(24,000 \text{ in-lbf})(1.5 \text{ in})}{8.68 \text{ in}^4} \\ = 4147 \text{ lbf/in}^2$$

(b) Using the composite structures analysis methodology, the maximum torsional shear stress in the brass is

$$\tau = \frac{nTr}{J} = \frac{(1.56)(24,000 \text{ in-lbf})(1.0 \text{ in})}{8.68 \text{ in}^4} \\ = 4313 \text{ lbf/in}^2$$

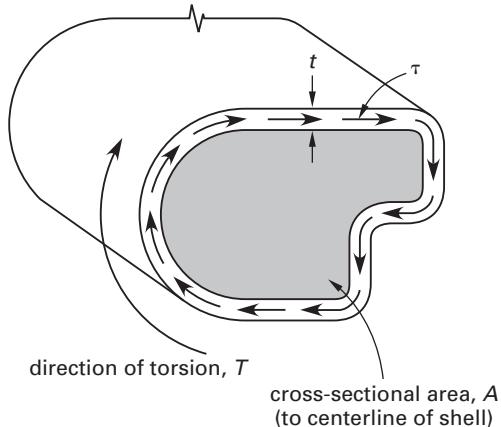

## 17. TORSION IN THIN-WALLED, NONCIRCULAR SHELLS

Shear stress due to torsion in a thin-walled, noncircular shell (also known as a *closed box*) acts around the perimeter of the shell, as shown in Fig. 45.11. The shear

stress,  $\tau$ , is given by Eq. 45.60.  $A$  is the area enclosed by the centerline of the shell.

$$\tau = \frac{T}{2At} \quad 45.60$$

**Figure 45.11 Torsion in Thin-Walled Shells**

The shear stress at any point is not proportional to the distance from the centroid of the cross section. Rather, the *shear flow, q*, around the shell is constant, regardless of whether the wall thickness is constant or variable.<sup>25</sup> The shear flow is the shear per-unit length of the centerline path.<sup>26</sup> At any point where the shell thickness is  $t$ ,

$$q = \tau t = \frac{T}{2A} \quad [\text{constant}] \quad 45.61$$

When the wall thickness,  $t$ , is constant, the angular twist depends on the perimeter,  $p$ , of the shell as measured along the centerline of the shell wall.

$$\gamma = \frac{TLp}{4A^2tG} \quad 45.62$$

## 18. TORSION IN SOLID, NONCIRCULAR MEMBERS

When a noncircular solid member is placed in torsion, the shear stress is not proportional to the distance from the centroid of the cross section. The maximum shear usually occurs close to the point on the surface that is nearest the centroid.

Shear stress,  $\tau$ , and angular deflection (angle of twist),  $\gamma$ , due to torsion are functions of the cross-sectional shape. They cannot be specified by simple formulas that apply to all sections. Table 45.6 lists the governing equations

<sup>25</sup>The concept of shear flow can also be applied to a regular beam in bending, although there is little to be gained by doing so. Removing the dimension  $b$  in the general beam shear stress equation,  $q = VQ/I$ .

<sup>26</sup>Shear flow is not analogous to magnetic flux or other similar quantities because the shear flow path does not need to be complete (i.e., does not need to return to its starting point).

**Table 45.6 Torsion in Solid, Noncircular Shapes**

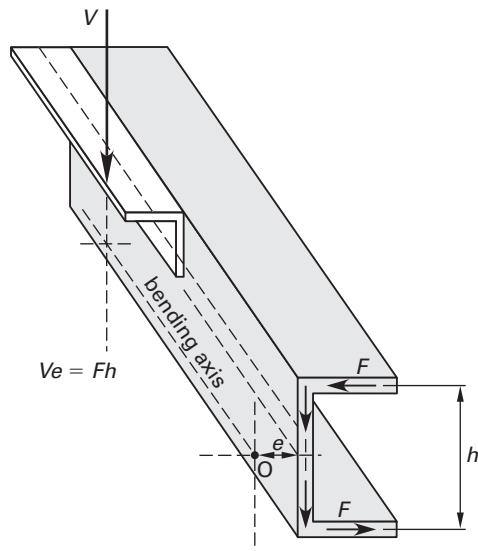

cross section	$K$ in formula $\gamma = TL/KG$	$\tau_{\max}$
ellipse	$\frac{\pi a^3 b^3}{a^2 + b^2}$ (maximum at ends of minor axis)	$\frac{2T}{\pi ab^2}$
square	$0.1406a^4$	$\frac{T}{0.208a^3}$ (maximum at midpoint of each side)
rectangle	*	$\frac{T(3a + 1.8b)}{8a^2b^2}$ (maximum at midpoint of each longer side)
	$*ab^3\left(\frac{16}{3} - \left(\frac{3.36b}{a}\right)\left(1 - \frac{b^4}{12a^4}\right)\right)$	
equilateral triangle	$\frac{a^4\sqrt{3}}{80}$	$\frac{20T}{a^3}$ (maximum at midpoint of each side)
slotted tube	$\frac{2\pi rt^3}{3}$	$\frac{T(6\pi r + 1.8t)}{4\pi^2r^2t^2}$ (maximum along both edges remote from ends)
I-beam	$\frac{2bt_f^3 + ht_w^3}{3}$	$\frac{3Tt_f}{2bt_f^3 + ht_w^3}$ [ $t_w < t_f$ ]

for several basic cross sections. These formulas have been derived by dividing the member into several concentric, thin-walled, closed shells and summing the torsional strength provided by each shell.

## 19. SHEAR CENTER FOR BEAMS

A beam with a symmetrical cross section supporting a transverse force that is offset from the longitudinal centroidal axis will be acted upon by a torsional moment, and the beam will tend to “roll” about a longitudinal axis known as the *bending axis* or *torsional axis*. For solid, symmetrical cross sections, this bending axis passes through the centroid of the cross section. However, for an asymmetrical beam (e.g., a channel beam on its side), the bending axis passes through the *shear center* (*flexural center*, *torsional center*, or *center of twist*), not the centroid. (See Fig. 45.12.) The shear center is a point that does not experience rotation (i.e., is a point about which all other points rotate) when the beam is in torsion.

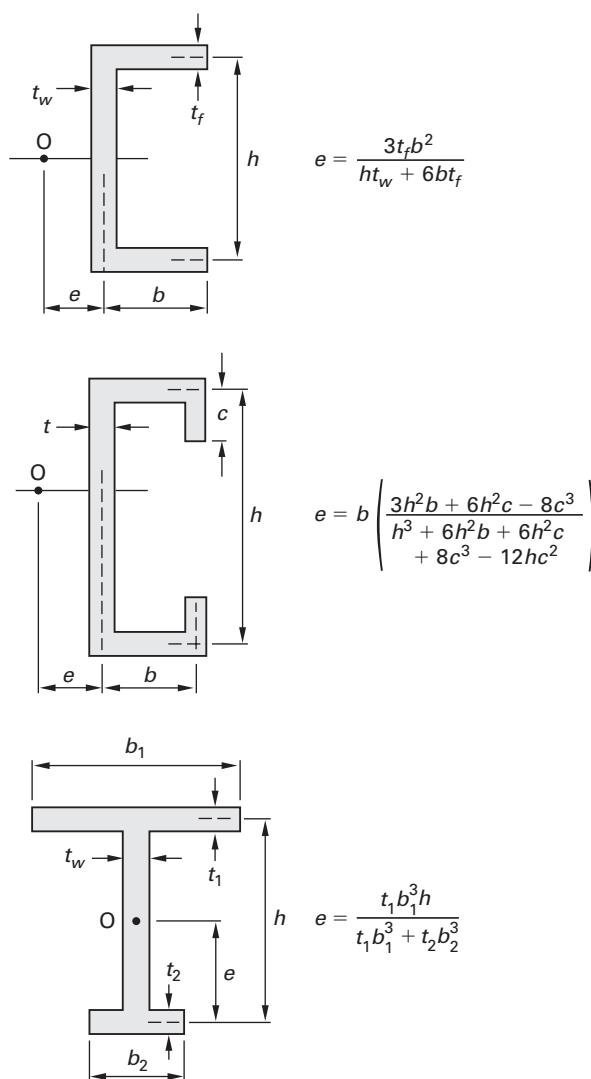

**Figure 45.12** Channel Beam in Pure Bending  
(shear resultant,  $V$ , directed through shear center,  $O$ )

For beams with transverse loading, simple bending without torsion can only occur if the transverse load (*shear resultant*,  $V$ , or *shear force of action*) is directed through the shear center. Otherwise, a torsional moment calculated as the product of the shear resultant and the torsional eccentricity will cause the beam to twist. The *torsional eccentricity* is the distance between the line of action of the shear resultant and the shear center.

The shear center is always located on an axis of symmetry. The location of the shear center for any particular beam geometry is determined by setting the torsional moment equal to the shear resisting moment, as calculated from the total shear flow and the appropriate moment arm. In practice, however, shear centers for common shapes are located in tables similar to Fig. 45.13.

**Figure 45.13** Shear Centers of Selected Thin-Walled Open Sections\*

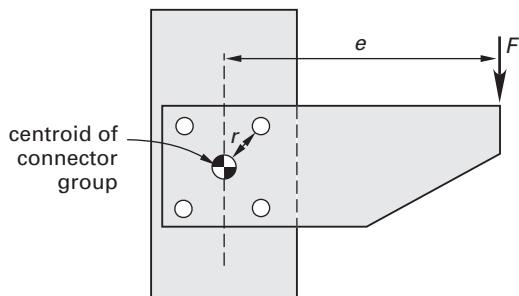

\*Distance  $e$  from shear center,  $O$ , measured from the reference point shown. Distance  $e$  is not the torsional eccentricity, which is the separation of the shear center and the line of action of the shear force.

## 20. ECCENTRICALLY LOADED BOLTED CONNECTIONS

An eccentrically loaded connection is illustrated in Fig. 45.14. The bracket's natural tendency is to rotate about the centroid of the connector group. The shear stress in the connectors includes both the direct vertical shear and the torsional shear stress. The sum of these shear stresses is limited by the shear strength of the critical connector, which in turn determines the capacity of the connection, as limited by bolt shear strength.<sup>27</sup>

<sup>27</sup>This type of analysis is known as an *elastic analysis* of the connection. Although it is traditional, it tends to greatly underestimate the capacity of the connection.

**Figure 45.14** Eccentrically Loaded Connection

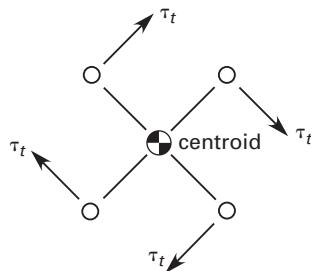

Analysis of an eccentric connection is similar to the analysis of a shaft under torsion. The shaft torque,  $T$ , is analogous to the moment,  $Fe$ , on the connection. The shaft's radius corresponds to the distance from the centroid of the fastener group to the *critical fastener*. The critical fastener is the one for which the vector sum of the vertical and torsional shear stresses is the greatest.

$$\tau = \frac{Tr}{J} = \frac{Fer}{J} \quad 45.63$$

The polar moment of inertia,  $J$ , is calculated from the parallel axis theorem. Since bolts and rivets have little resistance to twisting in their holes, their individual polar moments of inertia are omitted.<sup>28</sup> Only the  $r_i^2 A$  terms in the parallel axis theorem are used.  $r_i$  is the distance from the fastener group centroid to the centroid (i.e., center) of the  $i$ th fastener, which has an area of  $A_i$ .

$$J = \sum_i r_i^2 A_i \quad 45.64$$

The torsional shear stress is directed perpendicularly to a line between each fastener and the connector group centroid. The direction of the shear stress is the same as the rotation of the connection. (See Fig. 45.15.)

**Figure 45.15** Direction of Torsional Shear Stress

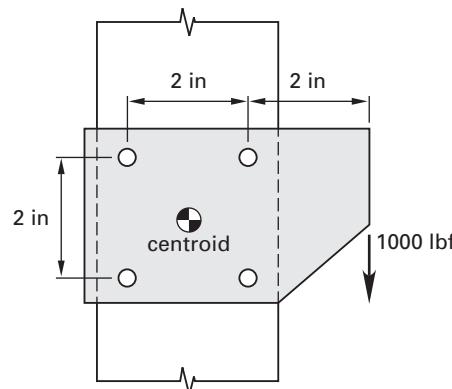

Once the torsional shear stress has been determined in the critical fastener, it is added in a vector sum to the direct vertical shear stress. The direction of the vertical shear stress is the same as that of the applied force.

$$\tau_v = \frac{F}{nA} \quad 45.65$$

Typical connections gain great strength from the frictional slip resistance between the two surfaces. By pre-loading the connection bolts, the normal force between the plates is greatly increased. The connection strength from friction will rival or exceed the strength from bolt shear in connections that are designed to take advantage of preload.

### Example 45.6

All fasteners used in the bracket shown have a nominal  $1/2$  in diameter. What is the stress in the most critical fastener?

*Solution*

Since the fastener group is symmetrical, the centroid is centered within the four fasteners. This makes the eccentricity of the load equal to 3 in. Each fastener is located a distance  $r$  from the centroid, where

$$r = \sqrt{x^2 + y^2} = \sqrt{(1 \text{ in})^2 + (1 \text{ in})^2} = 1.414 \text{ in}$$

The area of each fastener is

$$A_i = \frac{\pi d^2}{4} = \left( \frac{\pi (0.5 \text{ in})^2}{4} \right) = 0.1963 \text{ in}^2$$

Using the parallel axis theorem for polar moments of inertia and disregarding the individual torsional resistances of the fasteners,

$$\begin{aligned} J &= \sum_i r_i^2 A_i = (4)(1.414 \text{ in})^2 (0.1963 \text{ in}^2) \\ &= 1.570 \text{ in}^4 \end{aligned}$$

<sup>28</sup>In spot-welded and welded stud connections, the torsional resistance of each connector can be considered.

The torsional shear stress in each fastener is

$$\tau_t = \frac{Fer}{J} = \frac{(1000 \text{ lbf})(3 \text{ in})(1.414 \text{ in})}{1.570 \text{ in}^4} = 2702 \text{ lbf/in}^2$$

Each torsional shear stress can be resolved into a horizontal shear stress,  $\tau_{tx}$ , and a vertical shear stress,  $\tau_{ty}$ . Both of these components are equal to

$$\tau_{tx} = \tau_{ty} = \frac{(\sqrt{2}) \left( 2702 \frac{\text{lbf}}{\text{in}^2} \right)}{2} = 1911 \text{ lbf/in}^2$$

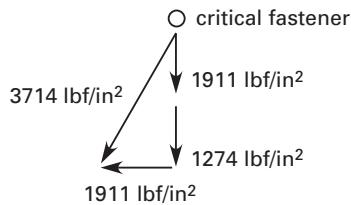

The direct vertical shear downward is

$$\tau_v = \frac{F}{nA} = \frac{1000 \text{ lbf}}{(4)(0.1963 \text{ in}^2)} = 1274 \text{ lbf/in}^2$$

The two right fasteners have vertical downward components of torsional shear stress. The direct vertical shear is also downward. These downward components add, making both right fasteners critical.

The total stress in each of these fasteners is

$$\begin{aligned} \tau &= \sqrt{\tau_{tx}^2 + (\tau_{ty} + \tau_v)^2} \\ &= \sqrt{\left( 1911 \frac{\text{lbf}}{\text{in}^2} \right)^2 + \left( 1911 \frac{\text{lbf}}{\text{in}^2} + 1274 \frac{\text{lbf}}{\text{in}^2} \right)^2} \\ &= 3714 \text{ lbf/in}^2 \end{aligned}$$

## 21. ECCENTRICALLY LOADED WELDED CONNECTIONS

The traditional elastic analysis of an eccentrically loaded welded connection is virtually the same as for a bolted connection, with the additional complication of having to determine the polar moment of inertia of the welds.<sup>29</sup> This can be done either by taking the welds as lines or by assuming each weld has an arbitrary thickness,  $t$ . After finding the centroid of the weld group, the rectangular moments of inertia of the individual welds are taken about that centroid using the parallel axis theorem. These rectangular moments of inertia are

<sup>29</sup>Steel building design does not use an elastic analysis to design eccentric brackets, either bolted or welded. The design methodology is highly proceduralized and codified.

added to determine the polar moment of inertia. This laborious process can be shortened by use of App. 45.A.

The torsional shear stress, calculated from  $Mr/J$  (where  $r$  is the distance from the centroid of the weld group to the most distant weld point), is added vectorially to the direct shear to determine the maximum shear stress at the critical weld point.

## 22. FLAT PLATES

Flat plates under uniform pressure are separated into two edge-support conditions: simply supported and built-in edges.<sup>30</sup> Commonly accepted working equations are summarized in Table 45.7. It is assumed that (a) the plates are of "medium" thickness (meaning that the thickness is equal to or less than one-fourth of the minimum dimension of the plate), (b) the pressure is no more than will produce a maximum deflection of one-half of the thickness, (c) the plates are constructed of isotropic, elastic material, and (d) the stress does not exceed the yield strength.

### Example 45.7

A steel pipe with an inside diameter of 10 in (254 mm) is capped by welding round mild steel plates on its ends. The allowable stress is 11,100 lbf/in<sup>2</sup> (77 MPa). The internal gage pressure in the pipe is maintained at 500 lbf/in<sup>2</sup> (3.5 MPa). What plate thickness is required?

#### SI Solution

A fixed edge approximates the welded edges of the plate. From Table 45.7, the maximum bending stress is

$$\sigma_{\max} = \frac{3pr^2}{4t^2}$$

$$t = \sqrt{\frac{3pr^2}{4\sigma_{\max}}} = \sqrt{\frac{(3)(3.5 \text{ MPa}) \left( \frac{254 \text{ mm}}{2} \right)^2}{(4)(77 \text{ MPa})}} = 23.4 \text{ mm}$$

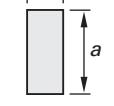

#### Customary U.S. Solution

A fixed edge approximates the welded edges of the plate. From Table 45.7, the maximum bending stress is

$$\begin{aligned} \sigma_{\max} &= \frac{3pr^2}{4t^2} \\ t &= \sqrt{\frac{3pr^2}{4\sigma_{\max}}} = \sqrt{\frac{(3)\left(500 \frac{\text{lbf}}{\text{in}^2}\right)\left(\frac{10 \text{ in}}{2}\right)^2}{(4)\left(11,100 \frac{\text{lbf}}{\text{in}^2}\right)}} \\ &= 0.919 \text{ in} \end{aligned}$$

<sup>30</sup>Fixed-edge conditions are theoretical and are seldom achieved in practice. Considering this fact and other simplifying assumptions that are made to justify the use of Table 45.7, a value of  $\nu = 0.3$  can be used without loss of generality.

**Table 45.7** Flat Plates Under Uniform Pressure

shape	edge condition	maximum stress	deflection at center
circular 	simply supported	$\frac{3}{8}pr^2(3 + \nu)$ (at center)	$\frac{3}{16}pr^4(1 - \nu)(5 + \nu)$ $Et^3$

## 23. SPRINGS

An *ideal spring* is assumed to be perfectly elastic within its working range. The deflection is assumed to follow *Hooke's law*.<sup>31</sup> The *spring constant*,  $k$ , is also known as the *stiffness*, *spring rate*, *scale*, and *k-value*.<sup>32</sup>

$$F = k\delta \quad 45.66$$

$$k = \frac{F_1 - F_2}{\delta_1 - \delta_2} \quad 45.67$$

A spring stores energy when it is compressed or extended. By the *work-energy principle*, the energy storage is equal to the work required to displace the spring. The potential energy of a spring whose ends have been displaced a total distance  $\delta$  is

$$\Delta E_p = \frac{1}{2}k\delta^2 \quad 45.68$$

<sup>31</sup>A spring can be perfectly elastic even though it does not follow Hooke's law. The deviation from proportionality, if any, occurs at very high loads. The difference in theoretical and actual spring forces is known as the *straight line error*.

<sup>32</sup>Another unfortunate name for the spring constant,  $k$ , that is occasionally encountered is the *spring index*. This is not the same as the spring index,  $C$ , used in helical coil spring design. The units will determine which meaning is intended.

If a mass,  $m$ , is dropped from height  $h$  onto and captured by a spring, the compression,  $\delta$ , can be found by equating the change in potential energy to the energy storage.

$$mg(h + \delta) = \frac{1}{2}k\delta^2 \quad [\text{SI}] \quad 45.69(a)$$

$$m\left(\frac{g}{g_c}\right)(h + \delta) = \frac{1}{2}k\delta^2 \quad [\text{U.S.}] \quad 45.69(b)$$

Within the elastic region, this energy can be recovered by restoring the spring to its original unstressed condition. It is assumed that there is no permanent set, and no energy is lost through external friction or *hysteresis* (internal friction) when the spring returns to its original length.<sup>33</sup>

The entire applied load is felt by each spring in a series of springs linked end-to-end. The *equivalent (composite) spring constant* for springs in series is

$$\frac{1}{k_{\text{eq}}} = \frac{1}{k_1} + \frac{1}{k_2} + \frac{1}{k_3} + \dots \quad [\text{series springs}] \quad 45.70$$

<sup>33</sup>There is essentially no hysteresis in properly formed compression, extension, or open-wound helical torsion springs.

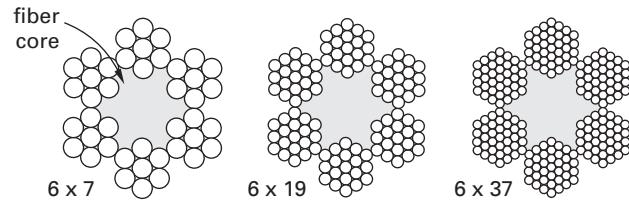

Springs in parallel (e.g., concentric springs) share the applied load. The equivalent spring constant for springs in parallel is

$$k_{\text{eq}} = k_1 + k_2 + k_3 + \dots \quad [\text{parallel springs}] \quad 45.71$$

## 24. WIRE ROPE

Wire rope is constructed by first winding individual wires into strands and then winding the strands into rope. (See Fig. 45.16.) Wire rope is specified by its diameter and numbers of strands and wires. The most common *hoisting cable* is 6 × 19, consisting of six strands of 19 wires each, wound around a core. This configuration is sometimes referred to as "standard wire rope." Other common configurations are 6 × 7 (stiff *transmission* or *haulage rope*), 8 × 19 (*extra-flexible hoisting rope*), and the abrasion-resistant 6 × 37.<sup>34</sup> The diameter and area of a wire rope are based on the circle that just encloses the rope.

**Figure 45.16** Wire Rope Cross Sections

Wire rope can be obtained in a variety of materials and cross sections. In the past, wire ropes were available in iron, cast steel, traction steel (TS), mild plow steel (MPS), and plow steel (PS) grades. Modern wire ropes are generally available only in improved plow steel (IPS) and extra-improved plow steel (EIP) grades.<sup>35</sup> *Monitor* and *blue center steels* are essentially the same as improved plow steel. Table 45.8 gives minimum strengths of wire materials.

While manufacturer's data should be relied on whenever possible, general properties of 6 × 19 wire rope are given in Table 45.9.

In Table 45.9, the ultimate strength,  $S_{\text{ut},r}$ , is the ultimate tensile load that the rope can carry without breaking. This is different from the ultimate strength,  $S_{\text{ut},w}$ , of each wire given in Table 45.8. The rope's tensile strength will

<sup>34</sup>The designations 6 × 19 and 6 × 37 are only nominal designations. Improvements in wire rope design have resulted in the use of strands with widely varying numbers of wire. For example, none of the 6 × 37 ropes actually have 37 wires per strand. Typical 6 × 37 constructions include 6 × 33 for diameters under  $\frac{1}{2}$  in, 6 × 36 Warrington Seale (the most common 6 × 37 Class construction) offered in diameters  $\frac{1}{2}$  in through  $\frac{15}{8}$  in, and 6 × 49 Filler Wire Seale over  $\frac{13}{4}$  in diameter.

<sup>35</sup>The term "plow steel" is somewhat traditional, as hard-drawn AISI 1070 or AISI 1080 might actually be used.

**Table 45.8** Minimum Strengths of Wire Materials

material	ultimate strength, $S_{\text{ut},w}$ (ksi)

<sup>c</sup>Tons of 2000 pounds

be only 80–95% of the combined tensile strengths of the individual wires. The modulus of elasticity for steel ropes is more a function of how the rope is constructed than the type of steel used. (See Table 45.10.)

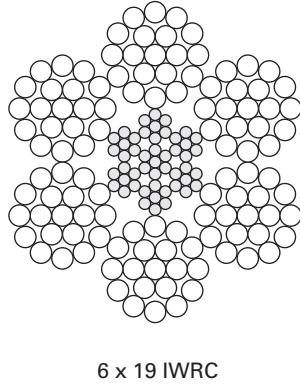

The central core can be of natural (e.g., hemp) or synthetic fibers or, for higher-temperature use, steel strands or cable. Core designations are FC for *fiber core*, IWRC for *independent wire rope core*, and WSC for *wire-strand core*. Wire rope is protected against corrosion by lubrication carried in the saturated fiber core. Steel-cored ropes are approximately 7.5% stronger than fiber-cored ropes. Figure 45.17 shows a 6 × 19 IWRC configuration.

*Structural rope*, *structural strand*, and *aircraft cabling* are similar in design to wire rope but are intended for permanent installation in bridges and aircraft, respectively. Structural rope and strand are galvanized to prevent corrosion, while aircraft cable is usually manufactured

**Table 45.10** Typical Characteristics of Steel Wire Ropes

configuration	mass (lbm/ft)	area (in <sup>2</sup> )	minimum sheave diameter	modulus of elasticity (psi)
6 × 7	$1.50d_r^2$	$0.380d_r^2$	42–72 $d_r$	$14 \times 10^6$
6 × 19	$1.60d_r^2$	$0.404d_r^2$	30–45 $d_r$	$12 \times 10^6$
6 × 37	$1.55d_r^2$	$0.404d_r^2$	18–27 $d_r$	$11 \times 10^6$
8 × 19	$1.45d_r^2$	$0.352d_r^2$	21–31 $d_r$	$10 \times 10^6$

(Multiply lbm/ft by 1.49 to obtain kg/m.)

(Multiply in<sup>2</sup> by 6.45 to obtain cm<sup>2</sup>.)(Multiply psi by 6.9 × 10<sup>-6</sup> to obtain GPa.)**Figure 45.17** 6 × 19 IWRC Configuration

6 × 19 IWRC

from corrosion-resistant steel.<sup>36,37</sup> Galvanized ropes should not be used for hoisting, as the galvanized coating will be worn off. Structural rope and strand have a nominal tensile strength of 220 ksi (1.5 GPa) and a modulus of elasticity of approximately 20,000 ksi (140 GPa) for diameters between 3/8 in and 4 in (0.95 cm and 10.2 cm).

The most common winding is *regular lay*, in which the wires are wound in one direction and the strands are wound around the core in the opposite direction. Regular lay ropes do not readily kink or unwind. Wires and strands in *lang lay* ropes are wound in the same direction, resulting in a wear-resistant rope that is more prone to unwinding. Lang lay ropes should not be used to support loads that are held in free suspension.

In addition to considering the primary tensile dead load, the significant effects of bending and sheave-bearing pressure must be considered when selecting wire rope. Self-weight may also be a factor for long cables. Appropriate dynamic factors should be applied to allow for

<sup>36</sup>Manufacture of structural rope and strand in the United States are in accordance with ASTM A603 and ASTM A586, respectively.

<sup>37</sup>Galvanizing usually reduces the strength of wire rope by approximately 10%.

acceleration, deceleration, and impacts. In general for hoisting and hauling, the working load should not exceed 20% of the breaking strength (i.e., a minimum factor of safety of 5 should be used).<sup>38</sup>

If  $d_w$  is the nominal wire strand diameter in inches,<sup>39</sup>  $d_r$  is the nominal wire rope diameter in inches, and  $d_{sh}$  is the sheave diameter in inches, the stress from bending around a drum or sheave is given by Eq. 45.72.  $E_w$  is the modulus of elasticity of the wire material (approximately  $3 \times 10^7$  psi (207 GPa for steel), not the rope's modulus of elasticity, though the latter is widely used in this calculation).<sup>40</sup>

$$\sigma_b = \frac{d_w E_w}{d_{sh}} \quad 45.72$$

To reduce stress and eliminate permanent set in wire ropes, the diameter of the sheave should be kept as large as is practical, ideally 45–90 times the rope diameter. Alternatively, the minimum diameter of the sheave or drum may be stated as 400 times the diameter of the individual outer wires in the rope.<sup>41</sup> Table 45.10 lists minimum diameters for specific rope types.

For any allowable bending stress, the allowable load is calculated simply from the aggregate total area of all wire strands.

$$F_a = \sigma_{a,bending} \times \text{number of strands} \times A_{\text{strand}} \quad 45.73$$

To prevent wear and fatigue of the sheave or drum, the radial bearing pressure should be kept as low as possible. Actual maximum bearing pressures are highly dependent on the sheave material, type of rope, and application. For 6 × 19 wire ropes, the acceptable bearing pressure can be as low as 500 psi (3.5 MPa) for cast-iron sheaves and as high as 2500 psi (17 MPa) for alloy steel sheaves. The approximate bearing pressure of the wire rope on the sheave or drum depends on the tensile force in the rope and is given by Eq. 45.74.

$$p_p = \frac{2F_t}{d_r d_{sh}} \quad 45.74$$

Fatigue failure in wire rope can be avoided by keeping the ratio  $p_p/S_{ut,w}$  below approximately 0.014 for 6 × 19 wire rope.<sup>42</sup> ( $S_{ut,w}$  is the ultimate tensile strength of the wire material, not of the rope.)

<sup>38</sup>Factors of safety are much higher and may range as high as 8–12 for elevators and hoists carrying passengers.

<sup>39</sup>For 6 × 19 standard wire rope, the outer wire strands are typically 1/13–1/16 of the wire rope diameter. For 6 × 7 haulage rope, the ratio is approximately 1/9.

<sup>40</sup>Although  $E$  in Eq. 45.72 is often referred to as “the modulus of elasticity of the wire rope,” it is understood that  $E$  is actually the modulus of elasticity of the wire rope material.

<sup>41</sup>For elevators and mine hoists, the sheave-to-wire diameter ratio may be as high as 1000.

<sup>42</sup>A maximum ratio of 0.001 is often quoted for wire rope regardless of configuration.

### 1. INTRODUCTION TO INDETERMINATE STATICS

A structure that is *statically indeterminate* is one for which the equations of statics are not sufficient to determine all reactions, moments, and internal forces. Additional formulas involving deflection are required to completely determine these variables.

Although there are many configurations of statically indeterminate structures, this chapter is primarily concerned with beams on more than two supports, trusses with more members than are required for rigidity, and miscellaneous composite structures.

### 2. DEGREE OF INDETERMINACY

The *degree of indeterminacy* (*degree of redundancy*) is equal to the number of reactions or members that would have to be removed in order to make the structure statically determinate. For example, a two-span beam on three simple supports is indeterminate (redundant) to the first degree. The degree of indeterminacy of a pin-connected, two-dimensional truss is given by Eq. 46.1.

$$I = r + m - 2j \quad 46.1$$

The degree of indeterminacy of a pin-connected, three-dimensional truss is

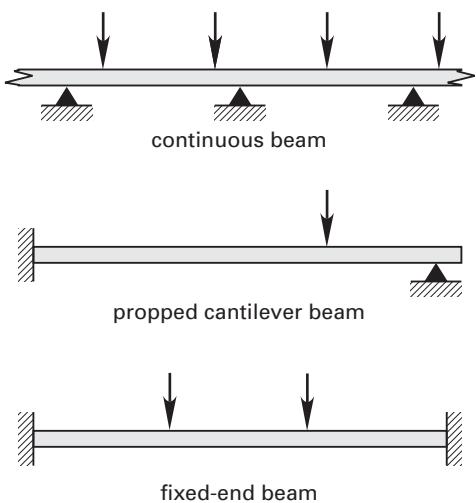

$$I = r + m - 3j \quad 46.2$$

Rigid frames have joints that transmit moments. The degree of indeterminacy of two-dimensional rigid plane frames is more complex. In Eq. 46.3, *s* is the number of *special conditions* (also known as the number of *equations of conditions*). *s* is 1 for each internal hinge or a shear release, 2 for each internal roller, and 0 if neither hinges nor rollers are present.

$$I = r + 3m - 3j - s \quad 46.3$$

### 3. INDETERMINATE BEAMS

Three common configurations of beams can easily be recognized as being statically indeterminate. These are the *continuous beam*, *proped cantilever beam*, and *fixed-end beam*, as illustrated in Fig. 46.1.

**Figure 46.1** Types of Indeterminate Beams

#### 4. REVIEW OF ELASTIC DEFORMATION

When an axial force,  $F$ , acts on an object with length  $L$ , cross-sectional area  $A$ , and modulus of elasticity  $E$ , the deformation<sup>1</sup> is

$$\delta = \frac{FL}{AE} \quad 46.4$$

When an object with initial length  $L_o$  and coefficient of thermal expansion  $\alpha$  experiences a temperature change of  $\Delta T$  degrees, the deformation is

$$\delta = \alpha L_o \Delta T \quad 46.5$$

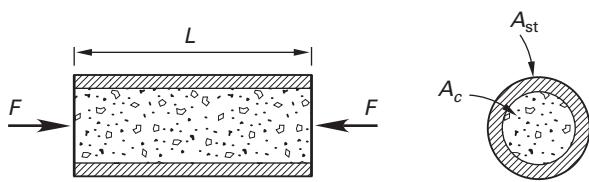

#### 5. CONSISTENT DEFORMATION METHOD

The *consistent deformation method*, also known as the *compatibility method*, is one of the methods of solving indeterminate problems. This method is simple to learn and to apply. First, geometry is used to develop a relationship between the deflections of two different members (or for one member at two locations) in the structure. Then, the deflection equations for the two different members at a common point are written and equated, since the deformations must be the same at a common point. This method is illustrated by the following examples.

##### Example 46.1

A pile carrying an axial compressive load is constructed of concrete with a steel jacket. The end caps are rigid, and the steel-concrete bond is perfect. What are the forces in the steel and concrete if a load  $F$  is applied?

<sup>1</sup>The terms *deformation* and *elongation* are often used interchangeably in this context.

*Solution*

Let  $F_c$  and  $F_{st}$  be the loads carried by the concrete and steel, respectively. Then,

$$F_c + F_{st} = F$$

The deformation of the steel is given by Eq. 46.4.

$$\delta_{st} = \frac{F_{st}L}{A_{st}E_{st}}$$

Similarly, the deflection of the concrete is

$$\delta_c = \frac{F_c L}{A_c E_c}$$

But,  $\delta_c = \delta_{st}$  since the bonding is perfect. Therefore,

$$\frac{F_c L}{A_c E_c} - \frac{F_{st} L}{A_{st} E_{st}} = 0$$

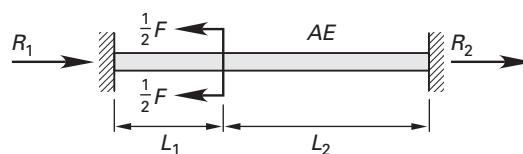

The first and last equations are solved simultaneously for  $F_c$  and  $F_{st}$ .

$$F_c = \frac{F}{1 + \frac{A_{st}E_{st}}{A_c E_c}}$$

$$F_{st} = \frac{F}{1 + \frac{A_c E_c}{A_{st} E_{st}}}$$

##### Example 46.2

A uniform bar is clamped at both ends and the axial load applied near one of the supports. What are the reactions?

*Solution*

The first required equation is

$$R_1 + R_2 = F$$

The shortening of section 1 due to the reaction  $R_1$  is

$$\delta_1 = \frac{-R_1 L_1}{AE}$$

The elongation of section 2 due to the reaction  $R_2$  is

$$\delta_2 = \frac{R_2 L_2}{AE}$$

However, the bar is continuous, so  $\delta_1 = -\delta_2$ . Therefore,

$$R_1 L_1 = R_2 L_2$$

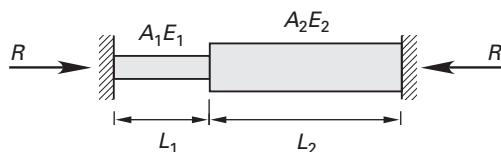

The first and last equations are solved simultaneously to find  $R_1$  and  $R_2$ .

$$R_1 = \frac{F}{1 + \frac{L_1}{L_2}}$$

$$R_2 = \frac{F}{1 + \frac{L_2}{L_1}}$$

### Example 46.3

The nonuniform bar shown is clamped at both ends and constrained from changing length. What are the reactions if a temperature change of  $\Delta T$  is experienced?

*Solution*

The thermal deformations of sections 1 and 2 can be calculated directly. Use Eq. 46.5.

$$\delta_1 = \alpha_1 L_1 \Delta T$$

$$\delta_2 = \alpha_2 L_2 \Delta T$$

The total deformation is  $\delta = \delta_1 + \delta_2$ . However, the deformation can also be calculated from the principles of mechanics.

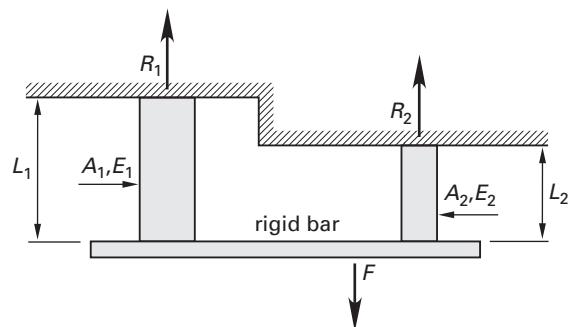

$$\delta = \frac{RL_1}{A_1 E_1} + \frac{RL_2}{A_2 E_2}$$

Combine these equations and solve directly for  $R$ .

$$R = \frac{(\alpha_1 L_1 + \alpha_2 L_2) \Delta T}{\frac{L_1}{A_1 E_1} + \frac{L_2}{A_2 E_2}}$$

### Example 46.4

The beam shown is supported by dissimilar members. The bar is rigid and remains horizontal.<sup>2</sup> The beam's mass is insignificant. What are the forces in the members?

*Solution*

The required equilibrium condition is

$$R_1 + R_2 = F$$

The elongations of the two tension members are

$$\delta_1 = \frac{R_1 L_1}{A_1 E_1}$$

$$\delta_2 = \frac{R_2 L_2}{A_2 E_2}$$

Since the horizontal bar remains horizontal,  $\delta_1 = \delta_2$ .

$$\frac{R_1 L_1}{A_1 E_1} = \frac{R_2 L_2}{A_2 E_2}$$

The first and last equations are solved simultaneously to find  $R_1$  and  $R_2$ .

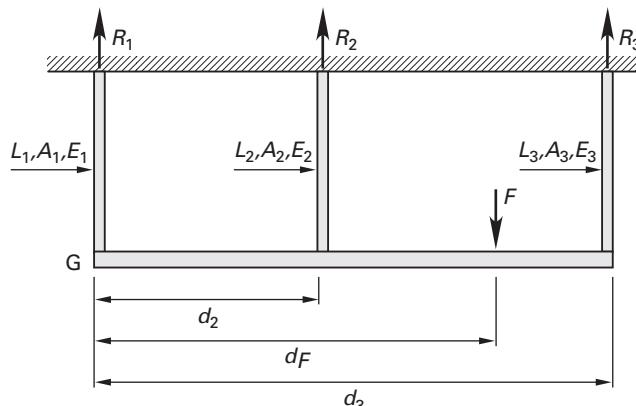

$$R_1 = \frac{F}{1 + \frac{L_1 A_2 E_2}{L_2 A_1 E_1}}$$

$$R_2 = \frac{F}{1 + \frac{L_2 A_1 E_1}{L_1 A_2 E_2}}$$

### Example 46.5

The beam shown is supported by dissimilar members. The bar is rigid but is not constrained to remain horizontal. The beam's mass is insignificant. Develop the simultaneous equations needed to determine the reactions in the vertical members.

<sup>2</sup>This example is easily solved by summing moments about a point on the horizontal beam.

*Solution*

The forces in the supports are  $R_1$ ,  $R_2$ , and  $R_3$ . Any of these may be tensile (positive) or compressive (negative).

$$R_1 + R_2 + R_3 = F$$

The changes in length are given by Eq. 46.4.

$$\delta_1 = \frac{R_1 L_1}{A_1 E_1}$$

$$\delta_2 = \frac{R_2 L_2}{A_2 E_2}$$

$$\delta_3 = \frac{R_3 L_3}{A_3 E_3}$$

Since the bar is rigid, the deflections will be proportional to the distance from point  $G$ .

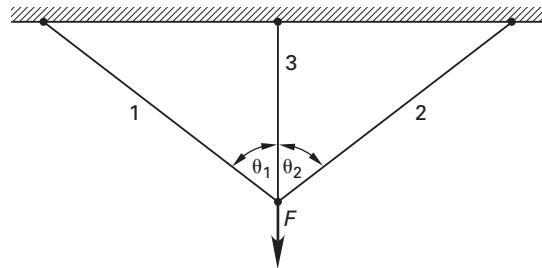

$$\delta_2 = \delta_1 + \left( \frac{d_2}{d_3} \right) (\delta_3 - \delta_1)$$

Moments can be summed about point  $G$  to give a third equation.

$$\begin{aligned} M_G &= R_3 d_3 + R_2 d_2 - F d_F \\ &= 0 \end{aligned}$$

### Example 46.6

A load is supported by three tension members. Develop the simultaneous equations needed to find the forces in the three members.

*Solution*

The equilibrium requirement is

$$F_{1y} + F_3 + F_{2y} = F$$

$$F_1 \cos \theta_1 + F_3 + F_2 \cos \theta_2 = F$$

Assuming the elongations are small compared to the member lengths, the angles  $\theta_1$  and  $\theta_2$  are unchanged. Then, the vertical deflections are the same for all three members.

$$\frac{F_1 L_1 \cos \theta_1}{A_1 E_1} = \frac{F_3 L_3}{A_3 E_3} = \frac{F_2 L_2 \cos \theta_2}{A_2 E_2}$$

These equations can be solved simultaneously to find  $F_1$ ,  $F_2$ , and  $F_3$ . (It may be necessary to work with the  $x$ -components of the deflections in order to find a third equation.)

### 6. SUPERPOSITION METHOD

Two-span (three-support) beams and propped cantilevers are indeterminate to the first degree. Their reactions can be determined from a variation of the consistent deformation procedure known as the *superposition method*.<sup>3</sup> This method requires finding the deflection with one or more supports removed and then satisfying the known conditions.

*step 1:* Remove enough redundant supports to reduce the structure to a statically determinate condition.

*step 2:* Calculate the deflections at the locations of the removed redundant supports. Use consistent sign conventions.

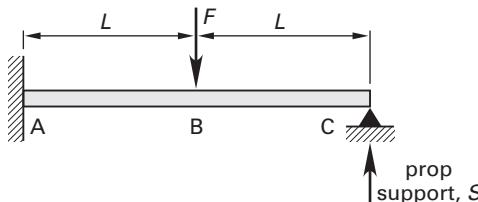

*step 3:* Apply each redundant support as an isolated load, and find the deflections at the redundant support points as functions of the redundant support forces.

*step 4:* Use superposition to combine (i.e., add) the deflections due to the actual loads and the redundant support loads. The total deflections must agree with the known deflections (usually zero) at the redundant support points.

<sup>3</sup>Superposition can also be used with higher-order indeterminate problems. However, the simultaneous equations that must be solved may make superposition unattractive for manual calculations.

**Example 46.7**

A propped cantilever is loaded by a concentrated force at midspan. Determine the reaction,  $S$ , at the prop.

**Solution**

Start by removing the unknown prop reaction at point C. The cantilever beam is then statically determinate. The deflection and slope at point B can be found or derived from the elastic beam deflection equations. For a cantilever with end load, the deflection and slope are calculated as follows. (See App. 44.A, Case 1.) (The deflection at point B is the same as for a tip-loaded cantilever of length  $L$ .)

$$\text{deflection at point B: } \delta_B = \frac{-FL^3}{3EI}$$

$$\text{slope at point B: } y'_B = \frac{-FL^2}{2EI}$$

The slope remains constant to the right of point B. The deflection at point C due to the load at point B is

$$\delta_{C,F} = \delta_B + y'_B L = \frac{-5FL^3}{6EI}$$

The upward deflection at the cantilever tip due to the prop support,  $S$ , alone is given by

$$\delta_{C,S} = \frac{S(2L)^3}{3EI} = \frac{8SL^3}{3EI}$$

It is known that the actual deflection at point C is zero (the boundary condition). Therefore, the prop support,  $S$ , can be determined as a function of the applied load.

$$\delta_{C,S} + \delta_{C,F} = 0$$

$$\frac{8SL^3}{3EI} - \frac{5FL^3}{6EI} = 0$$

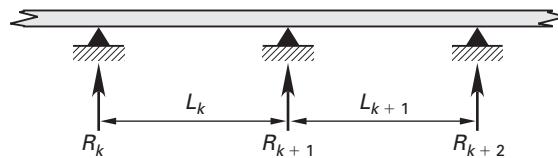

$$S = \frac{5F}{16}$$

**7. THREE-MOMENT EQUATION**

A continuous beam has two or more spans (i.e., three or more supports) and is statically indeterminate. (See Fig. 46.2.) The *three-moment equation* is a method of determining the reactions on continuous beams. It

relates the moments at any three adjacent supports. The three-moment method can be used with a two-span beam to directly find all three reactions.

**Figure 46.2** Portion of a Continuous Beam

When a beam has more than two spans, the equation must be used with three adjacent supports at a time, starting with a support whose moment is known. (The moment is known to be zero at a simply supported end. For a cantilever end, the moment depends only on the loads on the cantilever portion.)

In its most general form, the three-moment equation is applicable to beams with nonuniform cross sections. In Eq. 46.6,  $I_k$  is the moment of inertia of span  $k$ .

$$\begin{aligned} \frac{M_k L_k}{I_k} + 2M_{k+1} \left( \frac{L_k}{I_k} + \frac{L_{k+1}}{I_{k+1}} \right) + \frac{M_{k+2} L_{k+1}}{I_{k+1}} \\ = -6 \left( \frac{A_k a}{I_k L_k} + \frac{A_{k+1} b}{I_{k+1} L_{k+1}} \right) \end{aligned} \quad 46.6$$

Equation 46.6 uses the following special nomenclature.

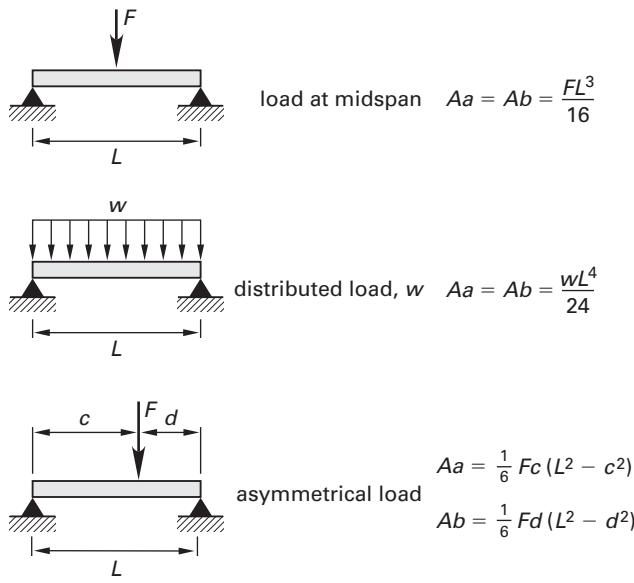

- a distance from the left support to the centroid of the moment diagram on the left span
- b distance from the right support to the centroid of the moment diagram on the right span
- $I_k$  the moment of inertia of the open span between supports  $k$  and  $k+1$
- $L_k$  length of the span between supports  $k$  and  $k+1$
- $M_k$  bending moment at support  $k$
- $A_k$  area of moment diagram between supports  $k$  and  $k+1$ , assuming that the span is simply and independently supported

The products  $Aa$  and  $Ab$  are known as *first moments of the areas*. It is convenient to derive simplified expressions for  $Aa$  and  $Ab$  for commonly encountered configurations. Several are presented in Fig. 46.3.

For beams with uniform cross sections, the moment of inertia terms can be eliminated.

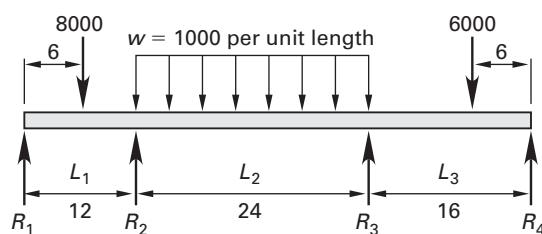

$$\begin{aligned} M_k L_k + 2M_{k+1}(L_k + L_{k+1}) + M_{k+2} L_{k+1} \\ = -6 \left( \frac{A_k a}{L_k} + \frac{A_{k+1} b}{L_{k+1}} \right) \end{aligned} \quad 46.7$$

**Figure 46.3** Simplified Three-Moment Equation Terms

### Example 46.8

Find the four reactions supporting the beam.  $EI$  is constant.

*Solution*

*Spans 1 and 2:*

Since the three-moment method can be applied to only two spans at a time, work first with the left and middle spans (spans 1 and 2).

From Fig. 46.3, the quantities  $A_1a$  and  $A_2b$  are

$$A_1a = \frac{FL^3}{16} = \frac{(8000)(12)^3}{16} = 864,000$$

$$A_2b = \frac{wl^4}{24} = \frac{(1000)(24)^4}{24} = 13,824,000$$

Since the left end of the beam is simply supported,  $M_1$  is zero. From Eq. 46.7, the three-moment equation becomes

$$2M_2(L_1 + L_2) + M_3L_2 = -6\left(\frac{A_1a}{L_1} + \frac{A_2b}{L_2}\right)$$

$$2M_2(12 + 24) + M_3(24) = (-6)\left(\frac{864,000}{12} + \frac{13,824,000}{24}\right)$$

After simplification,

$$3M_2 + M_3 = -162,000$$

*Spans 2 and 3:*

From the previous calculations,

$$A_2a = A_2b = 13,824,000$$

From Fig. 46.3 for the third span,

$$\begin{aligned} A_3b &= \frac{1}{6}Fd(L^2 - d^2) \\ &= \left(\frac{1}{6}\right)(6000)(6)\left((16)^2 - (6)^2\right) \\ &= 1,320,000 \end{aligned}$$

Since the right end is simply supported,  $M_4 = 0$  and the three-moment equation is

$$\begin{aligned} M_2L_2 + 2M_3(L_2 + L_3) &= -6\left(\frac{A_2a}{L_2} + \frac{A_3b}{L_3}\right) \\ M_2(24) + 2M_3(24 + 16) &= (-6)\left(\frac{13,824,000}{24} + \frac{1,320,000}{16}\right) \end{aligned}$$

After simplifying,

$$0.3M_2 + M_3 = -49,388$$

There are two equations in two unknowns ( $M_2$  and  $M_3$ ). A simultaneous solution yields

$$M_2 = -41,708$$

$$M_3 = -36,875$$

*Finding reactions:*

$M_2$  can be written in terms of the loads and reactions to the left of support 2. Assuming clockwise moments are positive,

$$M_2 = 12R_1 - (6)(8000) = -41,708$$

$$R_1 = 524.3$$

Once  $R_1$  is known, moments can be taken from support 3 to the left.

$$\begin{aligned} M_3 &= (36)(524.3) + 24R_2 - (30)(8000) - (12)(24,000) \\ &= -36,875 \end{aligned}$$

$$R_2 = 19,677.1$$

Similarly,  $R_4$  and  $R_3$  can be determined by working from the right end to the left. Assuming counterclockwise moments are positive,

$$M_3 = 16R_4 - (10)(6000) = -36,875$$

$$R_4 = 1445.3$$

$$\begin{aligned} M_2 &= (40)(1445) + 24R_3 - (34)(6000) - (12)(24,000) \\ &= -41,708 \end{aligned}$$

$$R_3 = 16,353.3$$

*Check:*

Check for equilibrium in the vertical direction.

$$\begin{aligned} \sum \text{loads} &= 8000 + 24,000 + 6000 \\ &= 38,000 \end{aligned}$$

$$\begin{aligned} \sum \text{reactions} &= 524.3 + 19,677.1 + 1445.3 + 16,353.3 \\ &= 38,000 \end{aligned}$$

## 8. FIXED-END MOMENTS

When the end of a beam is constrained against rotation, it is said to be a *fixed end* (also known as a *built-in end*). The ends of fixed-end beams are constrained to remain horizontal. Cantilever beams have a single fixed end. Some beams, as illustrated in Fig. 46.1, have two fixed ends and are known as *fixed-end beams*.<sup>4</sup>

Fixed-end beams are inherently indeterminate. To reduce the work required to find end moments and reactions, tables of fixed-end moments are often used.

## 9. INDETERMINATE TRUSSES

It is possible to manually calculate the forces in all members of an indeterminate truss. However, due to the time required, it is preferable to limit such manual calculations to trusses that are indeterminate to the first

degree. The following *dummy unit load method* can be used to solve trusses with a single redundant member.

*step 1:* Draw the truss twice. Omit the redundant member on both trusses. (There may be a choice of redundant members.)

*step 2:* Load the first truss (which is now determinate) with the actual loads.

*step 3:* Calculate the force,  $S$ , in each of the members. Assign a positive sign to tensile forces.

*step 4:* Load the second truss with two unit forces acting collinearly toward each other along the line of the redundant member.

*step 5:* Calculate the force,  $u$ , in each of the members.

*step 6:* Calculate the force in the redundant member from Eq. 46.8.

$$S_{\text{redundant}} = \frac{-\sum \frac{SuL}{AE}}{\sum \frac{u^2 L}{AE}} \quad 46.8$$

If  $AE$  is the same for all members,

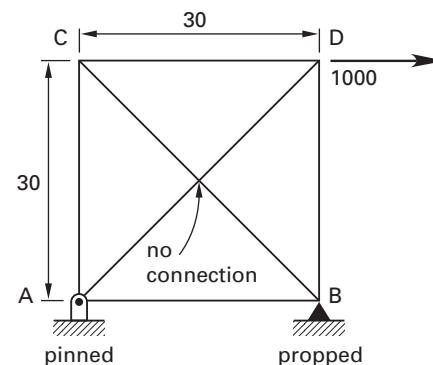

$$S_{\text{redundant}} = \frac{-\sum SuL}{\sum u^2 L} \quad 46.9$$

The true force in member  $j$  of the truss is

$$F_{j,\text{true}} = S_j + S_{\text{redundant}} u_j \quad 46.10$$

### Example 46.9

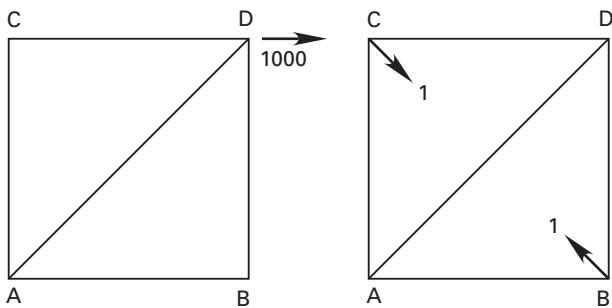

Find the force in members BC and BD.  $AE = 1$  for all members except for CB, which is 2, and AD, which is 1.5.

<sup>4</sup>The definition is loose. The term *fixed-end beam* can also be used to mean any indeterminate beam with at least one built-in end (e.g., a propped cantilever).

**Solution**

The two trusses are shown appropriately loaded.

member	<i>L</i>	<i>AE</i>	<i>S</i>	<i>u</i>	$\frac{SuL}{AE}$	$\frac{u^2 L}{AE}$
AB	30	1	0	-0.707 (C)	0	15
BD	30	1	-1000 (C)	-0.707	21,210	15
DC	30	1	0	-0.707	0	15
CA	30	1	0	-0.707	0	15
CB	42.43	2	0	1.0	0	21.22
AD	42.43	1.5	1414 (T)	1.0	39,997	28.29
					<u>61,207</u>	<u>109.51</u>

From Eq. 46.8,

$$S_{BC} = \frac{-\sum \frac{SuL}{AE}}{\sum \frac{u^2 L}{AE}} = \frac{-61,207}{109.51} = -558.9 \text{ (C)}$$

From Eq. 46.10,

$$\begin{aligned} F_{BD,\text{true}} &= S_{BD} + S_{\text{redundant}} u_{BD} \\ &= -1000 + (-558.9)(-0.707) \\ &= -604.9 \text{ (C)} \end{aligned}$$

## 10. INFLUENCE DIAGRAMS

Shear, moment, and reaction influence diagrams (influence lines) can be drawn for any point on a beam or truss. This is a necessary first step in the evaluation of stresses induced by moving loads. It is important to realize, however, that the influence diagram applies only to one point on the beam or truss.

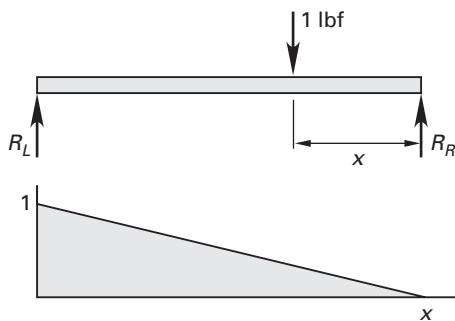

### Influence Diagrams for Beam Reactions

In a typical problem, the load is fixed in position and the reactions do not change. If a load is allowed to move across a beam, the reactions will vary. An influence diagram can be used to investigate the value of a chosen reaction as the load position varies.

To make the influence diagram as general in application as possible, a unit load is used. As an example, consider a 20 ft, simply supported beam and determine the effect on the left reaction of moving a 1 lbf load across the beam.

If the load is directly over the right reaction ( $x = 0$ ), the left reaction will not carry any load. Therefore, the ordinate of the influence diagram is zero at that point. (Even though the right reaction supports 1 lbf, this influence diagram is being drawn for one point only—the left reaction.) Similarly, if the load is directly over the left reaction ( $x = L$ ), the ordinate of the influence diagram will be 1. Basic statics can be used to complete the rest of the diagram, as shown in Fig. 46.4.

**Figure 46.4** Influence Diagram for Reaction of Simple Beam

Use this rudimentary example of an influence diagram to calculate the left reaction for any placement of any load by multiplying the actual load by the ordinate of the influence diagram.

$$R_L = P \times \text{ordinate} \quad 46.11$$

Even though the influence diagram was drawn for a point load, it can still be used when the beam carries a uniformly distributed load. In the case of a uniform load of  $w$  distributed over the beam from  $x_1$  to  $x_2$ , the left reaction can be calculated from Eq. 46.12.

$$\begin{aligned} R_L &= \int_{x_1}^{x_2} (w \times \text{ordinate}) dx \\ &= w \times \text{area under curve} \quad 46.12 \end{aligned}$$

### Example 46.10

A 500 lbf load is placed 15 ft from the right end of a 20 ft, simply supported beam. Use the influence diagram to determine the left reaction.

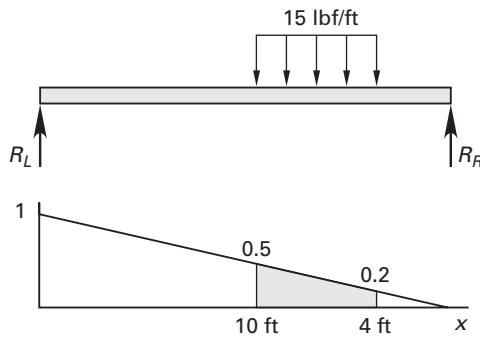

**Solution**

Since the influence line increases linearly from 0 to 1, the ordinate is the ratio of position to length. That is, the ordinate is  $15/20 = 0.75$ . From Eq. 46.11, the left reaction is

$$R_L = (0.75)(500 \text{ lbf}) = 375 \text{ lbf}$$

**Example 46.11**

A uniform load of 15 lbf/ft is distributed between  $x = 4$  ft and  $x = 10$  ft along a 20 ft, simply supported beam. What is the left reaction?

**Solution**

From Eq. 46.12, the left reaction can be calculated from the area under the influence diagram between the limits of loading.

$$A = \left(\frac{1}{2}\right)(10 \text{ ft})(0.5) - \left(\frac{1}{2}\right)(4 \text{ ft})(0.2) = 2.1 \text{ ft}$$

The left reaction is

$$R_L = \left(15 \frac{\text{lbf}}{\text{ft}}\right)(2.1 \text{ ft}) = 31.5 \text{ lbf}$$

**Finding Reaction Influence Diagrams Graphically**

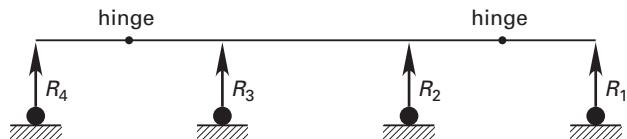

Since the reaction will always have a value of 1 when the unit load is directly over the reaction and since the reaction is always directly proportional to the distance  $x$ , the reaction influence diagram can be easily determined from the following steps.

*step 1:* Remove the support being investigated.

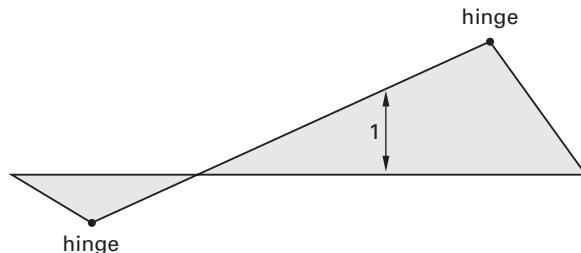

*step 2:* Displace (lift) the beam upward a distance of one unit at the support point. The resulting beam shape will be the shape of the reaction influence diagram.

**Example 46.12**

What is the approximate shape of the reaction influence diagram for reaction 2?

**Solution**

Pushing up at reaction 2 such that the deflection is one unit results in the shown shape.

**Influence Diagrams for Beam Shears**

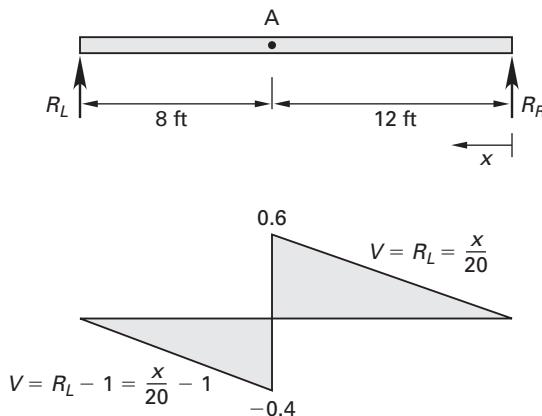

A shear influence diagram (not the same as a shear diagram) illustrates the effect on the shear at a particular point in the beam of moving a load along the beam's length. As an illustration, consider point A along the simply supported beam of length 20.

In all cases, principles of statics can be used to calculate the shear at point A as the sum of loads and reactions on the beam from point A to the left end. (With the appropriate sign convention, summation to the right end could be used as well.) If the unit load is placed between the right end ( $x = 0$ ) and point A, the shear at point A will consist only of the left reaction, since there are no other loads between point A and the left end. From the reaction influence diagram, the left reaction varies linearly. At  $x = 12$  ft, the location of point A, the shear is  $V = R_L = 12/20 = 0.6$ .

When the unit load is between point A and the left end, the shear at point A is the sum of the left reaction (upward and positive) and the unit load itself (downward and negative). Therefore,  $V = R_L - 1$ . At  $x = 12$  ft, the shear is  $V = 0.6 \text{ lbf} - 1 \text{ lbf} = -0.4 \text{ lbf}$ .

Figure 46.5 is the shear influence diagram. In the diagram, the shear goes through a reversal of 1, and the slopes of the two inclined sections are the same.

Shear influence diagrams are used in the same manner as reaction influence diagrams. The shear at point A for any position of the load can be calculated by multiplying the ordinate of the diagram by the actual load. Distributed loads are found by multiplying the uniform load by the area under the diagram between the limits of loading. If the loading extends over positive and

**Figure 46.5** Shear Influence Diagram for Simple Beam

negative parts of the curve, the sign of the area is considered when performing the final summation.

If it is necessary to determine the distribution of loading that will produce the maximum shear at a point whose influence diagram is available, the load should be positioned in order to maximize the area under the diagram.<sup>5</sup> This can be done by “covering” either all of the positive area or all of the negative area.<sup>6</sup>

### Shear Influence Diagrams by Virtual Displacement

A difficulty in drawing shear influence diagrams for continuous beams on more than two supports is finding the reactions. The method of *virtual displacement* or *virtual work* can be used to find the influence diagram without going through that step.

*step 1:* Replace the point being investigated (i.e., point A) with an imaginary link with unit length. (It may be necessary to think of the link as having a length of 1 ft, but the link does not add to or subtract from any length of the beam.) If the point being investigated is a reaction, place a hinge at that point and lift the hinge upward a unit distance.

*step 2:* Push the two ends of the beam (with the link somewhere in between) toward each other a very small amount until the linkage is vertical. The distance between supports does not change, but the linkage allows the beam sections to assume a slope. The sections to the left and right of the linkage displace  $\delta_1$  and  $\delta_2$ , respectively, from their equilibrium positions. The slope of both sections is the same. Points of support remain in contact with the beam.

<sup>5</sup>If the *minimum shear* is requested, the maximum negative shear is implied. The minimum shear is not zero in most cases.

<sup>6</sup>Usually, the dead load is assumed to extend over the entire length of the beam. The uniform live loads are distributed in any way that will cause the maximum shear.

*step 3:* Determine the ratio of  $\delta_1$  and  $\delta_2$ . Since the slope on the two sections is the same, the longer section will have the larger deflection. If  $L = a + b$  is the length of the beam, the relationships between the deflections can be determined from Eq. 46.14 through Eq. 46.16.

$$\delta_1 + \delta_2 = 1 \quad 46.13$$

$$\frac{\delta_1}{\delta_2} = \frac{a}{b} \quad 46.14$$

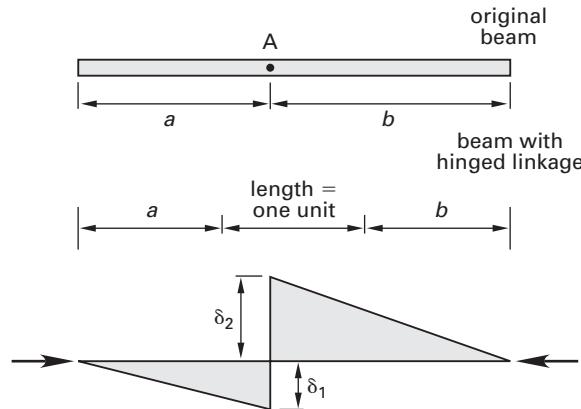

$$\delta_1 = \left(\frac{a}{L}\right)\delta \quad 46.15$$

$$\delta_2 = \left(\frac{b}{L}\right)\delta \quad 46.16$$

Since  $\delta = \delta_1 + \delta_2$  was chosen as 1, Eq. 46.15 and Eq. 46.16 really give the relative proportions of the unit link that extend below and above the reference line in Fig. 46.6.

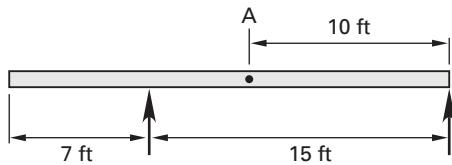

Knowing that the total shear reversal through point A is one unit and that the slopes are the same, the relative proportions of the reversal below and above the line will determine the shape of the displaced beam. The shape of the influence diagram is the shape taken on by the beam.

*step 4:* As required, use equations of straight lines to obtain the shear influence ordinate as a function of position along the beam.

**Figure 46.6** Virtual Beam Displacements

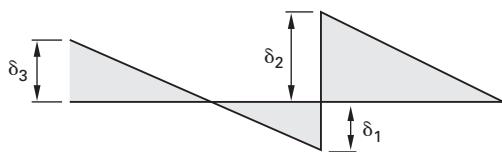

### Example 46.13

For the simply supported beam shown, draw the shear influence diagram for a point 10 ft from the right end.

*Solution*

If a unit link is placed at point A and the beam ends are pushed together, the following shape will result. The beam must remain in contact with the points of support, and the two slopes are the same.

The overhanging 7 ft of beam do not change the shape of the shear influence diagram between the supports. The deflections can be evaluated assuming a 15 ft long beam using Eq. 46.15 and Eq. 46.16.

$$\delta_1 = \frac{a}{L} = \frac{5 \text{ ft}}{15 \text{ ft}} = 0.333$$

$$\delta_2 = \frac{b}{L} = \frac{10 \text{ ft}}{15 \text{ ft}} = 0.667$$

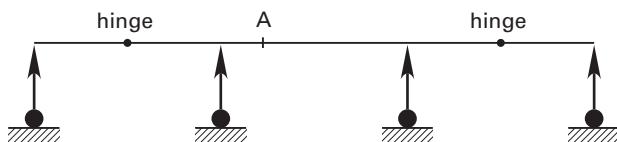

The slope in both sections of the beam is the same. This slope can be used to calculate  $\delta_3$ .

$$m = \frac{\delta_1}{a} = \frac{0.333}{5 \text{ ft}} = 0.0667 \text{ 1/ft}$$

$$\delta_3 = (7 \text{ ft}) \left( 0.0667 \frac{1}{\text{ft}} \right) = 0.467$$

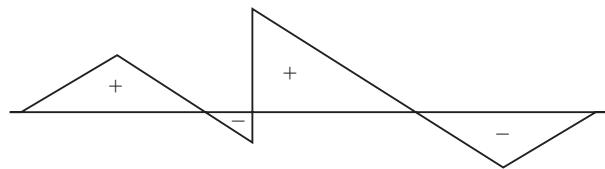

#### Example 46.14

Where should a uniformly distributed load be placed on the following beam to maximize the shear at section A?

*Solution*

Using the principle of virtual displacement, the following shear influence diagram results by inspection. (It is not necessary to calculate the relative displacements to answer this question. It is only necessary to identify the positive and negative parts of the influence diagram.)

To maximize the shear, the uniform load should be distributed either over all positive or all negative sections of the influence diagram.

#### Moment Influence Diagrams by Virtual Displacement

A moment influence diagram (not the same as a moment diagram) gives the moment at a particular point for any location of a unit load. The method of virtual displacement can be used in this situation to simplify finding the moment influence diagram. (See Fig. 46.7.)

*step 1:* Replace the point being investigated (i.e., point A) with an imaginary hinge.

*step 2:* Rotate the beam one unit rotation by applying equal but opposite moments to each of the two beam sections. Except where the point being investigated is at a support, this unit rotation can be achieved simply by “pushing up” on the beam at the hinge point.

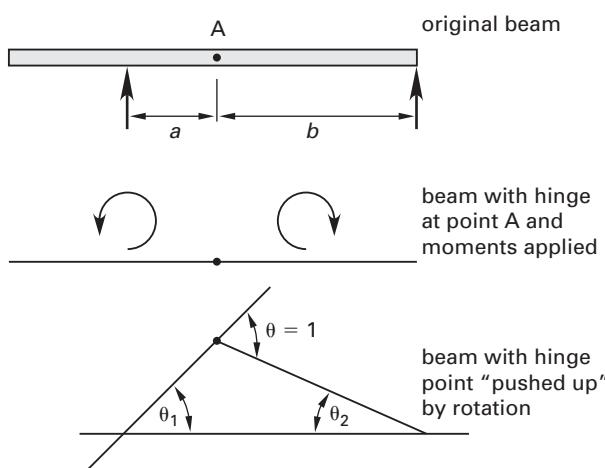

*step 3:* The angles made by the sections on either side of the hinge will be proportional to the lengths of the opposite sections. (Since the angle is small for a virtual displacement, the angle and its tangent, or slope, are the same.)

$$\theta_1 = \frac{b}{L} \quad 46.17$$

$$\theta_2 = \frac{a}{L} \quad 46.18$$

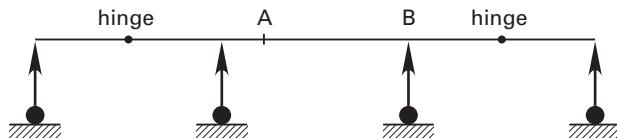

$$L = a + b \quad 46.19$$

**Figure 46.7** Moment Influence Diagram by Virtual Displacement

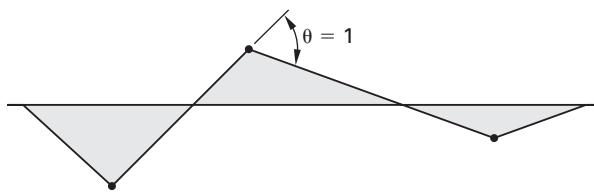

**Example 46.15**

What are the approximate shapes of the moment influence diagrams for points A and B on the beam shown?

**Solution**

By placing an imaginary hinge at point A and rotating the two adjacent sections of the beam, the following shape results.

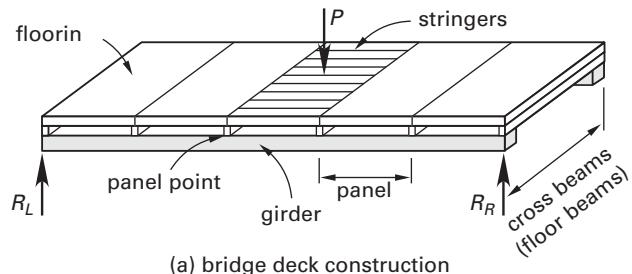

The moment influence diagram for point B is found by placing an imaginary hinge at point B and applying a rotating moment. Since the beam must remain in contact with all supports, and since there is no hinge between the two middle supports, the moment influence diagram must be horizontal in that region.

**Shear Influence Diagrams on Cross-Beam Decks**

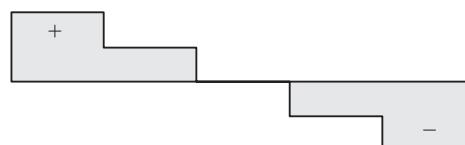

When girder-type construction is used to construct a road or bridge deck, the traffic loads will not be applied directly to the girder. Rather, the loads will be transmitted to the girder at panel points from cross beams (floor beams). Figure 46.8 shows a typical construction detail involving girders and cross beams.

A load applied to the deck stringers will be transmitted to the girder only at the panel points. Because the girder experiences a series of concentrated loads, the shear between panel points is horizontal. Since the shear is always constant between panel points, we speak of *panel shear* rather than shear at a point. Accordingly, shear influence diagrams are drawn for a panel, not for a point. Moment influence diagrams are similarly drawn for a panel.

**Figure 46.8** Cross-Beam Decking

(a) bridge deck construction

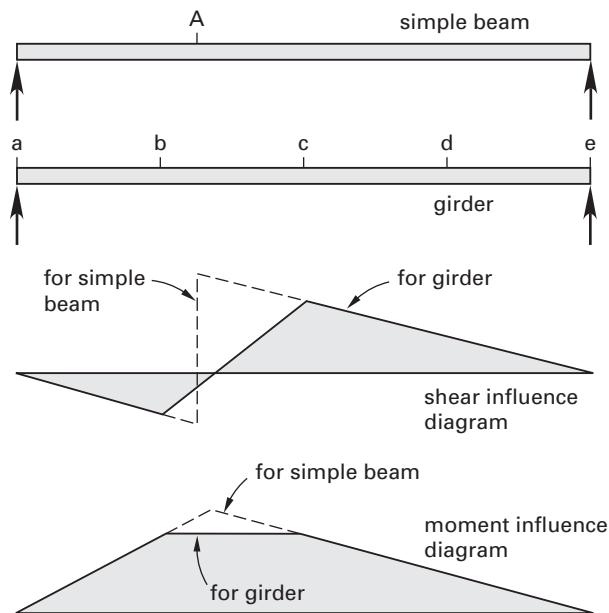

(b) shear diagram for girder

**Influence Diagrams on Cross-Beam Decks**

Shear and moment influence diagrams for girders with cross beams are identical to simple beams, except for the panel being investigated. Once the influence diagram has been drawn for the simple beam, the influence diagram ordinates at the ends of the panel being investigated are connected to obtain the influence diagram for the girder. This is illustrated in Fig. 46.9.

**Figure 46.9** Comparison of Influence Diagrams for Simple Beams and Girders (panel bc)

## Influence Diagrams for Truss Members

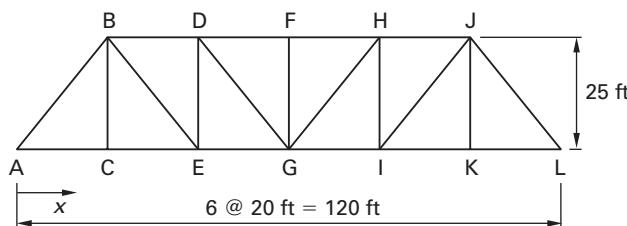

Since members in trusses are assumed to be axial members, they cannot carry shears or moments. Therefore, shear and moment influence diagrams do not exist for truss members. However, it is possible to obtain an influence diagram showing the variation in axial force in a given truss member as the load varies in position.

There are two general cases for finding forces in truss members. The force in a horizontal truss member is proportional to the moment across the member's panel. The force in an inclined truss member is proportional to the shear across that member's panel.

So, even though only the axial load in a truss member may be wanted, it is still necessary to construct the shear and moment influence diagrams for the entire truss in order to determine the applications of loading on the truss that produce the maximum shear and moment across the member's panel.

### Example 46.16

(a) Draw the influence diagram for vertical shear in panel DF of the through truss shown. (b) What is the maximum force in member DG if a 1000 lbf load moves across the truss?

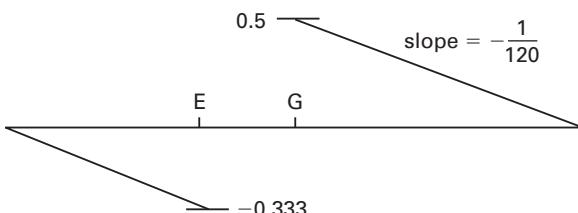

### Solution

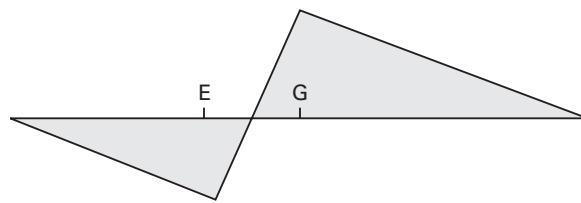

(a) Allow a unit load to move from joint L to joint G along the lower chords. If the unit vertical load is at a distance  $x$  from point L, the right reaction will be  $+(1 - (x/120))$ . The unit load itself has a value of  $-1$ , so the shear at distance  $x$  is just  $-x/120$ .

Allow a unit load to move from joint A to joint E along the lower chords. If the unit load is a distance  $x$  from point L, the left reaction will be  $x/120$ , and the shear at distance  $x$  will be  $(x/120) - 1$ .

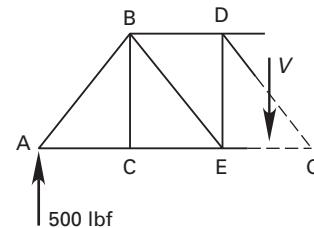

These two lines can be graphed.

The influence line is completed by connecting the two lines as shown. Therefore, the maximum shear in panel DF will occur when a load is at point G on the truss.

(b) If the 1000 lbf load is at point G, the two reactions at points A and L will each be 500 lbf. The cut-and-sum method can be used to calculate the force in member DG simply by evaluating the vertical forces on the free body to the left of point G.

For equilibrium to occur,  $V$  must be 500 lbf. This vertical shear is entirely carried by member DG. The length of member DG is

$$\sqrt{(20 \text{ ft})^2 + (25 \text{ ft})^2} = 32 \text{ ft}$$

The force in member DG is

$$\left(\frac{32 \text{ ft}}{25 \text{ ft}}\right)(500 \text{ lbf}) = 640 \text{ lbf}$$

### Example 46.17

(a) Draw the moment influence diagram for panel DF on the truss shown in Ex. 46.16. (b) What is the maximum force in member DF if a 1000 lbf load moves across the truss?

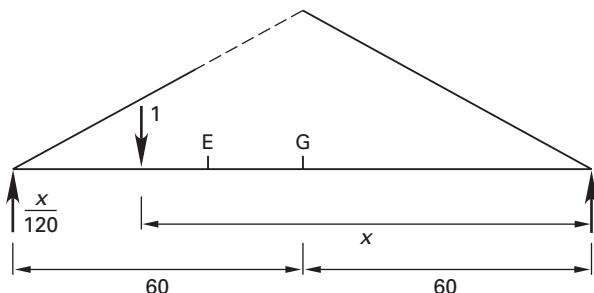

### Solution

(a) The left reaction is  $x/120$ , where  $x$  is the distance from the unit load to the right end. If the unit load is to the right of point G, the moment can be found by summing moments from point G to the left. The moment is  $(x/120)(60) = 0.5x$ .

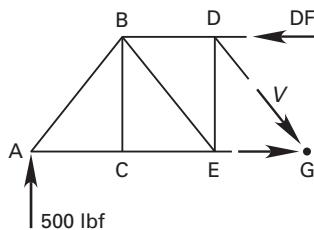

If the unit load is to the left of point E, the moment will again be found by summing moments about point G. The distance between the unit load and point G is  $x - 60$ .

$$\left(\frac{x}{120}\right)(60) - (1)(x - 60) = 60 - 0.5x$$

These two lines can be graphed. The moment for a unit load between points E and G is obtained by connecting the two end points of the lines derived above. Therefore, the maximum moment in panel DF will occur when the load is at point G on the truss.

(b) If the 1000 lbf load is at point G, the two reactions at points A and L will each be 500 lbf. The method of sections can be used to calculate the force in member DF by taking moments about joint G.

$$\sum M_G = (500 \text{ lbf})(60 \text{ ft}) - (DF)(25 \text{ ft}) = 0$$

$$DF = 1200 \text{ lbf}$$

## 11. MOVING LOADS ON BEAMS

### Global Maximum Moment and Shear Stresses Anywhere on Beam

If a beam supports a single moving load, the maximum bending and shearing stresses at any point can be found by drawing the moment and shear influence diagrams for that point. Once the positions of maximum moment and maximum shear are known, the stresses at the point in question can be found from  $Mc/I$  and  $QV/Ib$ .

If a simply supported beam carries a set of moving loads (which remain equidistant as they travel across the beam), the following procedure can be used to find the *dominant load*. (The dominant load is the one that occurs directly over the point of maximum moment.)

*step 1:* Calculate and locate the resultant of the load group.

*step 2:* Assume that one of the loads is dominant. Place the group on the beam such that the distance from one support to the assumed dominant load is equal to the distance from the other support to the resultant of the load group.

*step 3:* Check to see that all loads are on the span and that the shear changes sign under the assumed dominant load. If the shear does not change sign under the assumed dominant load, the maximum moment may occur when only some of the load group is on the beam. If it does change sign, calculate the bending moment under the assumed dominant load.

*step 4:* Repeat steps 2 and 3, assuming that the other loads are dominant.

*step 5:* Find the maximum shear by placing the load group such that the resultant is a minimum distance from a support.

### Placement of Load Group to Maximize Local Moment

In the design of specific members or connections, it is necessary to place the load group in a position that will maximize the load on those members or connections. The procedure for finding these positions of local maximum loadings is different from the global maximum procedures.

The solution to the problem of local maximization is somewhat trial-and-error oriented. It is aided by use of the influence diagram. In general, the variable being evaluated (reaction, shear, or moment) is maximum when one of the wheels is at the location or section of interest.

When there are only two or three wheels in the load group, the various alternatives can be simply evaluated by using the influence diagram for the variable being evaluated. When there are many loads in the load group (e.g., a train loading), it may be advantageous to use heuristic rules for predicting the dominant wheel.

### 1. INTRODUCTION TO STRUCTURAL ANALYSIS

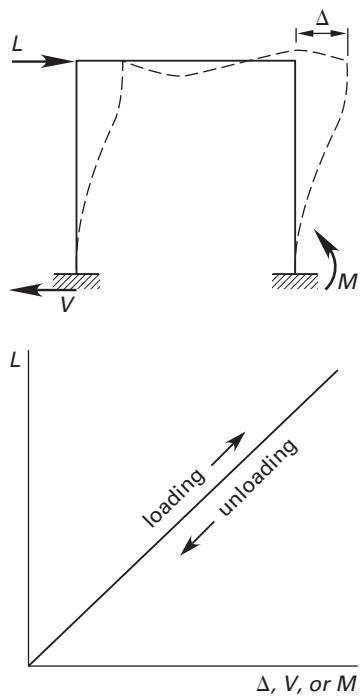

Structural analysis determines the reactions, internal forces, stresses, and deformations induced in a structure by loading. While loading from external forces is the most common situation, stress and deformation can also be caused by internal temperature changes and settling of foundations.

Prior to widespread use of computers in engineering design and analysis, various exact and approximate methods of manual analysis were developed for specific types of structures. While these traditional manual methods continue to be useful, the need for a variety of specialized techniques has been reduced significantly. This chapter concentrates on the manual techniques that remain most relevant in present-day structural analysis.

Structural analysis is categorized as either *static* or *dynamic*, depending on the need to evaluate inertial forces caused by acceleration. A *static analysis* does not consider inertial forces. In a *dynamic analysis*, the various forces and deformations are determined as functions of time. While computer analysis has enhanced the application of dynamic analysis in certain areas (e.g., earthquake loading), most structures continue to be designed using static analyses based on the maximum expected dynamic loads. This chapter is limited to a review of several common methods of structural analysis used for static loading.

Structural analysis can also be categorized on the basis of the level of refinement that is incorporated. *Linear elastic first-order analysis* is used to evaluate the majority of structures built today. The basic assumptions are that (a) the structure is perfectly linear and elastic in behavior, and (b) deformations can be neglected. The principle of *proportionality* is assumed to hold, so changing all of the loads by a certain percentage results in an equal percentage change in all of the internal forces, reactions, and deflections. (See Fig. 47.1.)

**Figure 47.1** Linear Elastic Behavior

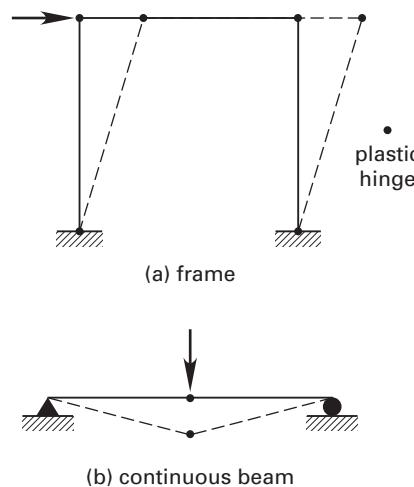

With a *linear elastic second-order analysis*, the assumption of elastic linear behavior is maintained, but the deflections are considered in the equilibrium equations. In a second-order analysis, equilibrium between internal and external forces is achieved in the final deformed configuration, not in the initial undeformed geometry.

Since the deformations of the structure cannot be computed precisely until the internal forces are obtained, a second-order solution is iterative. Due to computational difficulties in manual solutions, second-order effects have

been traditionally included as corrections applied during the design process. The moment magnifier method used to design columns in the ACI code and AISC Manual are typical examples. There is an increasing trend, however, to introduce second-order effects in computerized analyses. The *P-Δ* method described in Sec. 47.18 is a simplified second-order analysis technique.

With an *inelastic first-order analysis*, the potential for inelastic, disproportional behavior is considered, but equilibrium is assumed to occur in the undeformed configuration. *Plastic analysis* is a popular version of this method. The objective of plastic analysis is to obtain the *ultimate load* (maximum load) that the structure can carry. When supporting an ultimate load, the structure becomes a mechanism. A *mechanism* is a structure that can deform by rotation around a number of points. In highly stressed structures, these points are referred to as *plastic hinges* since the material at those points is loaded in the plastic region. (See Fig. 47.2.) Plastic analysis is often used in the design of continuous beams, where it is particularly easy to apply.

**Figure 47.2** Failure Mechanisms

With an *inelastic second-order analysis*, inelastic response in the material is permitted, and the equilibrium equations are satisfied in the deformed configuration. Inelastic second-order analysis is a well-developed tool, but it is too complex to be used in most designs.

## 2. TRADITIONAL METHODS

Statically determinate structures can easily be solved by applying the equations of equilibrium, and advanced methods are seldom needed. Therefore, specialized methods of structural analysis generally address indeterminate structures. Indeterminate structural analysis procedures can be classified as either force methods or displacement (deformation, deflection, etc.) methods, depending on whether forces or displacements are used

as basic unknowns. The classical *moment distribution* and *slope deflection methods* are displacement-based solutions. The *stiffness method*, typically used as the basis of modern computerized structural analysis, also is a displacement method. The *flexibility method* is a force-based approach.

### 3. REVIEW OF WORK AND ENERGY

For a simple structure displaced a distance,  $\Delta$ , in the direction of the applied force,  $P$ , a simple mathematical definition of *work* is the product of force times displacement. Analogously, the work of a *torque* (or moment),  $T$ , causing a rotation of  $\theta$  radians is torque times rotation.

$$W = P\Delta \quad [\text{linear displacement}] \quad 47.1$$

$$W = T\theta \quad [\text{rotation}] \quad 47.2$$

The change in energy,  $U$ , of an ideal conservative system is equal to the work done on the system.

$$W = U_2 - U_1 \quad 47.3$$

### 4. REVIEW OF LINEAR DEFORMATION

The linear deformation of a tension or compression member due to axial force,  $P$ , is

$$\delta = \frac{PL}{AE} \quad 47.4$$

### 5. THERMAL LOADING

Structures subjected to temperature changes can be evaluated using the methods in this chapter by adding the appropriate thermally induced forces and moments to the externally applied loads. For example, the thermally induced axial load in a constrained member with a uniform temperature change is

$$\begin{aligned} P_{\text{th}} &= \frac{\delta_{\text{constrained}} AE}{L} = \alpha(T_2 - T_1) \left( \frac{LAE}{L} \right) \\ &= \alpha(T_2 - T_1) AE \end{aligned} \quad 47.5$$

Bending moments will be induced in a structural member that experiences a temperature variation across its thickness (depth). If the temperature varies linearly with depth, and if the temperature difference is zero at the neutral axis (depth  $h/2$ ), the thermally induced moment will be given by Eq. 47.6.

$$M = \alpha(T_{\text{extreme fiber}} - T_{\text{neutral axis}}) \left( \frac{EI}{\frac{h}{2}} \right) \quad 47.6$$

Any arbitrary linear variation can be treated as the sum of a uniform temperature change plus a linear variation

with a value of zero at the section's neutral axis. In Eq. 47.5 and Eq. 47.6, tension is considered to be positive, and compression is negative. For an axially constrained beam experiencing an increase in temperature at its upper surface, the beam will bow upwards (to lengthen the upper surface), and the moment will be negative.

### 6. DUMMY UNIT LOAD METHOD

The *energy method*, typically referred to as the *dummy load method*, is based on the *virtual work principle*. (See Fig. 47.3.)

If a structure that is in equilibrium with a set of loads is given an arbitrary (virtual) deformation, the external work calculated from the applied loads and the virtual displacements is equal to the internal work of the internal stresses and the virtual strains.

**Figure 47.3** Virtual Work Concepts

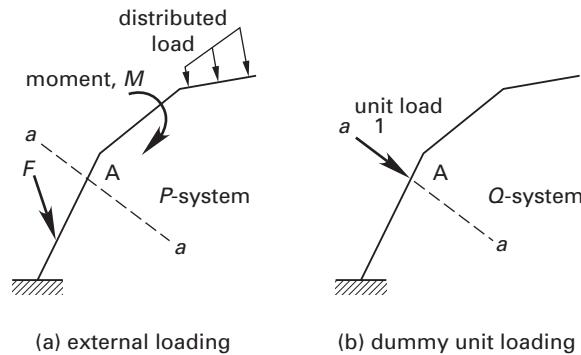

Figure 47.3 illustrates a generalized structure subjected to a general load distribution and whose component of displacement at point A in the direction of line  $aa$  is desired. The analysis begins by considering the structure to be loaded by a unit load at point A along line  $aa$ . For convenience, the system of actual loads is designated as the “*P*-system,” and the unit loading is designated as the “*Q*-system.” The work of unit load can be calculated from the *Q*-system stresses and the *P*-system strains.

$$W_Q = 1 \times \Delta = \int \sigma_Q \epsilon_P dV \quad 47.7$$

The integral in Eq. 47.7 is calculated as a discrete summation; the product is evaluated separately for stresses caused by moments, shears, axial forces, and torques. Some of the terms in Eq. 47.8 may be zero or may be significantly negligible to be neglected.

$$W_Q = W_m + W_v + W_a + W_t \quad 47.8$$

$$W_m = \int \frac{m_Q m_P}{EI} ds \quad 47.9$$

$$W_v = \int \frac{V_Q V_P}{GA} ds \quad 47.10$$

$$W_a = \int \frac{N_Q N_P}{EA} ds \quad 47.11$$

$$W_t = \int \frac{T_Q T_P}{GJ} ds \quad 47.12$$

The sign convention used with Eq. 47.8 through Eq. 47.12 is arbitrary, but it must be used consistently. If a certain direction is assumed positive in the  $P$ -system, the same direction must be taken as positive in the  $Q$ -system. A positive value of  $\Delta$  indicates that the displacement is in the direction of the unit load.

To compute rotations rather than deflections, Eq. 47.8 through Eq. 47.12 can still be used. The  $Q$ -system is loaded by a unit moment at the point where the rotation is wanted.  $m_Q$ ,  $V_Q$ ,  $N_Q$ , and  $T_Q$  are internal forces due to the unit moment rather than a unit load.

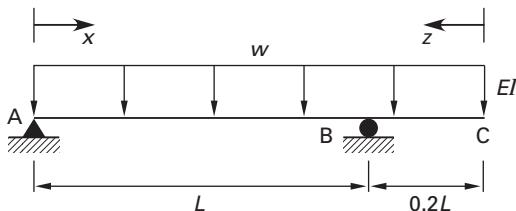

## 7. BEAM DEFLECTIONS BY THE DUMMY UNIT LOAD METHOD

A beam is a member that reacts to applied loads by bending. For most applications, axial stresses and torsion are both zero or negligible. And, except for deep beams (spans  $\leq 3 \times$  depth), it is acceptable to assume that the work due to shear loading is zero. In this case, Eq. 47.8 reduces to

$$W_Q = W_m = \int \frac{m_Q m_P}{EI} ds \quad 47.13$$

### Example 47.1

The simply supported cantilever beam shown is loaded uniformly. Shear deformation is negligible. What is the expression for the deflection at the cantilever end?

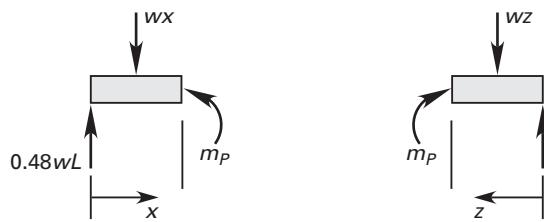

*Solution*

First, determine the moments,  $m_P$ , due to the applied loads. The moment diagram and the defining equations are determined from principles of statics. (The location  $x$  has its origin at A and increases from left to right, while  $z$  starts at point C and increases from right to left.)

$$m_P = 0.48wLx - 0.5wx^2 \quad [\text{segment AB}]$$

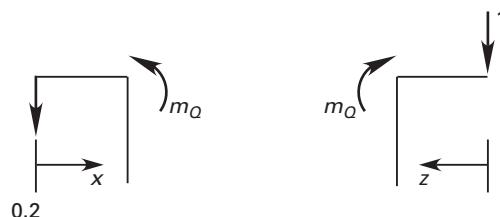

$$m_P = -0.5wz^2 \quad [\text{segment BC}]$$

Next, determine the moments due to the unit load.

$$m_Q = -0.2x \quad [\text{segment AB}]$$

$$m_Q = -z \quad [\text{segment BC}]$$

The deflection is the work done by a unit load. Substituting these expressions for  $m_P$  and  $m_Q$  into Eq. 47.13,

$$\begin{aligned} \Delta &= \int_0^L \frac{(0.48wLx - 0.5wx^2)(-0.2x)}{EI} dx \\ &\quad + \int_0^{0.2L} \frac{(-0.5wz^2)(-z)}{EI} dz \\ &= \frac{-0.0068wL^4}{EI} \quad [\text{upward deflection}] \end{aligned}$$

## 8. TRUSS DEFLECTIONS BY THE DUMMY UNIT LOAD METHOD

The applied loads on a truss are carried by axial forces solely, so Eq. 47.8 reduces to

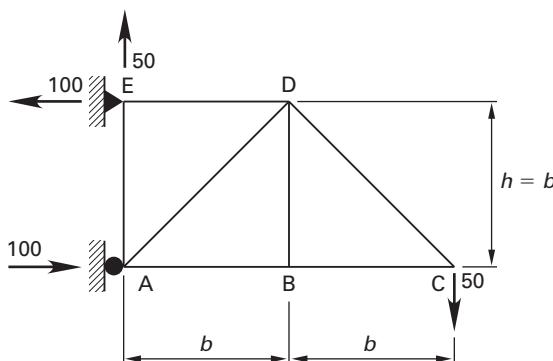

$$W_Q = W_a = \int \frac{N_Q N_P}{EA} ds \quad 47.14$$

Since the axial forces are constant in the truss members, the integral is evaluated as a summation over all of the members.

$$W_Q = W_a = \sum_i \frac{N_{Q,i} N_{P,i} L_i}{E_i A_i} \quad 47.15$$

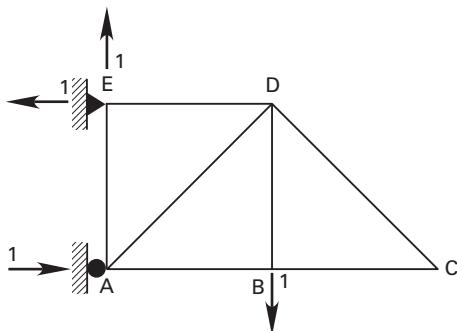

### Example 47.2

Use the dummy load method to determine the expression for the deflection at point B in the truss shown.

*Solution*

The unit-loaded truss is

The forces in the bars due to the applied load (on the  $P$ -system) as well as due to the unit load (on the  $Q$ -system) are determined by traditional methods of statics.

member	$N_P$	$N_Q$	$L_i$	$N_P N_Q L_i$
AB	-50.0	0.0	$b$	0.0
BC	-50.0	0.0	$b$	0.0
CD	70.71	0.0	$1.41b$	0.0
DE	100.0	1.0	$b$	100.0 $b$
EA	+50.0	1.0	$b$	50.0 $b$
AD	-70.71	-1.41	$1.41b$	141.4 $b$
BD	0.0	1.0	$b$	0.0
$\sum = 291.4b$				

The deflection is the work done by a unit load. Use Eq. 47.11.

$$\Delta = W_a = \sum_i \frac{N_{Q,i} N_{P,i} L_i}{E_i A_i}$$

$$= 291.4b/AE$$

## 9. FRAME DEFLECTIONS BY THE DUMMY UNIT LOAD METHOD

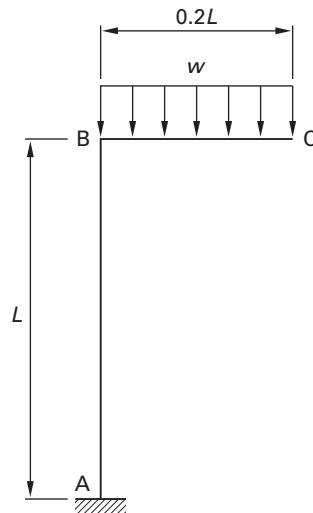

For typically proportioned frames, a good approximation of the deflection can usually be obtained by considering only the flexural contribution. There are cases, however, where axial and shear deformations are significant enough to be included. In particular, shear deformations can be significant in structures with deep

members, and axial deformations can have an important effect on the lateral displacements of tall frames subjected to wind or earthquake forces.

In rigid frames that resist loading primarily by flexure, using the unit dummy load method to calculate deflection is based on Eq. 47.9.

### Example 47.3

Use the dummy load method to determine an expression for the vertical deflection at point C in the frame shown. Neglect shear and axial deformations.

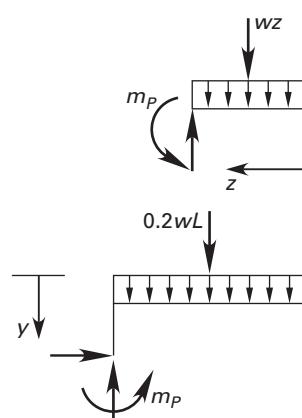

*Solution*

The moments on the frame as loaded are

$$m_P = 0.02wL^2 \quad [\text{bar AB}]$$

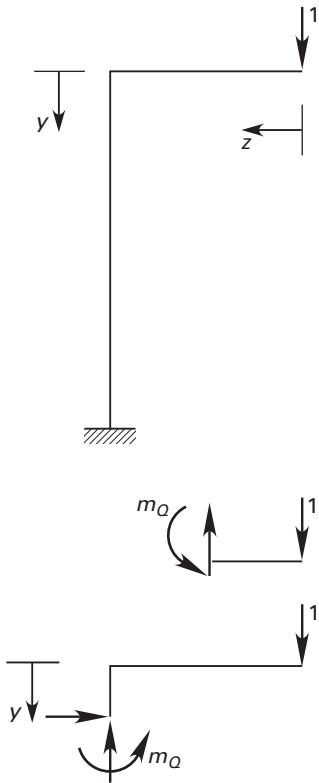

$$m_P = 0.5wz^2 \quad [\text{bar BC}]$$

The corresponding moments for the unit-loaded frame are

$$m_Q = 0.2L \quad [\text{bar AB}]$$

$$m_Q = z \quad [\text{bar BC}]$$

Substituting these expressions into Eq. 47.9,

$$\Delta = \int_0^L \frac{(0.02wL^2)(0.2L)}{EI} dy + \int_0^{0.2L} \frac{(0.5wz^2)z}{EI} dz$$

$$= \frac{0.0042wL^4}{EI}$$

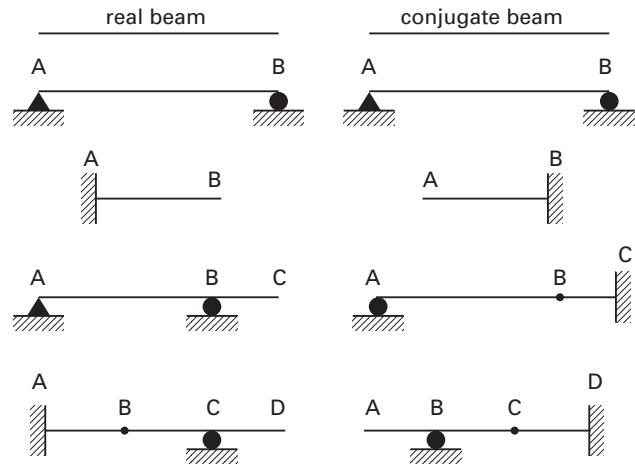

## 10. CONJUGATE BEAM METHOD

The conjugate beam method is a practical procedure for computing deflections in beams. In the conjugate beam method, a “conjugate beam” is loaded with the moment diagram for the real beam divided by the flexural stiffness product,  $EI$ . The conjugate beam has the same length as the real beam, but the support types are changed according to Table 47.1. (See Fig. 47.4.) When this is done, (a) the shear in the conjugate beam will be the same (numerically) as the slope on the real beam, and (b) the moment on the conjugate beam will be the same (numerically) as the deflection in the real beam.

**Table 47.1** Supports for Conjugate Beams

real beam	conjugate beam
exterior simple support	exterior simple support
interior support	hinge
hinge	interior support
free end	fixed end
fixed end	free end

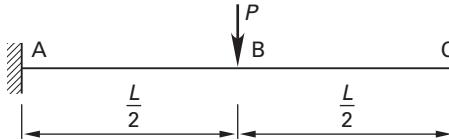

**Figure 47.4** Examples of Conjugate Beams

If the sign convention is such that downward loads on the real beam produce positive moments (the usual assumption), a positive moment on the conjugate beam corresponds to deflection downward. Likewise, slopes in the first and third quadrant are associated with shears that are up on the right side of a free-body diagram.

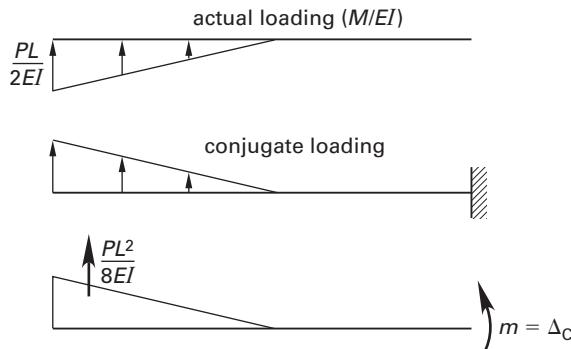

### Example 47.4

Use the conjugate beam method to determine an expression for the deflection at point C on the cantilever beam shown. The cross section and modulus of elasticity are constant along the length of the beam.

#### Solution

The moment diagram for the real beam is shown. The conjugate beam has a free end at the left (because the real beam is fixed at that point) and a fixed end at the right (because the real beam is free at that point). The loading of the conjugate beam is  $M/EI$ , but since  $EI$  is constant, the loading distribution on the conjugate beam is the same as the moment diagram on the real beam.

The moment on the conjugate beam at point C is equal to the deflection on the real beam.

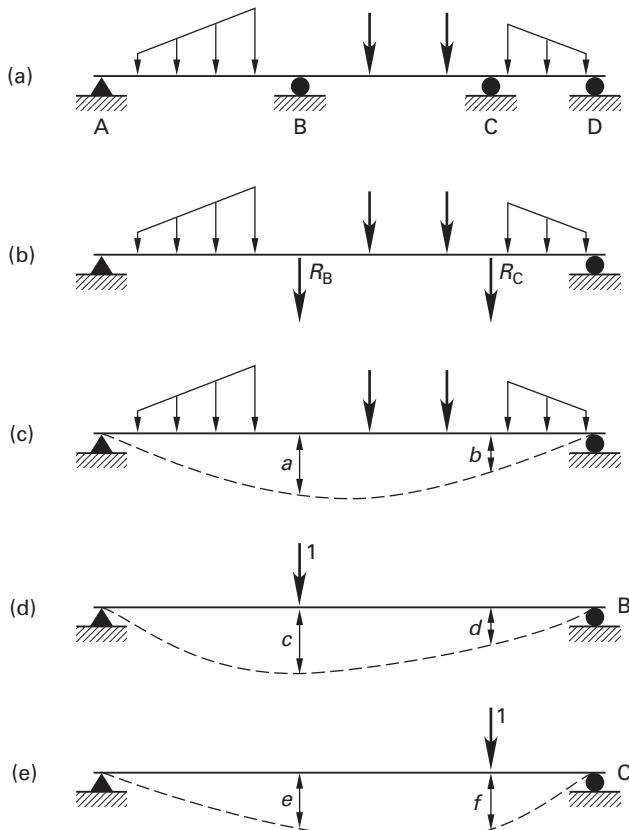

$$\Delta_C = \left( \frac{PL^2}{8EI} \right) \left( \frac{L}{2} + \left( \frac{2}{3} \right) \left( \frac{L}{2} \right) \right)$$

$$= \frac{5PL^3}{48EI}$$

## 11. INTRODUCTION TO THE FLEXIBILITY METHOD

The *flexibility method* (also known as the *method of consistent deformations*) is one of the fundamental methods of indeterminate structural analysis. In practice, a manual application of this method is only convenient with structures having degrees of indeterminacy,  $I$ , of 1, 2, and (with effort) 3, since the number of deflection terms that must be calculated is  $0.5I^2 + 1.5I$ . The basis of the flexibility method can be explained with the aid of Fig. 47.5(a), which shows a three-span continuous beam with an arbitrary loading.

**Figure 47.5** Flexibility Method

The beam in Fig. 47.5(a) is indeterminate to the second degree because there are five reactions and only three equations of statics to determine the reactions. However, any two of the four vertical reactions may be considered applied loads of unknown magnitudes. (The

forces selected are known as *redundants*.) The number of redundants that must be removed to render the structure statically determinate is known as the *degree of static indeterminacy*,  $I$ . The structure with the redundants removed is known as the *primary structure*.

In Fig. 47.5(a), the vertical reactions at B and C may be considered applied loads on a simply supported statically determinate beam. Since the beam must remain in contact with the supports at reaction points, the values of the deflections at points B and C must be zero. Figure 47.5(a) and Fig. 47.5(b) are equivalent.

To illustrate how the equations of compatibility are set up, assume that the deflections at B and C are to be computed using superposition. Referring to Fig. 47.5(c), the first components are the deflections from the applied loading, which are designated as  $a$  and  $b$ . The deflections due to the reaction at B,  $R_B$ , are proportional to the magnitude of the reaction, so it is convenient to compute the deflections for a unit reaction and then to scale them by  $R_B$ . Designate the deflections from  $R_B = 1$  as  $c$  and  $d$  (as shown in Fig. 47.5(d)) and those from  $R_C = 1$  as  $e$  and  $f$  (as shown in Fig. 47.5(e)). With this notation, the conditions of zero deflection at support points B and C can be mathematically expressed as Eq. 47.16 and Eq. 47.17. These two equations can be solved simultaneously to obtain  $R_B$  and  $R_C$ . Once the reactions are known, any quantity of interest can be readily computed using statics.

$$a + cR_B + eR_C = 0 \quad 47.16$$

$$b + dR_B + fR_C = 0 \quad 47.17$$

This method can be modified to account for settling of the supports, as well. If there was a settlement of  $\delta$  in at B, then the equations would be

$$a + cR_B + eR_C = \delta \quad 47.18$$

$$b + dR_B + fR_C = 0 \quad 47.19$$

## 12. BASIC FLEXIBILITY METHOD PROCEDURE

The following steps constitute the procedure for using the flexibility method.

**step 1:** Transform the structure into a statically determinate structure by eliminating redundant reactions, moments, or internal forces. A set of redundants for a given indeterminate structure is not unique. Although some choices may lead to less numerical effort than others, all selections are equally valid. It is important to keep in mind, however, that the statically determinate primary system that remains must be stable.

For trusses, the degree of static indeterminacy is a combination of external indeterminacy (from redundant reactions) and internal indeterminacy

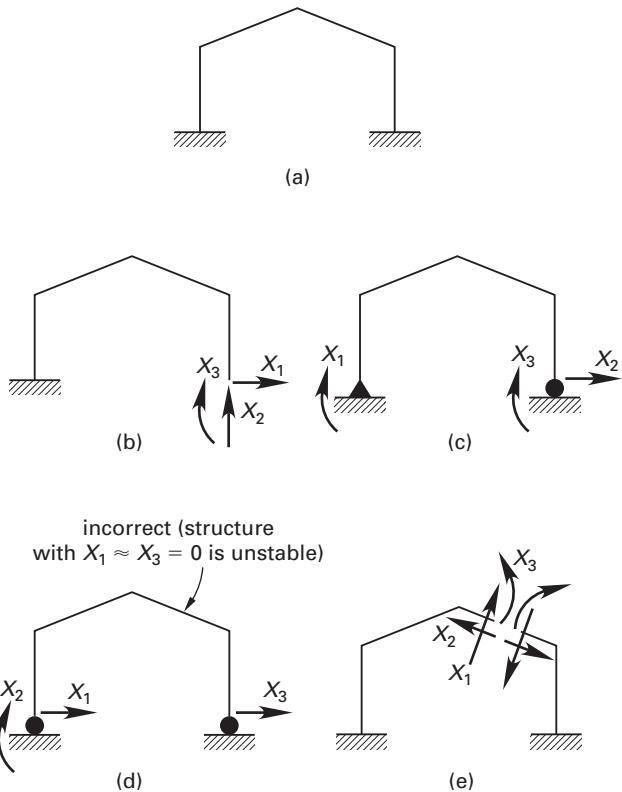

(from redundant members). The total degree of indeterminacy in trusses is

$$\begin{aligned} I &= \text{no. of reactions} \\ &\quad + \text{no. of members} \\ &\quad - 2(\text{no. of joints}) \end{aligned} \quad 47.20$$

If Eq. 47.20 is zero, the truss is statically determinate; if it is negative, the truss is unstable. In cases where  $I \geq 0$ , the truss must also be checked for stability.

Figure 47.6(a) illustrates a frame that is indeterminate to the third degree ( $I = 3$ ). Three possible primary structures obtained by considering some of the reactions as redundants are shown as Fig. 47.6(b), (c), (d), and (e). However, Fig. 47.6(d) is inappropriate because the primary structure cannot resist horizontal forces and, therefore, is unstable. The redundants also need not be reactions at all, but can be taken as internal forces. For example, the axial, shear, and moment at an arbitrarily located cut can be selected as redundants, as in Fig. 47.6(e). When internal forces are taken as redundants, the equilibrium forces act on both sides of the cut with opposite directions. For convenience, the redundants are designated as  $X_1, X_2, \dots, X_n$ , regardless of whether they are forces or moments. These  $X_i$  are collected in a vector  $\mathbf{X}$ .

**Figure 47.6** Frame and Its Primary Structures

$$\mathbf{X} = \begin{bmatrix} X_1 \\ X_2 \\ \vdots \\ X_n \end{bmatrix} \quad 47.21$$

*step 2:* Compute the deflections (or rotations) due to the applied loads at each of the locations (and in the directions) of the redundants. These deflections are designated as  $\delta_1, \delta_2, \dots, \delta_n$ . These  $\delta_i$  terms are collected in a deflection matrix  $\boldsymbol{\delta}$ .

$$\boldsymbol{\delta} = \begin{bmatrix} \delta_1 \\ \delta_2 \\ \vdots \\ \delta_n \end{bmatrix} \quad 47.22$$

For beams, it is generally appropriate to compute the deflections accounting only for flexural effects. For trusses, the deflections are due to axial elongations only. In most practical cases, frames can be solved accounting only for flexural deformations.

*step 3:* Compute the deflections for unit values of each of the redundants. These deflections are known as *flexibility coefficients* and are designated as  $f_{i,j}$ , where  $f_{i,j}$  is the deflection at location  $i$  due to a unit value of the redundant at location  $j$ . The flexibility coefficients are collected in a flexibility matrix  $\mathbf{F}$ . Matrix  $\mathbf{F}$  is symmetrical since  $f_{i,j} = f_{j,i}$ .

$$\mathbf{F} = \begin{bmatrix} f_{1,1} & f_{1,2} & \cdots & f_{1,n} \\ f_{2,1} & \cdots & f_{2,n} \\ \cdots & f_{3,n} \\ \vdots & & & \\ f_{n,1} & f_{n,2} & \cdots & f_{n,n} \end{bmatrix} \quad 47.23$$

*step 4:* Determine the settlements, if any, at the redundant supports. Collect these settlements in the settlement matrix  $\mathbf{S}$ . Where there is no settling, all entries in  $\mathbf{S}$  are zero (i.e.,  $\mathbf{S}$  is the null matrix).

*step 5:* Write the set of simultaneous equations that impose the geometrical requirements of compatibility. Using the format previously introduced, these equations are written in vector format.

$$\mathbf{FX} = \mathbf{S} - \boldsymbol{\delta} \quad 47.24$$

### 13. SYSTEMATIC FLEXIBILITY METHOD PROCEDURE

*Solution*

Most of the work in applying the flexibility method is associated with finding all of the deflections needed to set up the compatibility equations. While these deflections can be obtained using any applicable technique, the dummy load method is most frequently used in practice. The following systematic approach can be used to integrate these two methods.

*step 1:* Select the redundants and their positive directions.

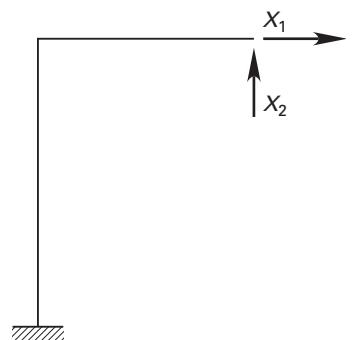

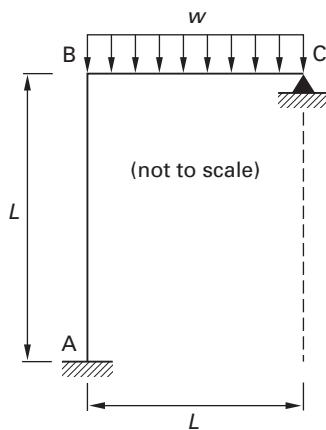

*step 2:* Determine equations that describe how internal forces vary throughout the structure. (For visualization purposes, it is often convenient to write these expressions on a sketch of the structure.) Designate the effects of the loads on the primary structure as “ $X = 0$ .”

*step 3:* Derive equations for the relevant internal forces due to the unit values of each redundant. Designate the effects of the first redundant as “ $X_1 = 1$ ,” for the second as “ $X_2 = 1$ ,” and so on.

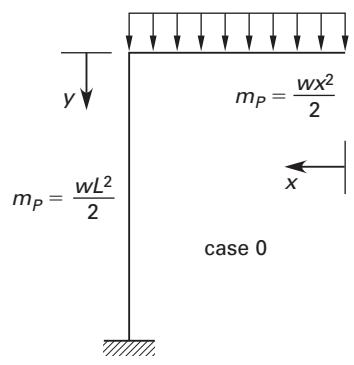

*step 4:* Compute the deflection terms. (Refer to Eq. 47.7 through Eq. 47.11.) For the terms in  $F$ , obtain  $f_{j,n}$  by integrating the product of the internal forces for  $X_j = 1$  times  $X_n = 1$ . For the terms in  $\delta$ , obtain  $\delta_n$  by integrating the product of the internal forces for  $X = 0$  times  $X_n = 1$ .

#### Example 47.5

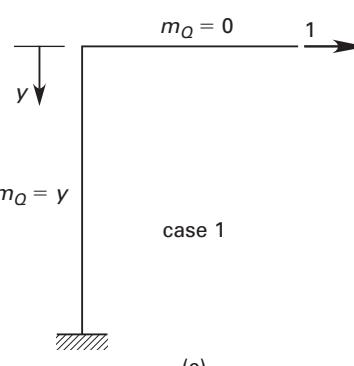

Use the flexibility method to draw the moment diagram for the frame shown. Neglect axial and shear deformations in the computations. Consider  $EI$  to be constant for both members.

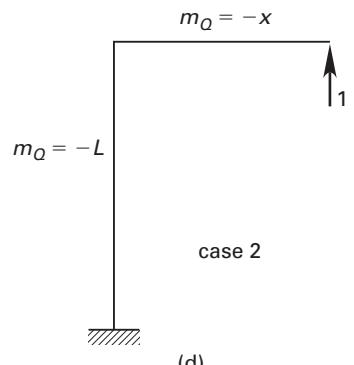

(a)

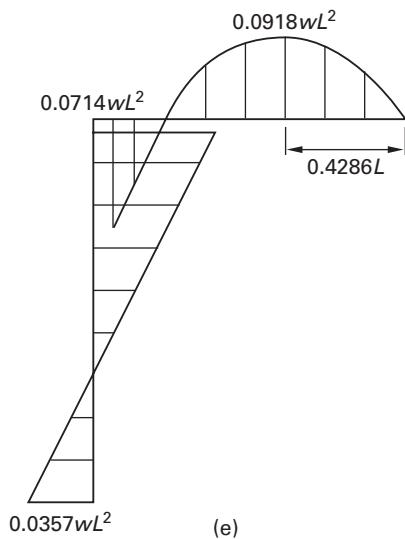

case 0

case 1

case 2

Refer to the illustration. From (a), the frame is indeterminate to the second degree. Select the two reactions at point C as the redundants. Expressions for the moments in the primary structure due to the loading as well as from the unit values of the redundants are shown in (b). From (c) and (d), the required deflection and flexibility coefficients are determined in the following expressions. Once the reactions are known, the moment diagram can be easily computed, as shown in (e).

$$\delta_1 = \int_0^L \frac{wL^2 y}{2EI} dy = \frac{wL^4}{4EI}$$

$$\delta_2 = \int_0^L \frac{-wx^3}{2EI} dx + \int_0^L \frac{-wL^3}{2EI} dy = \frac{-5wL^4}{8EI}$$

$$f_{1,1} = \int_0^L \frac{y^2}{EI} dy = \frac{L^3}{3EI}$$

$$f_{2,2} = \int_0^L \frac{x^2}{EI} dx + \int_0^L \frac{(-L)^2}{EI} dy = \frac{4L^3}{3EI}$$

$$f_{1,2} = f_{2,1} = \int_0^L \frac{y(-L)}{EI} dy = \frac{-L^3}{2EI}$$

Substitute these values into Eq. 47.24 and solve.

$$\begin{aligned} \frac{L^3}{EI} \begin{bmatrix} \frac{1}{3} & -\frac{1}{2} \\ -\frac{1}{2} & \frac{4}{3} \end{bmatrix} \begin{bmatrix} X_1 \\ X_2 \end{bmatrix} &= \frac{wL^4}{EI} \begin{bmatrix} -\frac{1}{4} \\ \frac{5}{8} \end{bmatrix} \\ \begin{bmatrix} X_1 \\ X_2 \end{bmatrix} &= wL \begin{bmatrix} -0.107 \\ 0.429 \end{bmatrix} \end{aligned}$$

## 14. STIFFNESS METHOD

The *stiffness method* is based on the fact that the behavior of any structure can be viewed as the superposition of the effect of loads on a structure with joints that do not displace and the effect of the joint displacements. (The term “displacement” is used in a generic sense to mean both translation and rotation.)

With the stiffness method, the traditional degree of static indeterminacy is not considered when obtaining a solution. Instead, the number of independent joint displacements, known as the *degree of kinematic indeterminacy*, determines the number of simultaneous equations. While the equations in the flexibility method describe conditions of compatibility, equations in the stiffness method are statements of equilibrium at the joints.

Consider the frame shown in Fig. 47.7(a). As shown in Fig. 47.7(b), the members are first assumed to behave as doubly fixed-ended beams, which is equivalent to stating that the joints do not translate or rotate. The magnitudes of the external joint forces needed to “lock” the joints are shown in Fig. 47.7(c) and can be readily obtained using simple statics. For example, restraining forces,  $Q$ , at joint B can be found from the equilibrium conditions at joint B.

$$V_{BA} - N_{BC} + Q_1 = 0 \quad [x\text{-direction}] \quad 47.25$$

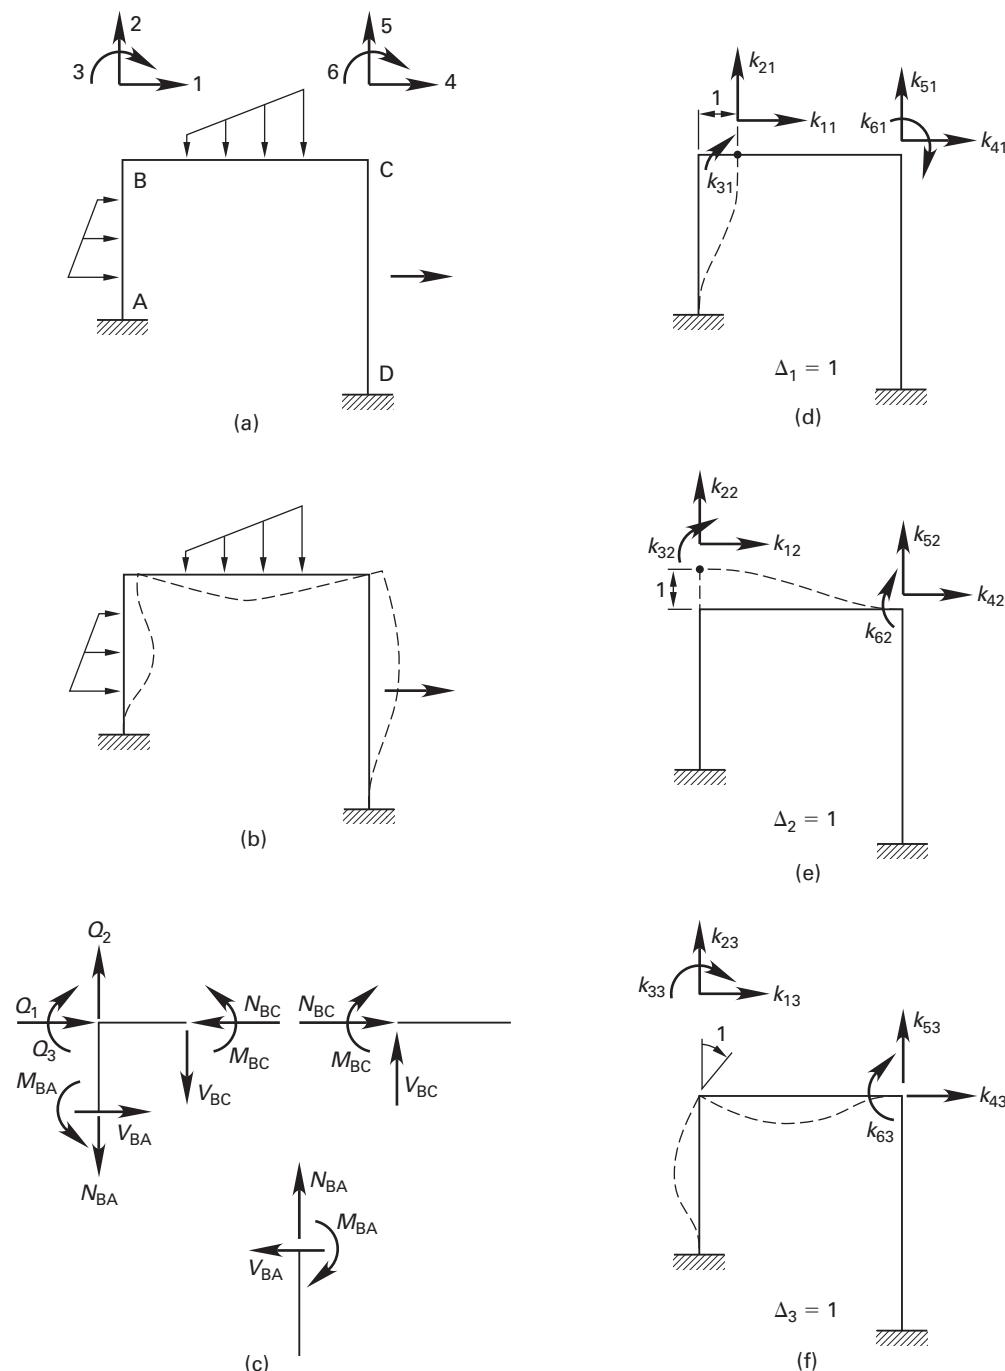

$$-N_{BA} - V_{BC} + Q_2 = 0 \quad [y\text{-direction}] \quad 47.26$$

$$-M_{BA} - M_{BC} + Q_3 = 0 \quad [\text{moments}] \quad 47.27$$

In many cases, the resulting locked joint will result in a fixed-end beam. The fixed-end moments (FEMs) can be read directly from App. 47.A for most common loading conditions.

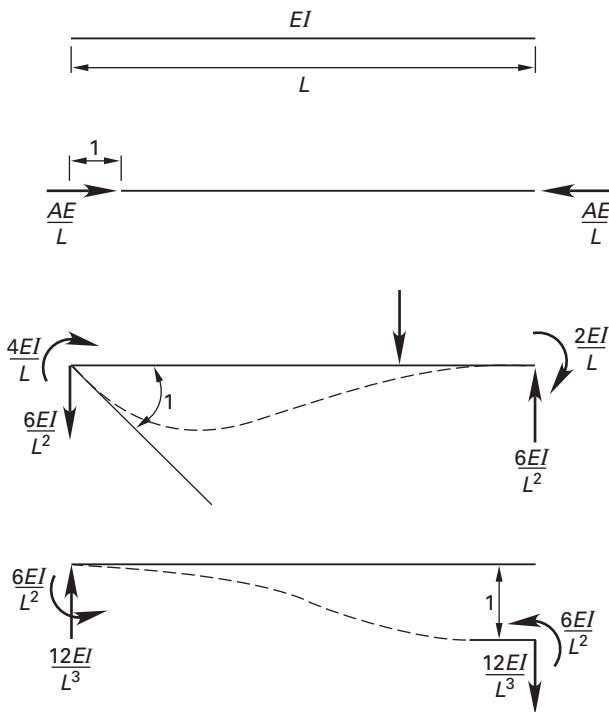

Since there are actually no restraining forces acting, the effect that the negative of the restraining  $Q$  forces have on the structure must be determined. A convenient way to do this is to compute the joint forces needed to impose a unit value at each of the possible joint movements (also known as *degrees of freedom*, DOF) while keeping the others restrained. These forces are easy to compute. Any joint load distribution can be expressed as a linear combination of the forces. The deformed structure with unit displacements imposed on the first three DOFs is illustrated in Fig. 47.7(d) through Fig. 47.7(f).

With beams, the stiffness method is simplified by the fact that the DOFs are only joint rotations. Truss bars are pinned at the joints, so for trusses, only the two translational DOFs need to be considered at each joint. Since the loads in trusses are also applied at the joints, the analysis of locked joints leads to zero bar forces. For frames, there are typically three DOFs at each joint. However, solutions assuming the bar elongations to be negligible are often quite accurate. This simplification can be used to reduce the number of DOFs for manual solutions.

**Figure 47.7** Stiffness Method

The external forces required to impose the unit displacements are designated using the letter  $k$  and two subscripts. The first subscript designates the DOF where the force is applied; the second subscript designates the DOF where the unit displacement was imposed.  $k_{i,j}$  is the force at DOF  $i$  due to a unit displacement at DOF  $j$ . (The terms "displacement" and "force" are used in a

generalized sense.) Some computational effort is saved by recognizing that the stiffness matrix,  $\mathbf{k}$ , is symmetrical, and  $k_{i,j} = k_{j,i}$ . The coefficients constituting  $\mathbf{k}$  are the forces required to impose unit displacements at the end of an individual bar. The typical case of a prismatic member is depicted in Fig. 47.8.

**Figure 47.8** Forces in the Prismatic Bar Due to Unit Displacements

Equation 47.28 indicates that the  $Q$  forces must vanish (i.e., be zero). (The vector  $\Delta$  collects the displacements at all of the DOFs.)

$$k\Delta + \mathbf{Q} = \mathbf{0} \quad 47.28$$

It is customary to write Eq. 47.28 in terms of a *load vector*,  $\mathbf{L}$ , that is the negative of the restraining force vector.

$$k\Delta - \mathbf{L} = \mathbf{0} \quad 47.29$$

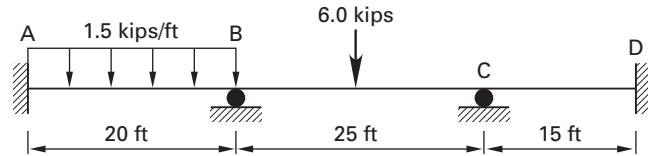

The actual conditions are obtained by summing the conditions that exist in the locked condition and the conditions from the unit displacements scaled by the appropriate  $\Delta$  values.

With the flexibility method, the number of simultaneous equations is equal to the degree of static indeterminacy. With the stiffness method, the number of simultaneous equations equals the number of degrees of freedom. When the number of equations is the same, the stiffness method is typically faster than the flexibility method. This is because the terms in the equations are obtained from tabulated fixed-end moments and stiffness coefficients using basic principles of statics. In contrast, in the flexibility method, one must go through the time-consuming process of computing the deflections from basic principles. Closed form solutions are typically unavailable for the loading conditions encountered.

#### Example 47.6

Use the stiffness method to draw the moment diagram for the three-span beam shown. The product of the

modulus of elasticity,  $E$ , and the centroidal moment of inertia,  $I$ , of the cross section is  $EI = 28 \times 10^6 \text{ in}^2\text{-kips}$ .

*Solution*

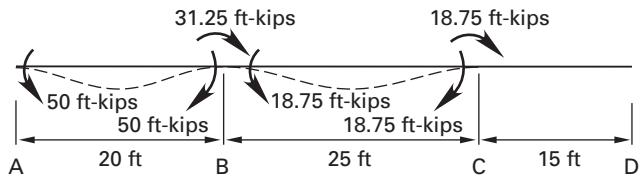

Since the supports at A and D are fixed, the only DOFs are the rotations at B and C. If these DOFs are locked, the structure will be made up of three fixed-ended beams. From App. 47.A, the restraining moments are

$$\text{FEM}_{AB} = \text{FEM}_{BA} = \frac{wL^2}{12} = \frac{\left(1.5 \frac{\text{kips}}{\text{ft}}\right)(20 \text{ ft})^2}{12} = 50 \text{ ft-kips}$$

$$\text{FEM}_{BC} = \text{FEM}_{CB} = \frac{PL}{8} = \frac{(6 \text{ kips})(25 \text{ ft})}{8} = 18.75 \text{ ft-kips}$$

For equilibrium at joints B and C, the restraining moment vector,  $\mathbf{Q}$ , is

$$\mathbf{Q} = [31.25 \text{ ft-kips}, 18.75 \text{ ft-kips}]$$

The deformed configuration corresponding to a unit rotation at point B (DOF no. 1) is shown. Let clockwise be the positive direction. Calculate the nonzero moments at the ends of the bars for this configuration. (All other moments are zero.)

$$M_{AB} = \frac{2EI}{L} = \frac{(2)(28 \times 10^6 \text{ in}^2\text{-kips})}{(20 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)^2} = 19,444 \text{ ft-kips}$$

$$M_{BA} = \frac{4EI}{L} = \frac{(4)(28 \times 10^6 \text{ in}^2\text{-kips})}{(20 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)^2} = 38,889 \text{ ft-kips}$$

$$M_{BC} = \frac{4EI}{L} = \frac{(4)(28 \times 10^6 \text{ in}^2\text{-kips})}{(25 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)^2} = 31,111 \text{ ft-kips}$$

$$M_{CB} = \frac{2EI}{L} = \frac{(2)(28 \times 10^6 \text{ in}^2\text{-kips})}{(25 \text{ ft})(12 \frac{\text{in}}{\text{ft}})^2}$$

$$= 15,556 \text{ ft-kips}$$

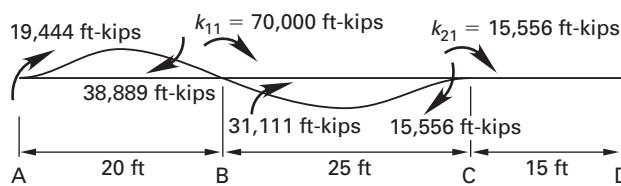

Consider the rotational equilibrium requirement at joints B and C.

$$k_{1,1} = M_{BA} + M_{BC} = 38,889 \text{ ft-kips} + 31,111 \text{ ft-kips}$$

$$= 70,000 \text{ ft-kips}$$

$$k_{2,1} = M_{CB} + M_{CD} = 15,556 \text{ ft-kips} + 0 \text{ ft-kips}$$

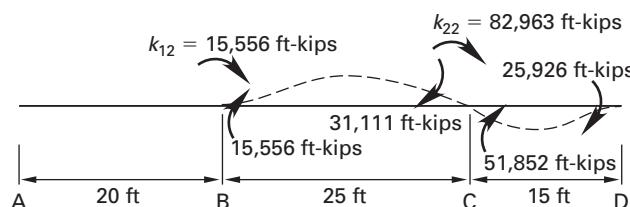

$$= 15,556 \text{ ft-kips}$$

Use the same procedure to determine the moments induced by the deformed structure corresponding to a unit rotation at DOF no. 2. (The coefficients  $k_{2,1}$  and  $k_{1,2}$  are equal since the stiffness matrix is symmetrical.)

$$k_{2,2} = 82,963 \text{ ft-kips}$$

$$k_{1,2} = 15,556 \text{ ft-kips}$$

The stiffness matrix is

$$\mathbf{k} = \begin{bmatrix} 70,000 & 15,556 \\ 15,556 & 82,963 \end{bmatrix}$$

Use Eq. 47.29. The "deflections" are actually rotations, so use  $\theta$  to represent the joint rotations.

$$\mathbf{k}\boldsymbol{\theta} = -\mathbf{Q}$$

$$\begin{bmatrix} 70,000 & 15,556 \\ 15,556 & 82,963 \end{bmatrix} \begin{bmatrix} \theta_B \\ \theta_C \end{bmatrix} = \begin{bmatrix} -31.25 \\ -18.75 \end{bmatrix}$$

The solution to this system of equations is  $\theta_B = -0.000413 \text{ rad}$  and  $\theta_C = -0.000149 \text{ rad}$ .

The actual moments at the ends of the members are obtained by superposition of the locked cases and the scaled contributions of the moments calculated from the unit values. For example, the moment at end  $M_{BA}$  is

$$M_{BA} = 50 \text{ ft-kips} + (-0.000413 \text{ rad})(38,889 \text{ ft-kips})$$

$$= 33.94 \text{ ft-kips}$$

Moments that are not at the ends of the bars can be obtained from statics once the end moments have been computed.

## 15. MOMENT DISTRIBUTION METHOD

The *moment distribution method* was developed by Prof. Hardy Cross in the early 1930s. The procedure is based on a locked-joint situation similar to stiffness. The name "moment distribution" derives from the fact that the external moments needed to obtain the locked condition are "distributed" using an iterative approach.

Although it is possible in principle to deal with axial deformations, practical moment distribution always assumes that the members do not change in length as a result of the applied loads. Moment distribution is particularly simple in cases where the fixed-length assumption is sufficient to ensure that the joints of the structure are fixed in space: This case is typically referred to as "structures without sidesway." Moment distribution can also be used when the joints in the structure displace (i.e., where there is sidesway), although the procedure is not as efficient.

The moment required to induce a unit rotation at the end of a bar when the far end is assumed to be fixed is known as the *stiffness*,  $K$ . Referring to Fig. 47.8, the flexural stiffness is  $K = 4EI/L$ . The *carryover factor*, COF, is defined as the ratio of the moment that appears at the far end in response to the applied moment. Referring to Fig. 47.8, the carryover factor is  $\text{COF} = 1/2$ .

Consider a situation where a number of bars meet at a common rigid joint while all of the far ends are fixed. Assume that the joint is subjected to an external applied moment,  $M$ . Each of the bars will support some portion of the applied moment. With  $m_i$  as the moment supported by bar  $i$ , the *distribution factor* for bar  $i$  (at the joint in question) is the fraction of the total applied moment distributed to another joint.

$$\text{DF}_i = \frac{m_i}{M} \quad 47.30$$

All of the bars that meet at the common joint rotate by an equal amount,  $\theta$ . The moment that is induced by a rotation is the product of the flexural stiffness times the rotation.

$$m_i = K_i \theta \quad 47.31$$

The sum of all the moments in the bars equal the applied moment.

$$\begin{aligned} M &= \sum_i m_i \\ &= \sum_i K_i \theta \end{aligned} \quad 47.32$$

Combining Eq. 47.30 and Eq. 47.32,

$$DF_i = \frac{K_i}{\sum_i K_i} \quad 47.33$$

The sum of all of the distribution factors at a rigid joint is 1.

$$\sum_i DF_i = 1 \quad 47.34$$

## 16. MOMENT DISTRIBUTION PROCEDURE: NO SIDESWAY

*step 1:* Draw a line diagram representation of the structure to be analyzed. This diagram will be used to record intermediate results.

*step 2:* Except for cantilevered sections that have  $K = 0$ , compute the flexural stiffness for each bar using Eq. 47.35 or Eq. 47.36.

$$K = \frac{4EI}{L} \quad \begin{array}{l} \text{opposite end fixed} \\ \text{or continuous interior} \end{array} \quad 47.35$$

$$K = \frac{3EI}{L} \quad \begin{array}{l} \text{opposite end pinned} \\ \text{or rollered} \end{array} \quad 47.36$$

*step 3:* Use Eq. 47.33 to compute the distribution factor at each end of the bars. Record the values on the drawing of the structure. Since the distribution factor is a ratio of flexural stiffnesses, a common factor (e.g., the product  $EI$ ) can be taken from the numerator and the denominator without affecting the results. It is convenient to remember that  $DF = 0$  at fixed ends (representing infinite stiffness) and  $DF = 1$  at simple supports.

*step 4:* Obtain the fixed-end moments from App. 47.A. (Adopt a consistent sign convention, such as “clockwise moments at the ends are positive.”) Record the fixed-end moments on the drawing at the ends of each bar.

*step 5:* Go to any joint and compute the “unbalanced moment” (or “out of balance,” OOB) by adding all the moments at the ends of the bars that meet there. Distribute the unbalanced moment to each bar. The distributed moments are equal to the product of the unbalanced moment times the distribution factor with the reversed sign. (Although the order used for releasing and locking the joints is arbitrary, convergence is fastest if the joint with the largest unbalance is handled first.)

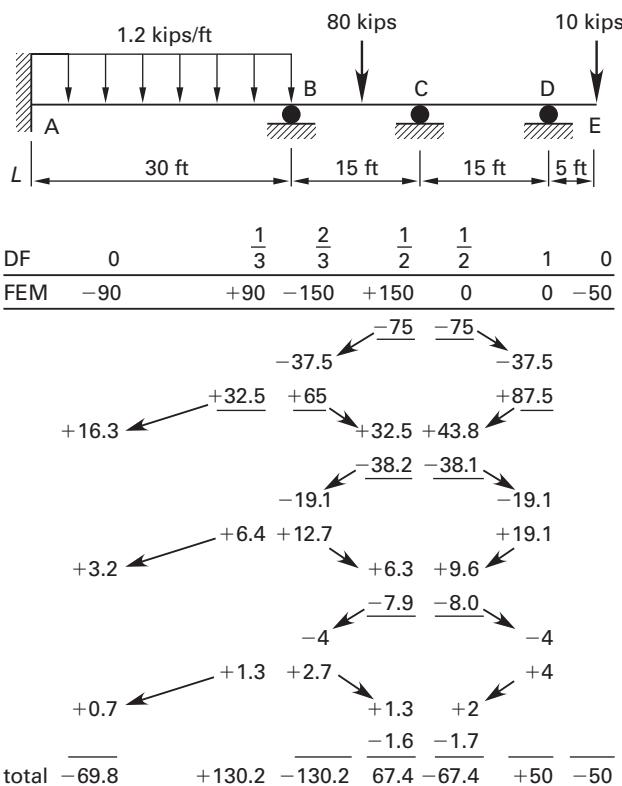

*step 6:* Carry the distributed moment to the far end of the corresponding bar by multiplying the distributed moment by the *carryover factor*. The carryover factor is 0.5 for joints with opposite ends that are fixed; it is 0 for joints with opposite ends that are pinned or cantilevered.

*step 7:* Repeat steps 5 and 6 until the unbalanced moment at the most unbalanced joint is insignificant (typically, less than 1% of the largest fixed-end moment).

*step 8:* Calculate the true moments at each bar end as the sum of moments that have been recorded at that end.

### Example 47.7

Use the moment distribution method to determine the end moments for the continuous beam shown.

### Solution

Use Eq. 47.35 to calculate the flexural stiffness of each bar. Since  $EI$  is constant and only the relative values of  $K$  affect the results, let  $4EI$  equal the length of the longest span (30 ft in this case). Then,

$$K_{AB} = \frac{4EI}{L} = \frac{30 \text{ ft}}{30 \text{ ft}} = 1$$

$$K_{BC} = \frac{30 \text{ ft}}{15 \text{ ft}} = 2$$

$$K_{CD} = \frac{30 \text{ ft}}{15 \text{ ft}} = 2$$

$$K_{DE} = 0 \quad [\text{cantilever}]$$

Determine the distribution factors.

$$DF_{AB} = 0 \quad [\text{fixed end}]$$

$$\begin{aligned} DF_{BA} &= \frac{K_{BA}}{\sum_i K_i} = \frac{1}{1+2} \\ &= 1/3 \end{aligned}$$

$$DF_{BC} = \frac{2}{1+2} = 2/3$$

$$DF_{CB} = \frac{2}{2+2} = 1/2$$

$$DF_{CD} = \frac{2}{2+2} = 1/2$$

$$DF_{DC} = \frac{2}{2+0} = 1 \quad [\text{free end}]$$

The fixed-end moments are determined from App. 47.A.

$$\begin{aligned} FEM_{AB} &= FEM_{BA} = \frac{wL^2}{12} \\ &= \frac{\left(1.2 \frac{\text{kips}}{\text{ft}}\right)(30 \text{ ft})^2}{12} \\ &= 90 \text{ ft-kips} \end{aligned}$$

$$\begin{aligned} FEM_{BC} &= FEM_{CB} = \frac{PL}{8} \\ &= \frac{(80 \text{ kips})(15 \text{ ft})}{8} \\ &= 150 \text{ ft-kips} \end{aligned}$$

$$FEM_{DE} = (10 \text{ kips})(5 \text{ ft}) = 50 \text{ ft-kips}$$

$$FEM_{ED} = 0 \quad [\text{free end}]$$

Start the moment distribution at joint C. The unbalanced moment of 150 ft-kips is reversed in sign and multiplied by the distribution factors, both of which are one half. This puts a balancing correction of -75 ft-kips on either side of joint C, for a total balancing correction of -150 ft-kips. (The horizontal lines under the moments of -75 ft-kips indicate that joint C has now been balanced.) Multiply the balancing moments by the carryover factors (0.5) and carry the products over to the far ends of BC and CD.

Continue by moving to joint B. The unbalanced moment is 90 ft-kips - 150 ft-kips - 37.5 ft-kips = -97.5 ft-kips, requiring a total balancing moment of 97.5 ft-kips. The balance is distributed according to

the distribution factors of one-third and two-thirds, resulting in 32.5 ft-kips and 65 ft-kips on the left and right sides of the joint, respectively. When the balance is multiplied by the COF, half of the distributed moments are carried over to the far side. (The horizontal lines indicate that the joint is balanced.)

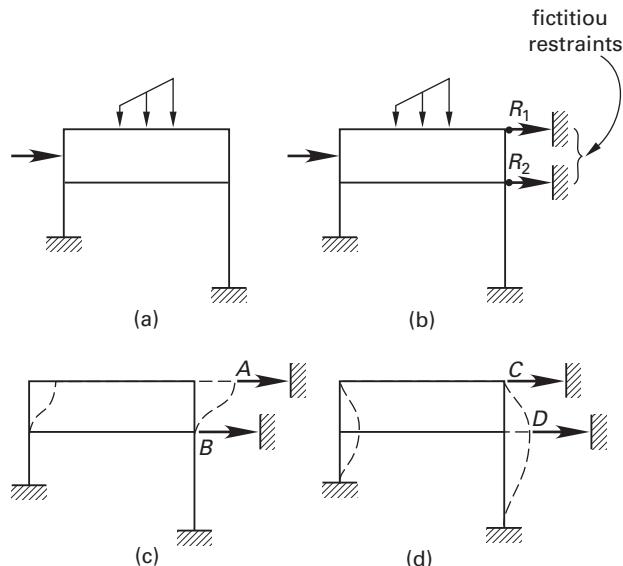

The procedure continues in this manner as the carry-over values decrease in magnitude. Finish at joint A by distributing the unbalanced moment of 2 ft-kips + 1.3 ft-kips, but do not perform the carryover step. (The process should finish with a distribution so that the joint will be balanced.)

The end moments are obtained by summing all the entries at each location.

## 17. STRUCTURES WITH SIDESWAY

Analyzing structures with sidesway with the moment distribution procedure uses superposition of elementary joint-restrained cases. Consider the two-story frame shown in Fig. 47.9(a). This frame has two sway DOFs: the horizontal translations at each of the two floors. The first step in the analysis is to obtain the solution for the structure when the translations are restricted. This step is schematically depicted in Fig. 47.9(b). The forces,  $R_1$  and  $R_2$ , against the fictitious restraints that are keeping the frame from swaying are obtained after the moment distribution is completed.

**Figure 47.9** Frames with Sidesway

The next step consists of obtaining moment diagrams associated with arbitrary translations at each of the locations where the restraints were previously introduced. In these analyses, the translations are initially imposed with the joints held against rotation. The unbalanced moments generated are distributed using

the standard moment distribution approach. The situation when the first restraint is “dragged” (while the second is held in place) is depicted prior to the moment distribution in Fig. 47.9(c). The deformed configuration when the second restraint is dragged an arbitrary amount is shown in Fig. 47.9(d). It is helpful to recall that the fixed-end moment generated by a relative displacement of magnitude  $\Delta$  is

$$\text{FEM} = \frac{6EI\Delta}{L^2} \quad 47.37$$

Once the moment distribution is complete, the forces at the fictitious restraints are computed using statics. For example, the force in the restraint at the second story is equal to the sum of the shear forces in the two columns.

The final solution is obtained as a linear combination of the no-sidesway case and scaled versions of the case with sidesway. The scaling is obtained by recognizing that the actual forces in the restraints are zero. For example, the requirements for the two-story frame of Fig. 47.9 are given by Eq. 47.38 and Eq. 47.39, in which  $A$ ,  $B$ ,  $C$ , and  $D$  are the forces in the restraints for the unit displacement condition, and  $\alpha$  and  $\beta$  are the scaling factors.

$$R_1 + \alpha A + \beta C = 0 \quad 47.38$$

$$R_2 + \alpha B + \beta D = 0 \quad 47.39$$

Designating the displaced moments from the sidesway evaluation at the first and second floors as  $M_{D,1}$  and  $M_{D,2}$ , respectively, the complete solution for the moment at any particular joint is

$$M = M_{\text{sidesway restrained}} + \alpha M_{D,1} + \beta M_{D,2} \quad 47.40$$

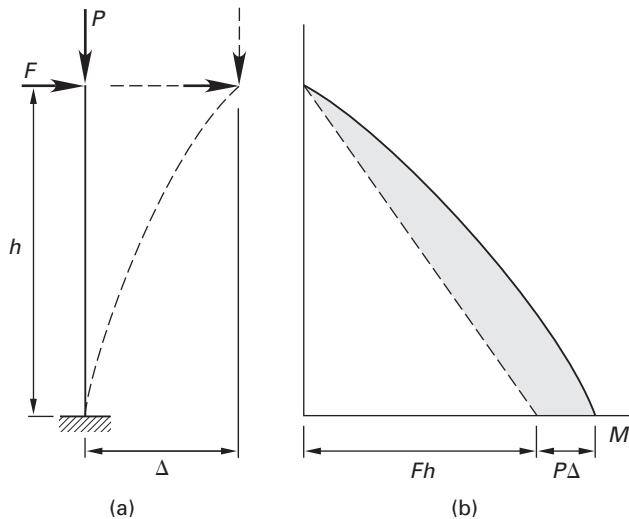

## 18. SECOND-ORDER ( $P$ - $\Delta$ ) ANALYSIS

In a first-order analysis, the loads are supported and equilibrium is achieved on the structural geometry that exists prior to the application of the loads. However, this is an approximation since equilibrium is actually achieved in a deformed configuration. In a second-order analysis, the effects of deformations on the equilibrium requirements are considered.

The approximation implicit in a first-order analysis is readily apparent in the cantilever column shown in Fig. 47.10(a). For the loading shown, the moment at the base in a first-order analysis is  $M = Fh$ . However, in the deformed configuration, the total moment at the base is actually  $M = Fh + P\Delta$ , as shown in Fig. 47.10(b). The total deflection,  $\Delta$ , results from load  $F$  and the moments induced by both  $F$  and  $P$  when acting on the deformed geometry.

Second-order analyses of complex structures are best performed on computers. ACI 318 and the *AISC Manual* encourage second-order analysis as the preferred approach for incorporating  $P$ - $\Delta$  effects in the design of slender columns.

**Figure 47.10** Second-Order Effect on a Cantilever

## 19. SIMPLIFIED SECOND-ORDER ANALYSIS

Second-order effects include bending members with respect to their chord, usually referred to as the  $P$ - $\delta$  effect, and the effects of joint translation, generally designated as the  $P$ - $\Delta$  effect. Structures where second-order effects are important are typically flexible and unbraced. In such structures, virtually all the difference between the correct solution and the results predicted by a first-order analysis derives from the  $P$ - $\Delta$  effect.

A simple iterative approach that incorporates the  $P$ - $\Delta$  effect in the analysis of building frames is schematically illustrated in Fig. 47.11. The steps are as follows.

*step 1:* Compute the deflections of the structure using a first-order analysis.

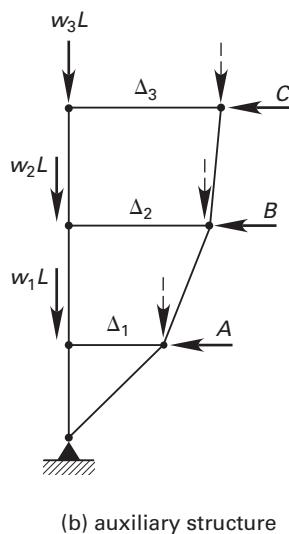

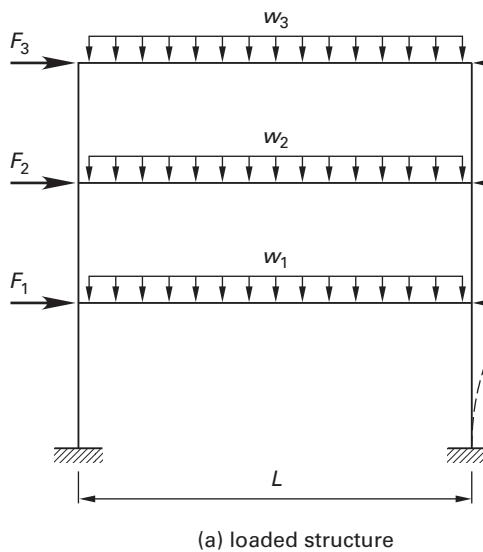

*step 2:* Consider that all the vertical loads are carried by an auxiliary structure consisting of a vertical stack of truss bars that is stabilized by horizontal links to the structure. This auxiliary structure experiences the displacements of the actual building.

*step 3:* Calculate the forces in the links (forces  $A$ ,  $B$ , and  $C$  in Fig. 47.11(b)) from the free-body diagram of the auxiliary structure.

*step 4:* Repeat step 1, adding the forces in the link bars to the applied lateral loads. The solution converges when the forces in the links do not change significantly from one iteration to the next.

## 20. PLASTIC ANALYSIS

A *plastic analysis* determines the maximum load that a structure can sustain. Alternatively, plastic analysis determines the plastic moment capacity required to support a certain factored load. Although plastic analysis is applicable to all aspects of structural design, it is

**Figure 47.11** P-Δ Analysis

primarily used in the design of frames and continuous steel beams.

In practical applications, plastic analysis assumes that a hinge is created when the moment at any section reaches the plastic moment. These hinges are known as *plastic hinges* because they are not points of zero moment, but locations where the moment is constant and equal to the plastic capacity  $M_p$ . The maximum load-carrying capacity of the structure is attained when there are sufficient hinges to turn the structure into a mechanism.

## 21. PLASTIC ANALYSIS OF BEAMS

Either the *equilibrium method* or the *virtual work method* can be used in a plastic analysis of a beam. The virtual work method is used in the following analysis, which determines an unknown plastic moment capacity for a given factored load. (This is the usual case when designing steel beams.)

**step 1:** Postulate a number of plastic hinges that turn the beam into a mechanism. (If more than one mechanism is possible, all must be considered. The mechanism requiring the largest moment capacity governs.)

**step 2:** Impose a unit displacement on the point of the structure that deflects the most after the mechanism forms.

**step 3:** Calculate the total internal work at hinges 1, 2, ...,  $i$ . (The values of the rotations,  $\theta_{p,i}$ , at all of the hinges are known once the unit deflection is imposed.)

$$W_{\text{internal}} = \sum_i M_{p,i} \theta_{p,i} \quad 47.41$$

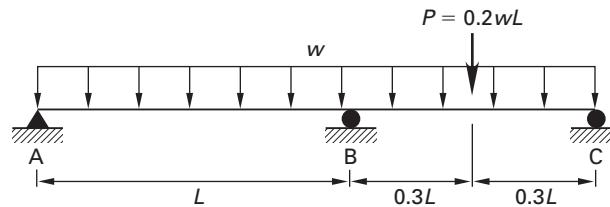

**step 4:** Calculate the total external work performed by loads 1, 2, ...,  $j$  from the loads,  $P_j$ , and the corresponding displacements,  $\Delta_j$ . The replacement of distributed loads by their resultants must be done on each of the segments of the mechanism independently. The loads  $P_i$  will typically include an appropriate load factor.

$$W_{\text{external}} = \sum_j P_j \Delta_j \quad 47.42$$

**step 5:** Equate the internal work to the external work and solve for  $M_p$ .

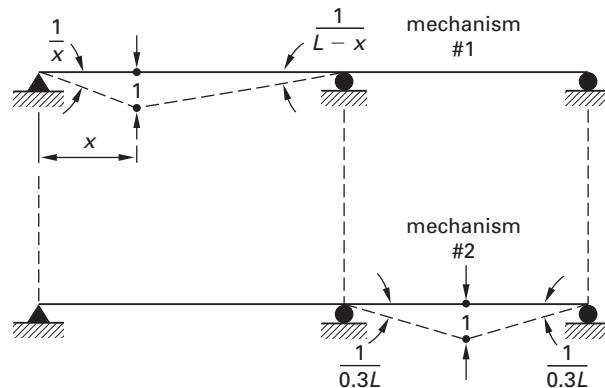

### Example 47.8

Use plastic analysis to calculate the maximum plastic moment from the loads acting on the two-span beam shown.

### Solution

Two distinct mechanisms are possible.

Consider the first mechanism involving failure in span AB. Due to a lack of symmetry, the location of the positive plastic hinge is not known in advance. Designating the distance between the support at A and the positive-moment plastic hinge as  $x$ , the external work is given by Eq. 47.42.

$$W_{\text{external}} = 0.5wx + 0.5w(L - x) = 0.5wL$$

The internal work is given by Eq. 47.41.

$$\theta_A \approx \tan \theta_A = \frac{y}{x} = \frac{1}{x}$$

$$\theta_B \approx \tan \theta_B = \frac{y}{L-x} = \frac{1}{L-x}$$

$$W_{\text{internal}} = U_{\text{internal}}$$

$$= M_p \left( \frac{1}{x} + \frac{1}{L-x} \right) + M_p \left( \frac{1}{L-x} \right)$$

Equate the external and internal work.

$$M_p = \frac{wLx(L-x)}{2(L+x)}$$

Determine the location of the maximum moment by taking the derivative with respect to  $x$ , and equate the result to zero.

$$x_{\text{maximum } M_p} = L(\sqrt{2} - 1)$$

The maximum moment is found by substituting  $x$  into the expression for  $M_p$ .

$$M_{p,\text{max}} = 0.08579wL^2$$

Now, consider the mechanism involving failure in span BC. The external work for a unit deflection is

$$W_{\text{external}} = (0.3wL + 0.2wL)(1) = 0.5wL$$

The internal work is

$$W_{\text{internal}} = U_{\text{internal}} = M_p \left( \frac{2}{0.3L} \right) + M_p \left( \frac{1}{0.3L} \right)$$

The plastic moment is found by setting the external and internal works equal to each other.

$$M_p = 0.05wL^2$$

The plastic moment is larger for the mechanism in span AB and controls.

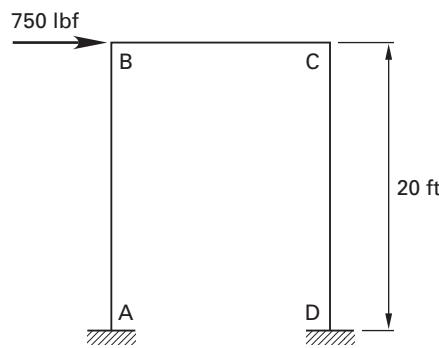

## 22. APPROXIMATE METHOD: ASSUMED INFLECTION POINTS

Approximate methods are useful when an exact solution is not needed, when time is short, or when it is desired to quickly check an exact solution. If the location of a point of inflection on a statically indeterminate structure is known or assumed, that knowledge can be used to generate moments for the remainder of the structure.

The curvature on a structure changes between positive and negative at a point of inflection. Accordingly, the moment is zero at that point. If the point of inflection is assumed, then the moment at that point is also known. The applicability of this method depends on being able to predict the locations of the inflection points. Figure 47.12 provides reasonable predictions of these locations.

### Example 47.9

Estimate the fixed-end moment at joint A.

#### Solution

From Fig. 47.12(b), assume that a point of inflection occurs on each vertical member at  $(0.55)(20 \text{ ft}) = 11 \text{ ft}$  above the supports. By symmetry and equilibrium, the shear at the inflection point is

$$V = \frac{750 \text{ lbf}}{2} = 375 \text{ lbf}$$

The moment at the base is

$$M = (11 \text{ ft})(375 \text{ lbf}) = 4125 \text{ ft-lbf}$$

The fixed-end moment is counterclockwise. Therefore,  $M_{AB} = -4125 \text{ ft-lbf}$ .

## 23. APPROXIMATE METHOD: MOMENT COEFFICIENTS

With certain restrictions, ACI 318 permits continuous beams and slabs constructed of reinforced concrete to be designed using tabulated moment coefficients. This section deals specifically with beams and one-way slabs (slabs that support moments in one direction only, ACI 318 Sec. 8.3). Approximate design of two-way slabs [ACI 318 Sec. 13.6], known as the *direct design method*, follows different rules and is not covered here.

The maximum moments at the ends and midpoints of continuously loaded spans are taken as fractions of the distributed load function,  $wL^2$ , where  $L$  is the span length between supports when computing shears and moments within the span.  $L$  is the average of adjacent spans when computing moment over a support.  $w$  is the ultimate factored load. The moment at some point along the beam is obtained from the *moment coefficient*,  $C_1$ .

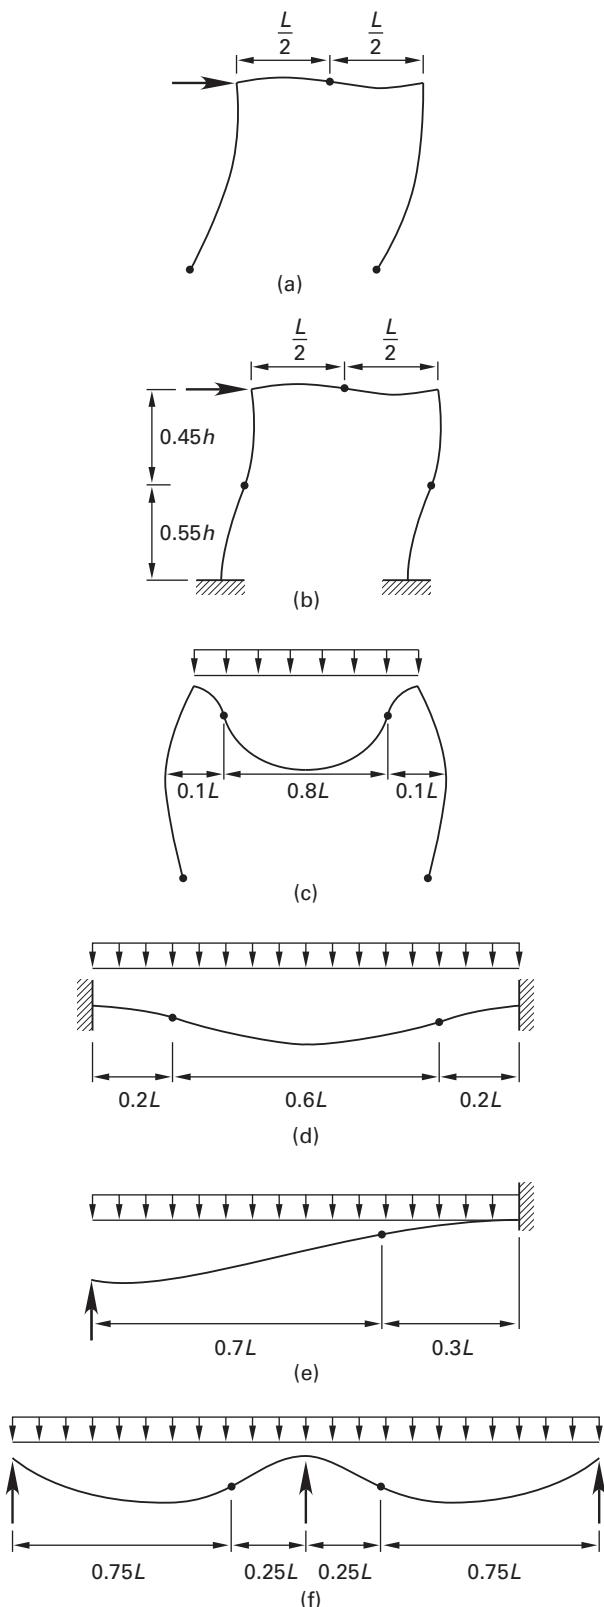

**Figure 47.12** Approximate Locations of Inflection Points

Table 47.2 contains the moment coefficients allowed by ACI 318.

$$M = C_1 w L^2 \quad 47.43$$

The method of moment coefficients can be used when the following conditions are met: (a) The load is continuously distributed, (b) construction is not prestressed, (c) there are two or more spans, (d) the longest span length is less than 20% longer than the shortest, and (e) the beams are prismatic, having the same cross section along their lengths.

**Table 47.2** ACI Moment Coefficients\*

condition	$C_1$
<i>positive moments near midspan</i>	
end spans	
simply supported	$\frac{1}{11}$
built-in support	$\frac{1}{14}$
interior spans	$\frac{1}{16}$
<i>negative moments at exterior face of first interior support</i>	
2 spans	$\frac{1}{9}$
3 or more spans	$\frac{1}{10}$
<i>negative moments at other faces or interior supports</i>	
all cases	$\frac{1}{11}$
<i>negative moments at face of all supports</i>	
slabs with spans not exceeding 10 ft, and beams with ratio of sum of column stiffnesses to beam stiffness exceed 8 at each end of the span	$\frac{1}{12}$
<i>negative moments at exterior built-in support</i>	
support is a cross beam or girder (spandrel beam)	$\frac{1}{24}$
support is a column	$\frac{1}{16}$

\*ACI 318 Sec. 8.3.3

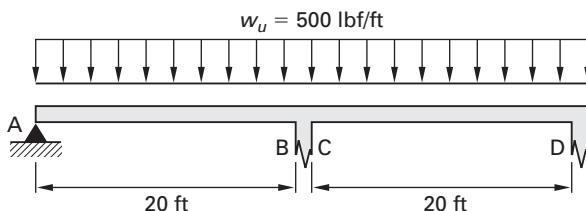

## 24. APPROXIMATE METHOD: SHEAR COEFFICIENTS

When the conditions in Sec. 47.23 are met, ACI 318 Sec. 8.3 also permits approximating the critical shear using *shear coefficients*. For shear, the design coefficient is used with the average span loading,  $(\frac{1}{2})wL$ . In Eq. 47.44,  $C_2$  has a value of 1.15 for end members at the first interior support. For shear at the face of all other supports,  $C_2 = 1$ .

$$V = C_2 \left( \frac{wL}{2} \right) \quad 47.44$$

### Example 47.10

Determine the critical moment, and draw the moment diagram for the uniformly loaded, continuous beam shown. Support A is simple; supports BC and D are built-in column supports. The ultimate factored loading is 500 lbf/ft. All of the conditions necessary to use ACI moment coefficients are satisfied.

*Solution*

The moment at point A is zero since it is a simple support. Point B is an exterior face of the first interior support over a two-span beam. The moment there is

$$M_B = \left(-\frac{1}{9}\right) \left(500 \frac{\text{lbf}}{\text{ft}}\right) (20 \text{ ft})^2 = -22,222 \text{ ft-lbf}$$

Point C is also an exterior face of a first interior support (counting from the opposite end).

$$M_C = M_B = -22,222 \text{ ft-lbf}$$

Point D is an exterior column support.

$$M_D = \left(-\frac{1}{16}\right) \left(500 \frac{\text{lbf}}{\text{ft}}\right) (20 \text{ ft})^2 = -12,500 \text{ ft-lbf}$$

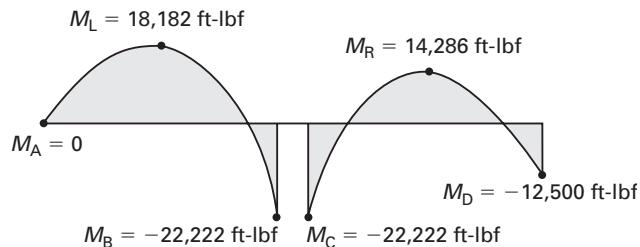

The left span is a simply supported end span. The maximum positive moment is

$$M_L = \left(\frac{1}{11}\right) \left(500 \frac{\text{lbf}}{\text{ft}}\right) (20 \text{ ft})^2 = 18,182 \text{ ft-lbf}$$

The right span is an end-span with a built-in support. The maximum positive moment is

$$M_R = \left(\frac{1}{14}\right) \left(500 \frac{\text{lbf}}{\text{ft}}\right) (20 \text{ ft})^2 = 14,286 \text{ ft-lbf}$$

The critical moment diagram is

## 25. APPROXIMATE METHOD: ENVELOPE OF MAXIMUM SHEAR

Since a live load can be placed or distributed anywhere along the beam length, it is convenient to draw the applied shear loading as a function of location. Such a drawing is known as a *shear envelope*. Since beams (particularly concrete beams) must remain ductile in failure, the shear envelope should be drawn accurately, if not conservatively. A conservative *envelope of maximum shear* for simple spans can be drawn by assuming a maximum shear condition for the ends (usually uniform dead and live loading over the entire span) and assuming a different maximum shear condition for the beam's midspan (usually, uniform live loading over the first half of the span), even though these two conditions cannot occur simultaneously. The shear envelope is assumed to vary linearly in between, which makes interpolation of shear at positions along the beam relatively simple.

## 1. CONCRETE

*Concrete (portland cement concrete)* is a mixture of cementitious materials, aggregates, water, and air. The cement paste consists of a mixture of portland cement and water. The paste binds the coarse and fine aggregates into a rock-like mass as the paste hardens during the chemical reaction (*hydration*). Table 48.1 lists the approximate volumetric percentage of each ingredient.

**Table 48.1** Typical Volumetric Proportions of Concrete Ingredients

component	air-entrained	non-air-entrained
coarse aggregate	31%	31%
fine aggregate	28%	30%
water	18%	21%
portland cement	15%	15%
air	8%	3%

## 2. CEMENTITIOUS MATERIALS

*Cementitious materials* include portland cement, blended hydraulic cements, expansive cement, and other cementitious additives, including fly ash, pozzolans, silica fume, and ground granulated blast-furnace slag.

*Portland cement* is produced by burning a mixture of lime and clay in a rotary kiln and grinding the resulting mass. Cement has a specific weight (density) of approximately 195 lbf/ft<sup>3</sup> (3120 kg/m<sup>3</sup>) and is packaged in standard sacks (bags) weighing 94 lbf (40 kg).

ASTM C150 describes the five classifications of portland cement.

*Type I—Normal portland cement:* This is a general-purpose cement used whenever sulfate hazards are absent and when the heat of hydration will not produce a significant rise in the temperature of the cement. Typical uses are sidewalks, pavement, beams, columns, and culverts.

*Type II—Modified portland cement:* This cement has a moderate sulfate resistance, but is generally used in hot weather for the construction of large structures. Its heat rate and total heat generation are lower than those of normal portland cement.

*Type III—High-early strength portland cement:* This type develops its strength quickly. It is suitable for use when a structure must be put into early use or when long-term protection against cold temperatures is not feasible. Its shrinkage rate, however, is higher than those of types I and II, and extensive cracking may result.

**Type IV—Low-heat portland cement:** For massive concrete structures such as gravity dams, low-heat cement is required to maintain a low temperature during curing. The ultimate strength also develops more slowly than for the other types.

**Type V—Sulfate-resistant portland cement:** This type of cement is appropriate when exposure to sulfate concentration is expected. This typically occurs in regions having highly alkaline soils.

Types I, II, and III are available in two varieties: normal and air-entraining (designated by an “A” suffix). The compositions of the three types of air-entraining portland cement (types IA, IIA, and IIIA) are similar to types I, II, and III, respectively, with the exception that an air-entraining admixture is added.

Many state departments of transportation use modified concrete mixes in critical locations in order to reduce *concrete-disintegration cracking (D-cracking)* caused by the freeze-thaw cycle. Coarse aggregates are the primary cause of D-cracking, so the maximum coarse aggregate size is reduced. However, a higher cement paste content causes *shrinkage cracking* during setting, leading to increased water penetration and corrosion of reinforcing steel. The cracking can be reduced or eliminated by using *shrinkage-compensating cement*, known as *type-K cement* (named after ASTM C845 type E-1(K)).

Type-K cement (often used in bridge decks) contains an aluminate that expands during setting, offsetting the shrinkage. The net volume change is near zero. The resulting concrete is referred to as *shrinkage-compensating concrete*.

Special cement formulations are needed to reduce *alkali-aggregate reactivity* (AAR)—the reaction of the alkalis in cement with compounds in the sand and gravel aggregate. AAR produces long-term distress in the forms of network cracking and spalling (popouts) in otherwise well-designed structures. AAR takes on two forms: the more common *alkali-silica reaction* (ASR) and the less-common *alkali-carbonate reaction* (ACR). ASR is countered by using low-alkali cement (ASTM C150) with an equivalent alkali content of less than 0.60% (as sodium oxide), using lithium-based admixtures, or “sweetening” the mixture by replacing approximately 30% of the aggregate with crushed limestone. ACR is not effectively controlled by using low-alkali cements. Careful selection, blending, and sizing of the aggregate are needed to minimize ACR.

A waste product of coal-burning power-generation stations, *fly ash*, is the most common *pozzolanic additive*. As cement sets, calcium silicate hydrate and calcium hydroxide are formed. While the former is a binder that holds concrete together, calcium hydroxide does not contribute to binding. However, fly ash reacts with some of the calcium hydroxide to increase binding. Also, since fly ash acts as a microfiller between cement particles, strength and durability are increased while permeability

is reduced. When used as a replacement for less than 45% of the portland cement, fly ash meeting ASTM C618's specifications enhances resistance to scaling from road-deicing chemicals.

*Microsilica (silica fume)* is an extremely fine particulate material, approximately 1/100th the size of cement particles. It is a waste product of electric arc furnaces. It acts as a “super pozzolan.” Adding 5–15% microsilica will increase the pozzolanic reaction as well as provide a microfiller to reduce permeability.

Microsilica reacts with calcium hydroxide in the same manner as fly ash. It is customarily used to achieve concrete compressive strengths in the 8000–9000 psi (55–62 MPa) range.

### 3. AGGREGATE

Because aggregate makes up 60–75% of the total concrete volume, its properties influence the behavior of freshly mixed concrete and the properties of hardened concrete. Aggregates should consist of particles with sufficient strength and resistance to exposure conditions such as freezing and thawing cycles. Also, they should not contain materials that will cause the concrete to deteriorate.

Most sand and rock aggregate has a specific weight of approximately 165 lbf/ft<sup>3</sup> (2640 kg/m<sup>3</sup>) corresponding to a specific gravity of 2.64.

*Fine aggregate* consists of natural sand or crushed stone up to 1/4 in (6 mm), with most particles being smaller than 0.2 in (5 mm). Aggregates, whether fine or coarse, must conform to certain standards to achieve the best engineering properties. They must be strong, clean, hard, and free of absorbed chemicals. Fine aggregates must meet the particle-size distribution (grading) requirements.

The seven standard ASTM C33 sieves (3/8 in, no. 4, no. 8, no. 16, no. 30, no. 50, and no. 100) for fine aggregates have openings ranging from 0.150 mm (no. 100 sieve) to 3/8 in (9.5 mm). The fine aggregate should have not more than 45% passing any sieve and retained on the next consecutive sieve, and its fineness modulus should be not less than 2.3 or more than 3.1. The *fineness modulus* is an empirical factor obtained by adding the cumulative weight percentages retained on each of a specific series (usually no. 4, no. 8, no. 16, no. 30, no. 50, and no. 100 for the fine aggregate) of sieves and dividing the sum by 100. (The dust or pan percentage is not included in calculating the cumulative percentage retained.) The higher the fineness modulus, the coarser the gradation will be.

*Coarse aggregates* consist of natural gravel or crushed rock, with pieces large enough to be retained on a no. 4 sieve (openings of 0.2 in or 4.75 mm). In practice, coarse aggregate is generally between 3/8 in and 1½ in (9.5 mm and 38 mm) in size. Also, coarse aggregates should meet

the gradation requirements of ASTM C33, which specifies 13 standard sieve sizes (4 in, 3½ in, 3 in, 2½ in, 2 in, 1½ in, 1 in, ¾ in, ½ in, ⅜ in, no. 4, no. 8, and no. 16) for coarse aggregate.

Coarse aggregate has three main functions in a concrete mix: (1) to act as relatively inexpensive filler, (2) to provide a mass of particles that are capable of resisting the applied loads, and (3) to reduce the volume changes that occur during the setting of the cement-water mixture.

## 4. WATER

Water in concrete has three functions: (1) Water reacts chemically with the cement. This chemical reaction is known as *hydration*. (2) Water wets the aggregate. (3) The water and cement mixture, which is known as *cement paste*, lubricates the concrete mixture and allows it to flow.

Water has a standard specific weight of 62.4 lbf/ft<sup>3</sup> (1000 kg/m<sup>3</sup>). 7.48 gallons of water occupy one cubic foot (1000 L occupy 1 m<sup>3</sup>). One ton (2000 lbf) of water has a volume of 240 gal.

Potable water that conforms to ASTM C1602 and that has no pronounced odor or taste can be used for producing concrete. (With some quality restrictions, ASTM C1602 also allows nonpotable water, including water from other concrete-production operations, to be used in concrete mixing.) Impurities in water may affect the setting time, strength, and corrosion resistance. Water used in mixing concrete should be clean and free from injurious amounts of oils, acids, alkalis, salt, organic materials, and other substances that could damage the concrete or reinforcing steel.

## 5. ADMIXTURES

*Admixtures* are routinely used to modify the performance of concrete. Advantages include higher strength, durability, chemical resistance, and workability; controlled rate of hydration; and reduced shrinkage and cracking. Accelerating and retarding admixtures fall into several different categories, as classified by ASTM C494.

- Type A: water-reducing
- Type B: set-retarding
- Type C: set-accelerating
- Type D: water-reducing and set-retarding
- Type E: water-reducing and set-accelerating
- Type F: high-range water-reducing
- Type G: high-range water-reducing and set-retarding

ASTM C260 covers air-entraining admixtures, which enhance freeze-thaw durability. ASTM C1017 deals exclusively with plasticizers to produce flowing concrete. ACI 212 recognizes additional categories, including corrosion inhibitors and dampproofing. Discontinuous steel fibers are routinely used in concrete as permitted in

accordance with ACI 318 Sec. 3.5.1. Finally, discrete synthetic fibers including carbon and alkali-resistant glass can be added to create *fiber-reinforced concrete*, which is becoming more popular.

*Water-reducing admixtures* disperse the cement particles throughout the plastic concrete, reducing water requirements by 5–10%. Water that would otherwise be trapped within the cement floc remains available to fluidize the concrete. Although water is necessary to produce concrete, using lesser amounts increases strength and durability and decreases permeability and shrinkage. The same slump can be obtained with less water.

*High-range water reducers*, also known as *superplasticizers*, function through the same mechanisms as regular water reducers. However, the possible water reduction is greater (e.g., 12–30%). Dramatic increases in slump, workability, and strength are achieved. *High-slump concrete* is suitable for use in sections that are heavily reinforced and in areas where consolidation cannot otherwise be attained. Also, concrete can be pumped at lower pump pressures, so the lift and pumping distance can be increased. Overall, superplasticizers reduce the cost of mixing, pumping, and finishing concrete.

*Set accelerators* increase the rate of cement hydration, shortening the setting time and increasing the rate of strength development. They are useful in cold weather (below 35–40°F or 2–4°C) or when urgent repairs are needed. While calcium chloride (CaCl<sub>2</sub>) is a very effective accelerator, nonchloride, noncorrosive accelerators can provide comparable performance. (ACI 212.3R does not allow chloride to be added to concrete used in prestressed construction, in concrete containing aluminum embedments, or in concrete cast against galvanized stay-in-place steel forms.)

*Set retarders* are used in hot environments and where the concrete must remain workable for an extended period of time, allowing extended haul and finishing times. A higher ultimate strength will also result. Most retarders also have water-reducing properties.

*Air-entraining mixtures* create microscopic air bubbles in the concrete. This improves the durability of hardened concrete subject to freezing and thawing cycles. The wet workability is improved, while bleeding and segregation are reduced.

*Corrosion-resisting compounds* are intended to inhibit rusting of the reinforcing steel and prestressing strands. Calcium nitrate is commonly used to inhibit the corrosive action of chlorides. It acts by forming a passivating protective layer on the steel. Calcium nitrate has essentially no effect on the mechanical and plastic properties of concrete.

In the *DELVO®* admixture system, the cement particles are coated with a stabilizer, halting the hydration process indefinitely. Setting can be reinitiated at will hours or days later. The manufacturer claims that the treatment has no effect on the concrete when it hardens.

## 6. SLUMP

The four basic concrete components (cement, sand, coarse aggregate, and water) are mixed together to produce a homogeneous concrete mixture. The *consistency* and *workability* of the mixture affect the concrete's ability to be placed, consolidated, and finished without segregation or bleeding. The slump test is commonly used to determine consistency and workability.

The *slump test* consists of completely filling a slump cone mold in three layers of about one-third of the mold volume. Each layer is rodded 25 times with a round, spherical-nosed steel rod of  $\frac{5}{8}$  in (16 mm) diameter. When rodding the subsequent layers, the previous layers beneath are slightly penetrated 1 in (25 mm) by the rod. After rodding, the mold is removed by raising it carefully in the vertical direction. The slump is the difference in the mold height and the resulting concrete pile height. Typical values are 1–4 in (25–100 mm).

Concrete mixtures that do not slump appreciably are known as *stiff mixtures*. Stiff mixtures are inexpensive because of the large amounts of coarse aggregate. However, placing time and workability are impaired. Mixtures with large slumps are known as *wet mixtures (watery mixtures)* and are needed for thin castings and structures with extensive reinforcing. Slumps for concrete that is machine-vibrated during placement can be approximately one-third less than for concrete that is consolidated manually.

## 7. DENSITY

The density, also known as *weight density*, *unit weight*, and *specific weight*, of normalweight concrete varies from about 140 lbf/ft<sup>3</sup> to about 160 lbf/ft<sup>3</sup> (2240 kg/m<sup>3</sup> to 2560 kg/m<sup>3</sup>), depending on the specific gravities of the constituents. For most calculations involving normal-weight concrete, the density may be taken as 145 lbf/ft<sup>3</sup> to 150 lbf/ft<sup>3</sup> (2320 kg/m<sup>3</sup> to 2400 kg/m<sup>3</sup>). Lightweight concrete can have a density as low as 90 lbf/ft<sup>3</sup> (1450 kg/m<sup>3</sup>). Although steel has a density of more than three times that of concrete, due to the variability in concrete density values and the relatively small volume of steel, the density of steel-reinforced concrete is typically taken as 150 lbf/ft<sup>3</sup> (2400 kg/m<sup>3</sup>) without any refinement for exact component contributions.

## 8. COMPRESSIVE STRENGTH

The concrete's *compressive strength*,  $f'_c$ , is the maximum stress a concrete specimen can sustain in compressive axial loading. It is also the primary parameter used in ordering concrete. When one speaks of "6000 psi (41 MPa) concrete," the compressive strength is being referred to. Compressive strength is expressed in psi or MPa. SI compressive strength may be written as "Cxx" (e.g., "C20"), where xx is the compressive strength in

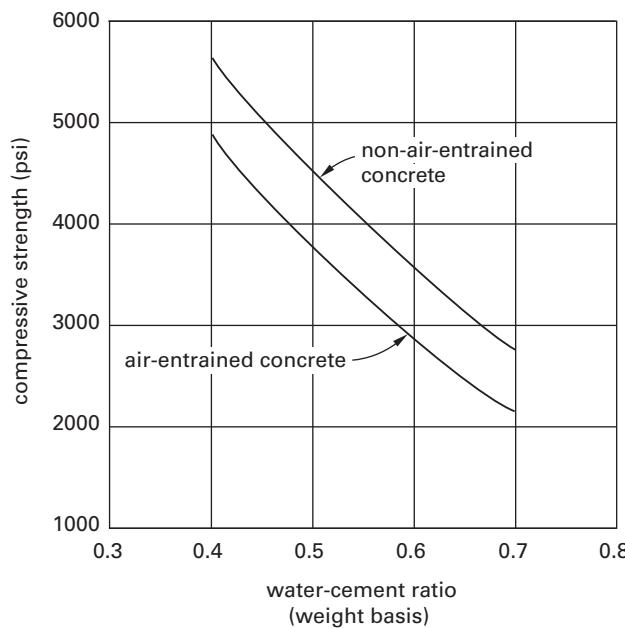

MPa. (MPa is equivalent to N/mm<sup>2</sup>, which is also commonly quoted.)

Typical compressive strengths range from 4000 psi to 6000 psi (27 MPa to 41 MPa) for traditional structural concrete, though concrete for residential slabs-on-grade and foundations will be lower in strength (e.g., 3000 psi or 21 MPa). 6000 psi (41 MPa) concrete is used in the manufacture of some concrete pipes, particularly those that are jacked in.

Cost is approximately proportional to concrete's compressive strength—a rule that applies to high-performance concrete as well as traditional concrete. For example, if 5000 psi (34 MPa) concrete costs \$100 per cubic yard, then 14,000 psi concrete will cost approximately \$280 per cubic yard.

Compressive strength is controlled by selective proportioning of the cement, coarse and fine aggregates, water, and various admixtures. However, the compressive strength of traditional concrete is primarily dependent on the mixture's water-cement ratio. (See Fig. 48.1.) Provided that the mix is of a workable consistency, strength varies directly with the water-cement ratio. (This is *Abrams' strength law*, named after Dr. Duff Abrams, who formulated the law in 1918.)

**Figure 48.1** Typical Concrete Compressive Strength Characteristics

The standard ASTM C39 compressive test specimen mold is a cylinder with a 6 in (150 mm) diameter and a 12 in (300 mm) height. Steel molds are more expensive than plastic molds, but they provide greater rigidity. (Some experts say specimens from steel molds test 3–15% higher.) The concrete is cured for a specific amount of time (three days, a week, 28 days, or more) at a specific temperature. Plain or lime-saturated heated water baths, as well as dry "hot boxes" heated by incandescent lights, are used for this purpose at some testing

labs. To ensure uniform loading, the ends are smoothed by grinding or are capped in sulfur. For testing of very high-strength concrete, the ends may need to be ground glass-smooth in lapidary machines.

Since the ultimate load for 15,000 psi (103 MPa) and higher concrete exceeds the capacity (typically 300,000 lbf (1.34 MN)) of most testing machines, testing firms are switching to smaller cylinders with diameters of 4 in (100 mm) and heights of 8 in (200 mm) rather than purchasing 400,000–600,000 lbf (1.8–2.7 MN) machines.

The specimen is axially loaded to failure at a specific rate. The compressive strength is calculated as the maximum axial load,  $P$ , divided by the cross-sectional area,  $A$ , of the cylinder. Since as little as 0.1 in difference in the diameter can affect the test results by 5%, the diameter must be measured precisely.

$$f'_c = \frac{P}{A} \quad 48.1$$

Compressive strength is normally measured on the 28th day after the specimens are cast. Since the strength of concrete increases with time, all values of  $f'_c$  must be stated with respect to a known age. If no age is given, a strength at a standard 28-day age is assumed.

The effect of the water-cement ratio on compressive strength (i.e., the more water the mix contains, the lower the compressive strength will be) is a different issue than the use of large amounts of surface water to cool the concrete during curing (i.e., *moist curing*). The strength of newly poured concrete can be increased significantly (e.g., doubled) if the concrete is kept cool during part or all of curing. This is often accomplished by covering new concrete with wet burlap or by spraying with water. Although best results occur when the concrete is moist-cured for 28 days, it is seldom economical to do so. A substantial strength increase can be achieved if the concrete is kept moist for as little as three days. Externally applied curing decelerators can also be used.

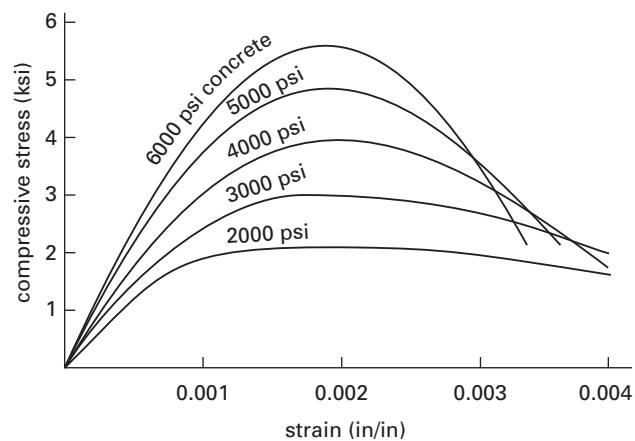

## 9. STRESS-STRAIN RELATIONSHIP

The stress-strain relationship for concrete is dependent on its strength, age at testing, rate of loading, nature of the aggregates, cement properties, and type and size of specimens. Typical stress-strain curves for concrete specimens loaded in compression at 28 days of age under a normal rate of loading are shown in Fig. 48.2.

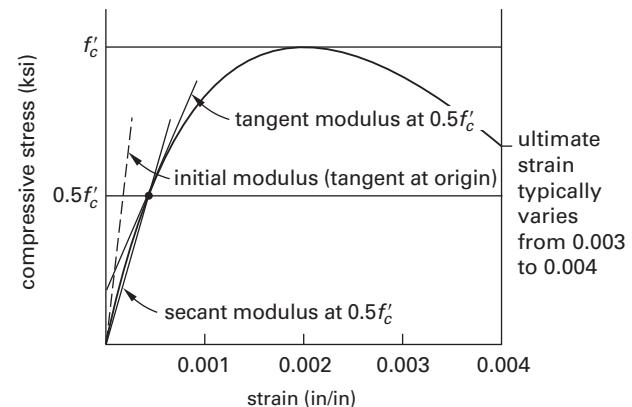

## 10. MODULUS OF ELASTICITY

The *modulus of elasticity* (also known as *Young's modulus*) is defined as the ratio of stress to strain in the elastic region. Unlike steel, the modulus of elasticity of concrete varies with compressive strength. Since the slope of the stress-strain curve varies with the applied stress, there are several ways of calculating the modulus of elasticity. Figure 48.3 shows a typical stress-strain

**Figure 48.2** Typical Concrete Stress-Strain Curves

**Figure 48.3** Concrete Moduli of Elasticity

curve for concrete with the *initial modulus*, the *tangent modulus*, and the *secant modulus* indicated.

The *secant modulus of elasticity* is specified by ACI 318 for use with specific weights that are between 90 lbf/ft<sup>3</sup> and 160 lbf/ft<sup>3</sup> (1440 kg/m<sup>3</sup> and 2560 kg/m<sup>3</sup>). Equation 48.2 is used for both instantaneous and long-term deflection calculations.  $w_c$  is in lbf/ft<sup>3</sup>(kg/m<sup>3</sup>), and  $E_c$  and  $f'_c$  are in lbf/in<sup>2</sup> (MPa) [ACI 318 Sec. 8.5.1].

$$E_c = 0.043 w_c^{1.5} \sqrt{f'_c} \quad [\text{SI}] \quad 48.2(a)$$

$$E_c = 33 w_c^{1.5} \sqrt{f'_c} \quad [\text{U.S.}] \quad 48.2(b)$$

For normalweight concrete, ACI 318 uses Eq. 48.3, which corresponds to a specific weight of approximately 145 lbf/ft<sup>3</sup> (2320 kg/m<sup>3</sup>) [ACI 318 Sec. 8.5.1].

$$E_c = 5000 \sqrt{f'_c} \quad [\text{SI}] \quad 48.3(a)$$

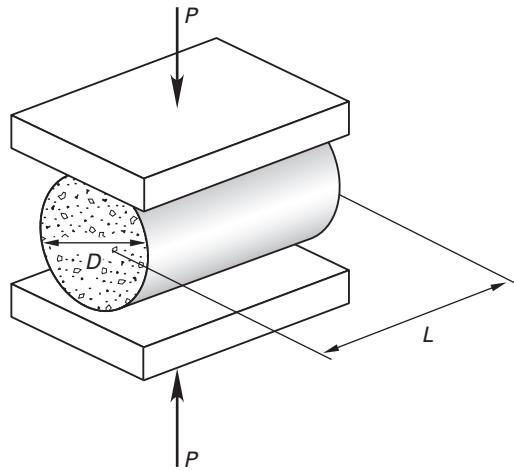

$$E_c = 57,000 \sqrt{f'_c} \quad [\text{U.S.}] \quad 48.3(b)$$

## 11. SPLITTING TENSILE STRENGTH

The extent and size of cracking in concrete structures are affected to a great extent by the tensile strength of the concrete. The ASTM C496 *split cylinder testing procedure* is the standard test to determine the tensile strength of concrete. A 6 in  $\times$  12 in (150 mm  $\times$  300 mm) cast or drill-core cylinder is placed on its side as in Fig. 48.4, and the minimum load,  $P$ , that causes the cylinder to split in half is used to calculate the splitting tensile strength.

$$f_{ct} = \frac{2P}{\pi DL} \quad 48.4$$

**Figure 48.4** Splitting Tensile Strength Test

ACI 318 Sec. 5.1.4 suggests that the splitting tensile strength  $f_{ct}$  can be calculated from correlations with compressive strength, and ACI 318 Sec. 8.6.1 indirectly gives such correlations. The general relationship between splitting tensile strength and compressive strength is

$$f_{ct, MPa} = 0.56\lambda\sqrt{f'_{c, MPa}} \quad [SI] \quad 48.5(a)$$

$$f_{ct} = 6.7\lambda\sqrt{f'_c} \quad [U.S.] \quad 48.5(b)$$

Lightweight concrete has a lower tensile strength than normalweight concrete, even if both have the same compressive strength. The lightweight aggregate factor,  $\lambda$ , is used to account for this lower tensile strength and is determined from Table 48.2. For concrete using a blend of lightweight and normalweight aggregates, ACI 318 Sec. 8.6.1 allows for linear interpolation to determine the lightweight aggregate factor. ACI 318 also permits the use of laboratory tests to correlate splitting tensile strength with compressive strength.

**Table 48.2** Lightweight Aggregate Factors,  $\lambda$

normalweight concrete	1.0
sand-lightweight concrete	0.85
all-lightweight concrete	0.75

## 12. MODULUS OF RUPTURE

The tensile strength of concrete in flexure is known as the *modulus of rupture*,  $f_r$ , and is an important parameter for evaluating cracking and deflection in beams. The tensile strength of concrete is relatively low, about 10–15% (and occasionally up to 20%) of the compressive strength. ASTM C78 gives the details of beam testing using *third-point loading*. The modulus of rupture is calculated from Eq. 48.6.

$$f_r = \frac{Mc}{I} \quad [\text{tension}] \quad 48.6$$

Equation 48.6 gives higher values for tensile strength than the *splitting tensile strength test* because the stress distribution in concrete is not linear as is assumed in Eq. 48.4. For normalweight concrete, ACI 318 prescribes that Eq. 48.7 should be used for modulus of rupture calculations. For all-lightweight concrete, the modulus of rupture is taken as 75% of the calculated values. Other special rules for lightweight concrete may apply [ACI 318 Sec. 9.5.2.3 and Sec. 8.6.1].

$$f_r = 0.62\lambda\sqrt{f'_c} \quad [\text{SI}] \quad 48.7(a)$$

$$f_r = 7.5\lambda\sqrt{f'_c} \quad [\text{U.S.}] \quad 48.7(b)$$

## 13. SHEAR STRENGTH

Concrete's true *shear strength* is difficult to determine in the laboratory because shear failure is seldom pure and is typically affected by other stresses in addition to the shear stress. Reported values of shear strength vary greatly with the test method used, but they are a small percentage (e.g., 25% or less) of the ultimate compressive strength.

## 14. POISSON'S RATIO

*Poisson's ratio* is the ratio of the lateral strain to the axial strain. It varies in concrete from 0.11 to 0.23, with typical values ranging from 0.17 to 0.21.

## 15. HIGH-PERFORMANCE CONCRETE

The American Concrete Institute (ACI) defines *high-performance concrete* (HPC) as "concrete meeting special combinations of performance and uniformity requirements that cannot always be achieved routinely using conventional constituents and normal mixing, placing, and curing practices" [ACI 116R]. *High-strength concrete* (HSC), a special case of high-performance concrete, is defined by the ACI Committee 363 report on high-strength concrete as concrete with a specified compressive strength for design of 6000 psi (41 MPa). However, the strength threshold at which concrete is considered high-strength depends on regional factors, such as characteristics and availability of raw materials, production capabilities, and the experience of local ready-mix producers in making high-strength concrete. Specifying concrete with strengths of

6000–10,000 psi (41–70 MPa) for high-rise construction is now routine. Ready-mix plants can deliver 9000–15,000 psi (62–103 MPa) concrete, and 20,000 psi (138 MPa) concrete has seen limited use.

High strength is achieved in a variety of ways. Superplasticizers and other mineral admixtures (e.g., pozzolans such as fly ash, silica fume, and precipitated silica) are the main components affecting strength.

HSC allows engineers to design structures with smaller structural members (i.e., columns and beams), reducing dead load and increasing usable space. Though HSC is more costly than standard concrete, the long-term benefits to the building owner can be substantial. The benefits of HSC use, however, may not be realized in areas where concrete member dimensions are governed by building code requirements concerning fire safety and so forth.

## 16. FIBER-REINFORCED CONCRETE

*Fiber-reinforced concrete* (FRC) contains small steel, polymer (polyolefin or polypropylene), carbon, or glass fibers approximately 0.5–2 in (12–50 mm) long dispersed randomly throughout the mix. (The term *carbon-fiber-reinforced concrete* (CFRC) is used with carbon reinforcement.) Synthetic fibers are specified by ASTM C1116, steel fibers by ASTM A820.

As setting concrete loses water, it shrinks. Fibers are added to control surface cracking during the setting process. These fibers intersect cracks that form during shrinkage. For control of surface cracking, fibers are added in a proportion of approximately 0.1% by volume corresponding to 1.5 lbm/ft<sup>3</sup> (24 kg/m<sup>3</sup>) of concrete.

Fibers can also be used to carry a portion of the service load, though the volumetric fraction must be much higher: 4–20%. Steel fibers are used in airport pavements, industrial floors, bridge decks, and tunnel lining. Glass fibers are used in precast products. The fibers carry the load once microcracking from flexural loading has occurred, at approximately 3500 psi (24 MPa). Microreinforced concretes with compressive strengths of 30,000 psi (207 MPa) and higher have been reported.

The addition of steel fibers to a concrete mix has little effect on compressive strength; the increase will generally be only a few percent and will seldom be greater than 20%. However, the post-cracking ductility and toughness (energy absorption), as well as tensile and flexural strengths, are increased. The orientation of the steel fibers affects the increase in tensile strength, with random orientation being generally less effective at increasing strength than orientation in the direction of the tensile stress. The tensile strength increase is typically 0–60% for random orientation and can exceed 130% for fibers oriented in the direction of stress. For flexural strength, strength increases are commonly 50–100%, and even higher values have been reported, so ultimate moment is increased and deflection is decreased. However, since even a 1% steel fiber volumetric content can double the

material cost of concrete, steel-fiber-reinforced concrete is limited to specialty applications, such as tunnel linings, bridge deck repairs, and design of members exposed to dynamic and impact loads.

## 17. POLYMER CONCRETE

*Polymer concrete* (*polymer-portland cement concrete*, PPCC) is a material primarily used for rapid repair (sealing or overlaying) of concrete, usually bridge decks. Sometimes dubbed *MMA concrete* after one of its components, it is delivered as two components that are mixed together prior to use: (1) a premixed powder of fine aggregates coated with polymers, initiators, and pigments; and (2) a liquid methyl-methacrylate (MMA) monomer. Setting is rapid, though complete curing may take several weeks. Final performance is similar or superior to traditional concrete.

Polymer concrete can be precast into products with compressive strengths up to 15,000 psi (103 MPa) and flexural strengths up to 300 psi (2.1 MPa). It is water- and corrosion-resistant, thin, lightweight, and colorfast, making it ideal for some bridge components.

## 18. LIGHTWEIGHT CONCRETE

Aggregate of rotary kiln-expanded shales or clays having a specific weight of 70 lb/ft<sup>3</sup> (1120 kg/m<sup>3</sup>) or less is known as *lightweight aggregate*, also known as *ASTM C330 aggregate*. It is used in the production of *lightweight concrete*. Lightweight concrete in which only the coarse aggregate is lightweight is known as *sand-lightweight concrete*. If both the coarse and fine aggregates are lightweight, the concrete is known as *all-lightweight concrete*. Unless noted otherwise, concrete in this book is assumed to be *normalweight concrete*.

## 19. SELF-PLACING CONCRETE

*Self-placing concrete* (also known as *self-compacting concrete*, *self-consolidating concrete*, *flowable concrete*, and *nonvibration concrete*) is used to reduce labor needs and construction time, particularly where congestion of steel reinforcing bars make the consolidation of concrete difficult. Such concrete does not require vibration and reduces site noise and placement defects. Self-placing concrete relies on viscosity agents to produce liquid-like flow characteristics.

## 20. ROLLER-COMPACTED CONCRETE

*Roller-compacted concrete* (RCC), also known as *rollcrete*, is a very lean, no-slump, almost-dry concrete, similar to damp gravel in consistency. It is primarily used in dams and other water-control structures, though use has been extended to heavy-duty pavements (e.g., logging roads, freight yards, and truck stopping areas) where a perfectly smooth surface is not required. RCC is attractive because of its low cost. Requiring less time

and labor to complete, an RCC dam costs about half the price of a conventional concrete gravity dam and about one-third less than an earth or a rockfill dam.

Scrapers and bulldozers spread and compact RCC in broad 1–2 ft (30–71 cm) thick lifts, and vibratory rollers or dozers consolidate it to the specified density with multiple (4–10) passes. A compressive strength of approximately 1000–4500 psi (7–30 MPa) is achieved, identical to the strength of a conventional mixture with the same water-cement ratio.

Seepage in RCC dams occurs primarily through the interfaces between the lifts, but this seepage can be controlled or eliminated with a variety of practices. The abutments and one or both faces should be constructed from normal concrete. Each new lift of RCC should be bedded in a  $\frac{1}{4}$ – $\frac{1}{2}$  in (6–12 mm) thin layer of high-slump cement-paste mortar. The time between lifts can be reduced, and slightly wetter mixes can be used. Other methods of reducing seepage include using more cement, fly ash, and water in the core of the dam; incorporating a PVC membrane between the cast-in-place face and the RCC; and building up the lifts in small 6 in (150 mm) layers. Since RCC tends to clump in temperatures greater than 90°F (32°C), in extreme cases placement can be limited to winter months or cooler nights.

## 21. SOIL CEMENT

*Soil cement* is a combination of soil, water, and a small amount of cement (about 10%). Soil cement is low in price, strong, and easy to work with, can take repeated wetting and heavy wave action, and can stand up to freeze-thaw cycles. Placed soil cement looks like concrete or rock. It has proven to be an ideal material for pavement base courses (where it is referred to as *cement-treated base*) but can also be used for river bank protection, reservoir and channel lining, facing for earthfill dams, seepage control, pipe bedding, and foundation stabilization.

**Table 48.3** ASTM Standards for Reinforcing Bars

customary U.S. bar no.	soft metric bar no.	nominal diameter (in)	nominal diameter (mm)	nominal area (in <sup>2</sup> )	nominal area (mm <sup>2</sup> )	nominal weight (lbf/ft)	nominal mass (kg/m)

(Multiply in by 25.4 to obtain mm.)

(Multiply in<sup>2</sup> by 6.452 to obtain cm<sup>2</sup>.)

(Multiply lbf/ft by 1.488 to obtain kg/m.)

## 22. CONTROLLED LOW-STRENGTH MATERIAL

*Controlled low-strength material* (CLSM) is a mixture of fly ash, fine aggregates, cement (about 5%), and water. Delivered in a semifluid state, it flows readily into place, needs no tamping or vibration, and achieves a compressive strength of 100 psi (700 kPa) within 24 hours. It has proven to be an efficient and economical backfilling material for floor leveling, culverts, bridge abutments, and trenches.

## 23. REINFORCING STEEL

Steel is an alloy consisting almost entirely of iron. It also contains small quantities of carbon, silicon, manganese, sulfur, phosphorus, and other elements. Carbon has the greatest effect on the steel's properties. The carbon content is normally less than 0.5% by weight, with 0.2–0.3% being common percentages.

The density of steel is essentially unaffected by its composition, and a value of 0.283 lbf/in<sup>3</sup> (7820 kg/m<sup>3</sup>) can be used.

Reinforcing steel for use in steel-reinforced concrete may be formed from billet steel, axle steel, or rail steel. Most modern reinforcing bars are made from new billet steel. (Special bars of titanium, stainless steel, corrosion-resistant alloys, and glass fiber composites may see extremely limited use in corrosion-sensitive applications.) The following ASTM designations are used for steel reinforcing bars. (See Table 48.3 for ASTM standards.)

ASTM A615: carbon steel, grades 40 (280 MPa), 60 (420 MPa), and 75 (520 MPa) (symbol "S")

ASTM A996: rail steel, grades 50 (350 MPa) and 60 (420 MPa) (symbols "R" and "L"; only "R" is permitted to be used by ACI 318), and axle steel, grades 40 (280 MPa) and 60 (420 MPa) (symbol "A")

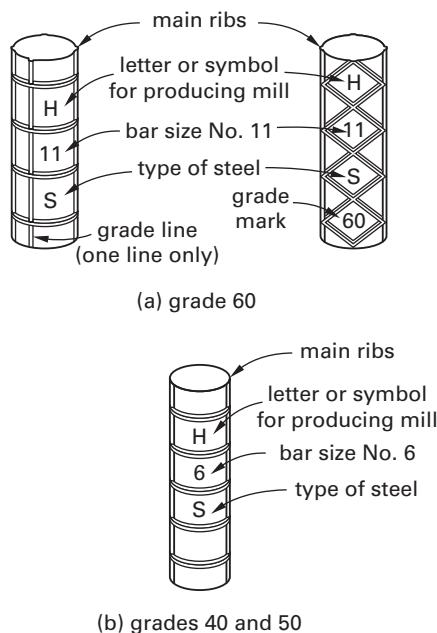

ASTM A706: low-alloy steel, grade 60 (420 MPa) (symbol "W")

ASTM A955: stainless steel (mechanical property requirements are the same as carbon-steel bars under ASTM A615)

ASTM A1035: low-carbon, chromium, steel bars (permitted only as transverse or as spiral reinforcement)

Reinforcing steel used for concrete structures comes in the form of bars (known as *rebar*), welded wire reinforcement, and wires. Reinforcing bars can be plain or deformed; however, most bars are manufactured deformed to increase the bond between concrete and steel. Figure 48.5 shows how the surface is deformed by rolling a pattern on the bar surface. The patterns used vary with the manufacturer.

**Figure 48.5 Deformed Bars**

Plain round reinforcing bars are designated by their nominal diameters in fractions of an inch or in millimeters (e.g.,  $\frac{1}{2}$  in,  $\frac{5}{8}$  in, etc.). Deformed bars are also round, with sizes designed in numbers of eighths of an inch or in millimeters. Standard deformed bars are manufactured in sizes no. 3 to no. 11, with two special large sizes, no. 14 and no. 18, also available on special order. Metric (SI) bar designations are based on a "soft" conversion of the bar diameter to millimeters. For example, the traditional no. 3 bar has a nominal diameter of  $\frac{3}{8}$  in, and this bar has a metric designation of no. 10 because it has a 9.5 mm diameter (approximately 10 mm). Hard metric conversions, where bars with slightly different diameters would be used in metric projects, were once

considered but ultimately rejected. Hard conversions are used in Canadian bar sizes, which have different designations and sizes. (See Table 48.4.)

**Table 48.4 Hard SI (Canadian) Bar Dimensions**

hard metric bar number	diameter (mm)	area (cm <sup>2</sup> )	mass (kg/m)
10M	11.3	1.0	0.784
15M	16.0	2.0	1.568
20M	19.5	3.0	2.352
25M	25.2	5.0	3.920
30M	29.9	7.0	5.488
35M	35.7	10.0	7.840
45M	43.7	15.0	11.760
55M	56.4	25.0	19.600

(Multiply mm by 0.03937 to obtain in.)

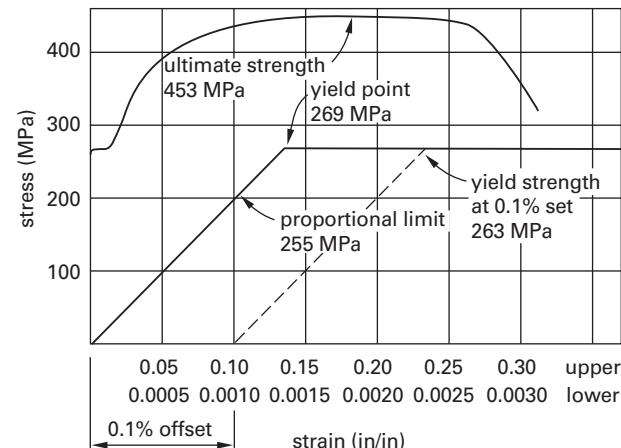

(Multiply cm<sup>2</sup> by 0.1550 to obtain in<sup>2</sup>.)

(Multiply kg/m by 0.6719 to obtain lbf/ft.)

## 24. MECHANICAL PROPERTIES OF STEEL

A typical stress-strain curve for ductile structural steel is shown in Fig. 48.6. The curve consists of elastic, plastic, and strain-hardening regions.

**Figure 48.6 Typical Stress-Strain Curve for Ductile Steel**

The *elastic region* is the portion of the stress-strain curve where the steel will recover its size and shape upon release of load. Within the *plastic region*, the material shows substantial deformation without noticeable change of the stress. Plastic deformation, or *permanent set*, is any deformation that remains in the material after the load has been removed. In the *strain-hardening region*, additional stress is necessary to produce additional strain. This portion of the stress-strain diagram is not important from the design point of view, because so much strain occurs that the functionality of the material is affected.

The slope of the linear portion within the elastic range is the *modulus of elasticity*. The modulus of elasticity for all types of ductile reinforcing steels is taken to be  $29 \times 10^6$  psi (200 GPa) [ACI 318 Sec. 8.5.2]. (The modulus of elasticity is sometimes quoted as  $30 \times 10^6$  psi (207 GPa). This value may apply to hard steels used for other purposes, but not to steel used for reinforcing concrete.)

The steel *grade* corresponds to its nominal yield tensile strength in ksi (thousands of pounds per square inch). Grade 60 steel with a yield strength of 60 ksi (413 MPa) is the most common, though grades 40 and 50 are also available upon request. SI values of steel strength are obtained using “soft” conversions. That is, steel properties are the same in customary U.S. and SI values. Only the designations are different.

## 25. EXPOSURE

Chloride has been used as a concrete additive for a long time. In some fresh concrete, calcium chloride is deliberately added to the mix as a low-cost means of increasing early strength. In cold weather, chloride speeds up the initial set before the cement paste freezes.

However, corrosion from chlorides is a major problem for steel-reinforced concrete. On roads and bridges, de-icing chemicals and environmental salt corrode from the outside in. In buildings, chloride from concrete accelerators works from the inside out. In both, chloride ions migrate through cracks to attack steel reinforcing bars.

Once corrosion has begun, the steel is transformed into expanding rust, putting pressure on surrounding concrete and causing the protective concrete layer to spall.

In addition to chloride attack, degradation from sulfates and fluctuations in temperature and moisture can significantly affect concrete durability. ACI 318 identifies four *exposure categories* that affect the design requirements for concrete to ensure adequate durability performance.

*exposure category F, freeze/thaw:* exterior concrete exposed to moisture and freeze/thaw cycling (with or without de-icing agents)

*exposure category S, sulfates:* concrete in contact with soil or water that contains deleterious amounts of soluble sulfate ions

*exposure category P, permeability:* concrete in contact with water requiring low permeability

*exposure category C, corrosion:* both reinforced and prestressed concrete exposed to conditions that warrant additional corrosion protection of reinforcement

Each category is then subdivided into more specific exposure conditions. Recommended water/cement ratios, air contents, and chloride and sulfate limits are also provided [ACI 318 Chap. 4]. Exposure categories are assigned

based on the severity of the anticipated exposure of structural concrete members.

## 26. ELECTRICAL PROTECTION OF REBAR

There are two major methods of using electricity to prevent chloride corrosion. *Cathodic protection* lowers the active corrosion potential of the reinforcing steel to immune or passive levels. Current is supplied from an external direct-current source. The current flows from an anode embedded in the concrete or from a surface-mounted anode mesh covered with 1.5–2 in (38–51 mm) of concrete. From there, the current passes through the electrolyte (the water and salt in the pores of the concrete) to the steel. The steel acts as the cathode, which is protected.

Installation of cathodic protection is simple. Power consumption is very low. Maintenance is essentially zero. Large areas should be divided into *zones*, each with its own power supply and monitoring equipment. This protection scheme has initial and ongoing expenses, as the system and power supply must remain in place throughout the life of the structure.

An alternative method, developed in Europe, also attaches steel mesh electrodes to the surface and uses a current. However, the treatment is maintained only for a limited amount of time (e.g., one to two months). An electrolytic cellulose paste is sprayed on and the current is applied. Chloride ions migrate from the rebar and are replaced by alkali ions from the paste. This raises the pH and forms a passivating oxide layer around the rebar. The mesh and cellulose are removed and discarded when the treatment is complete. Protection lasts for years. This electrolytic treatment may not be effective with epoxy-coated bars, prestressed structures (where chemical reactions can cause embrittlement), and bridge decks (due to the duration of shutdown required for treatment).

## 27. COATED REBAR

Corrosion-resistant *epoxy-coated rebar* (“green bar” or “purple bar”) has been in use in the United States since the 1970s, most of it in bridge decks and other structures open to traffic. After proper cleaning, standard rebar is given a 0.005–0.012 in (0.13–0.30 mm) electrostatic spray coating of epoxy. The epoxy is intended to be flexible enough to permit subsequent bending and cold working. Epoxy-coated bars must comply with ASTM standards A775 or A934.

Epoxy’s effectiveness, once described as “maintenance-free in corrosive environments,” is dependent on installation practices. Corrosion protection is less than expected when poor manufacturing quality and installation practices remove or damage portions of the coating. Corrosion of coated bars can be reduced by coating after bending and by using alternative “pipeline coatings,” which are thicker but less flexible than epoxy.

Epoxy-coated rebar is only one of several fabrication methods needed to prevent or slow chloride corrosion in *bridge decks*, including cathodic protection, lateral and longitudinal prestressing, less-porous and low-slump concrete, thicker topping layers (3 in (75 mm) or more), interlayer membranes and asphalt concrete, latex-modified or silica fume concrete overlays, corrosion-resistant additives, surface sealers (with or without overlays), galvanizing steel rebar, polymer impregnation, and polymer concrete.

## 1. CONCRETE MIX DESIGN CONSIDERATIONS

Concrete can be designed for compressive strength or durability in its hardened state. In its wet state, concrete should have good workability. *Workability* relates to the effort required to transport, place, and finish wet concrete without segregation or bleeding. Workability is often closely correlated with slump. (See Sec. 48.6.) Table 49.1 gives typical slumps by application. All other design requirements being met, the most economical mix should be selected.

*Durability* is defined as the ability of concrete to resist environmental exposure or service loadings. One of the most destructive environmental factors is the freeze/thaw

**Table 49.1** Typical Slumps by Application

application	slump (in (mm))	
	maximum	minimum
reinforced footings and foundations	3 (76)	1 (25)
plain footings and substructure walls	3 (76)	1 (25)
slabs, beams, and reinforced walls	4 (102)	1 (25)

pavements and slabs	3 (76)	1 (25)
heavy mass construction	2 (51)	1 (25)
roller-compacted concrete	0	0

(Multiply in by 25.4 to obtain mm.)

cycle. ASTM C666, "Standard Test Method for Resistance of Concrete to Rapid Freezing and Thawing," is the standard laboratory procedure for determining the freeze-thaw durability of hardened concrete. This test determines a *durability factor*, the number of freeze-thaw cycles required to produce a certain amount of deterioration.

ACI 318 Sec. 4.3.1 places maximum limits on the water-cement ratio and minimum limits on the strength for concrete with special exposures, including concrete exposed to freeze-thaw cycles, deicing chemicals, and chloride, and installations requiring low permeability.

Specifying an air-entrained concrete will improve the durability of concrete subject to freeze-thaw cycles or deicing chemicals. The amount of entrained air needed will depend on the exposure conditions and the size of coarse aggregate, as prescribed in ACI 318 Sec. 4.4.1.

## 2. STRENGTH ACCEPTANCE TESTING

When extensive statistical data are not available, acceptance testing of laboratory-cured specimens can be evaluated per ACI 318 Sec. 5.6.3. Cylinder sizes of either 4 in × 8 in (100 mm × 200 mm) or 6 in × 12 in (150 mm × 300 mm) are permitted. A *single strength test* is defined as the arithmetic average of the compressive strengths of at least two cylinders measuring 6 in × 12 in (150 mm × 300 mm) or at least three cylinders measuring 4 in × 8 in (100 mm × 200 mm). Single strength tests should be conducted at 28 days unless otherwise specified. The compressive strength of concrete is considered satisfactory if both criteria are met: (a) No single strength test falls below the specified compressive strength,  $f'_c$ , by more than 500 psi (3.45 MPa) when  $f'_c$  is 5000 psi (34.5 MPa) or less, or by more than 0.10 $f'_c$  when  $f'_c$  is more than 5000 psi

(34.5 MPa); (b) the average of every three consecutive strength tests equals or exceeds the specified compressive strength.

### 3. BATCHING

All concrete ingredients are weighed or volumetrically measured before being mixed, a process known as *batching*. Weighing is more common because it is simple and accurate. However, water and liquid admixtures can be added by either volume or weight. The following accuracies are commonly specified or assumed in concrete batching: cement, 1%; water, 1%; aggregates, 2%; and admixtures, 3%. ACI 318 Sec. 4.4.1 specifies the accuracy of air entrainment as 1½%.

### 4. WATER-CEMENT RATIO AND CEMENT CONTENT

Concrete strength is inversely proportional to the *water-cement ratio* (ACI 318 uses the more general term *water-cementitious materials ratio*), the ratio of the amount of water to the amount of cement in a mixture, usually stated as a decimal by weight. Typical values are approximately 0.45–0.60 by weight. (Alternatively, the water-cement ratio may be stated as the number of gallons of water per 94 lbf sack of cement, in which case typical values are 5–7 gal/sack.)

A mix is often described by the number of sacks of cement needed to produce 1 yd<sup>3</sup> of concrete. For example, a mix using six sacks of cement per cubic yard would be described as a *six-sack mix*. Another method of describing the cement content is the *cement factor*, which is the number of cubic feet of cement per cubic yard of concrete.

### 5. PROPORTIONING MIXES

The oldest method of proportioning concrete is the *arbitrary proportions method* (*arbitrary volume method* or *arbitrary weight method*). Ingredients of average properties are assumed, and various proportions are logically selected. Tabular or historical knowledge of mixes and compressive strengths may be referred to. Proportions of cement, fine aggregate, and coarse aggregate are designated (in that sequence). For example, 1:2:3 means that one part of cement, two parts of fine aggregate, and three parts of coarse aggregate are combined. The proportions are generally in terms of weight; volumetric ratios are rarely used. (In the rare instances where the mix proportions are volumetric, the ratio values must be multiplied by the bulk densities to get the weights of the constituents. Then weight ratios may be calculated and the absolute volume method applied directly.)

For more critical applications, the actual ingredients can be tested in various logical proportions. This is known as the *trial batch method* or the *trial mix method*.

This method is more time-consuming initially, since cured specimens must be obtained for testing.

Although some extra concrete ends up being brought to the job site, once determined, mix quantities should be rounded up, not down. Otherwise, the concrete volume delivered may be short.

### 6. ABSOLUTE VOLUME METHOD

The *yield* is the volume of wet concrete produced in a batch. Typical units are cubic yards (referred to merely as *yards*) but may also be cubic feet or cubic meters. The yield that results from mixing known quantities of ingredients can be found from the *absolute volume method*, also known as the *solid volume method* and *consolidated volume method*. This method uses the specific gravities or densities for all the ingredients to calculate the absolute volume each will occupy in a unit volume of concrete. The absolute volume (solid volume, consolidated volume, etc.) is

$$V_{\text{absolute}} = \frac{m}{(\text{SG})\rho_{\text{water}}} \quad [\text{SI}] \quad 49.1(a)$$

$$V_{\text{absolute}} = \frac{W}{(\text{SG})\gamma_{\text{water}}} \quad [\text{U.S.}] \quad 49.1(b)$$

The absolute volume method assumes that, for granular materials such as cement and aggregates, there will be no voids between particles. Therefore, the amount of concrete is the sum of the solid volumes of cement, sand, coarse aggregate, and water.

To use the absolute volume method, it is necessary to know the solid densities of the constituents. In the absence of other information, Table 49.2 can be used.

**Table 49.2** Summary of Approximate Properties of Concrete Components

cement	specific weight	195 lbf/ft <sup>3</sup> (3120 kg/m <sup>3</sup> )
	specific gravity	3.13–3.15
	weight of one sack	94 lbf (42 kg)
fine aggregate	specific weight	165 lbf/ft <sup>3</sup> (2640 kg/m <sup>3</sup> )
	specific gravity	2.64
coarse aggregate	specific weight	165 lbf/ft <sup>3</sup> (2640 kg/m <sup>3</sup> )
	specific gravity	2.64
water	specific weight	62.4 lbf/ft <sup>3</sup> (1000 kg/m <sup>3</sup> )
		7.48 gal/ft <sup>3</sup> (1000 L/m <sup>3</sup> )
		8.34 lbf/gal (1 kg/L)
		239.7 gal/ton (1 L/kg)
specific gravity		1.00

(Multiply lbf/ft<sup>3</sup> by 16.018 to obtain kg/m<sup>3</sup>.)

(Multiply lbf by 0.4536 to obtain kg.)

**Example 49.1**

A concrete mixture using 340 lbf of water per cubic yard has a water-cement ratio of 0.6 by weight. (a) Determine the ideal weight and volume of cement needed to produce 1.0 yd<sup>3</sup> of concrete. (b) How many sacks of cement are needed to produce a 4 in thick concrete slab 9 ft × 4 ft with this mix?

*Solution*

(a) The cement requirement is found from the water-cement ratio.

$$W_{\text{cement}} = \frac{W_{\text{water}}}{0.6} = \frac{340 \frac{\text{lbf}}{\text{yd}^3}}{0.6} = 567 \frac{\text{lbf}}{\text{yd}^3}$$

From Table 49.2, the specific weight of cement is 195 lbf/ft<sup>3</sup>. From Eq. 49.1(b), the volume of the cement is

$$V_{\text{cement}} = \frac{W_{\text{cement}}}{\gamma_{\text{cement}}} = \frac{567 \frac{\text{lbf}}{\text{yd}^3}}{195 \frac{\text{lbf}}{\text{ft}^3}} = 2.91 \frac{\text{ft}^3}{\text{yd}^3}$$

(b) The slab volume is

$$V_{\text{slab}} = \frac{(4 \text{ in})(9 \text{ ft})(4 \text{ ft})}{(12 \frac{\text{in}}{\text{ft}})(27 \frac{\text{ft}^3}{\text{yd}^3})} = 0.444 \text{ yd}^3$$

The cement weight needed is

$$W_{\text{cement}} = (0.444 \text{ yd}^3) \left( 567 \frac{\text{lbf}}{\text{yd}^3} \right) = 252 \text{ lbf}$$

From Table 49.2, each sack weighs 94 lbf. The number of sacks is

$$\frac{252 \text{ lbf}}{94 \frac{\text{lbf}}{\text{sack}}} = 2.7 \text{ sacks} \quad [3 \text{ sacks}]$$

**7. ADJUSTMENTS FOR WATER AND AIR**

In most problems, the weights and volumes of the components must be adjusted for air entrainment and aggregate water content. This determines the *adjusted weights* of the components.

The *saturated, surface-dry* (SSD) condition occurs when the aggregate holds as much water as it can without trapping any free water between the aggregate particles. Calculations of yield should be based on the SSD densities, and the water content should be adjusted (increased or decreased) to account for any deviation from the SSD condition. Any water in the aggregate

above the SSD water content must be subtracted from the water requirements. Any moisture content deficit below the SSD water content must be added to the water requirements.

The phrase “5% excess water” (or similar) is ambiguous and can result in confusion when used to specify batch quantities. There are two methods in field use, differing in whether the percentage is calculated on a wet or dry basis. Table 49.3 summarizes the batching relationships for both bases. (Though Table 49.3 is written for sand, it can also be used for coarse aggregate.)

There is also a similar confusion about air entrainment. The volumetric basis can be calculated either with or without entrained air. If “5% air” means that the concrete volume is 5% air, then the solid volume is only 95% of the final volume. The solid volume should be divided by 0.95 to obtain the final volume. However, if “5% air” means that the concrete volume is increased by 5% when the air is added, the solid volume should be multiplied by 1.05 to obtain the final volume.

The bases of these percentages must be known. If they are not, then either definition could apply. Regardless, the final volume is not affected significantly by either interpretation.

**Example 49.2**

A mix is designed as 1:1.9:2.8 by weight. The water-cement ratio is 7 gal per sack. (a) What is the concrete yield in cubic feet? (b) How much sand, coarse aggregate, and water is needed to make 45 yd<sup>3</sup> of concrete?

*Solution*

(a) The solution can be tabulated. Refer to Table 49.2.

material	ratio	weight per sack of cement (lbf)	solid density (lbf/ft <sup>3</sup> )	absolute volume (ft <sup>3</sup> /sack)
cement	1.0	1 × 94 = 94	195	$\frac{94}{195} = 0.48$
sand	1.9	1.9 × 94 = 179	165	$\frac{179}{165} = 1.08$
coarse	2.8	2.8 × 94 = 263	165	$\frac{263}{165} = 1.60$
water				$\frac{7}{7.48} = 0.94$
				4.10

The solid yield is 4.10 ft<sup>3</sup> of concrete per sack of cement.

(b) The number of one-sack batches is

$$\frac{(45 \text{ yd}^3) \left( 27 \frac{\text{ft}^3}{\text{yd}^3} \right)}{4.10 \frac{\text{ft}^3}{\text{sack}}} = 296.3 \text{ sacks}$$

**Table 49.3** Dry and Wet Basis Calculations

	dry basis	wet basis
fraction moisture, $f$	$\frac{W_{\text{excess water}}}{W_{\text{SSD sand}}}$	$\frac{W_{\text{excess water}}}{W_{\text{SSD sand}} + W_{\text{excess water}}}$
weight of sand, $W_{\text{wet sand}}$	$W_{\text{SSD sand}} + W_{\text{excess water}}$	$W_{\text{SSD sand}} + W_{\text{excess water}}$
	$(1 + f)W_{\text{SSD sand}}$	$\left(\frac{1}{1 - f}\right)W_{\text{SSD sand}}$
weight of SSD sand, $W_{\text{SSD sand}}$	$\frac{W_{\text{wet sand}}}{1 + f}$	$(1 - f)W_{\text{wet sand}}$
weight of excess water, $W_{\text{excess water}}$	$fW_{\text{SSD sand}}$	$fW_{\text{wet sand}}$
	$\frac{fW_{\text{wet sand}}}{1 + f}$	$\frac{fW_{\text{SSD sand}}}{1 - f}$

Order a minimum of 297 sacks of cement. Calculate the remaining order quantities from the cement weight and the mix ratios.

$$\begin{aligned} W_{\text{sand}} &= 1.9 W_{\text{cement}} \\ &= (1.9)\left(94 \frac{\text{lbf}}{\text{sack}}\right)(297 \text{ sacks}) \\ &= 53,044 \text{ lbf} \end{aligned}$$

$$\begin{aligned} W_{\text{coarse aggregate}} &= (2.8)\left(94 \frac{\text{lbf}}{\text{sack}}\right)(297 \text{ sacks}) \\ &= 78,170 \text{ lbf} \end{aligned}$$

$$\begin{aligned} V_{\text{water}} &= \left(7 \frac{\text{gal}}{\text{sack}}\right)(297 \text{ sacks}) \\ &= 2079 \text{ gal} \end{aligned}$$

### Solution

The solution can be tabulated. Refer to Table 49.2.

material	ratio	weight per sack of cement (lbf)	density (lbf/ft <sup>3</sup> )	absolute volume (ft <sup>3</sup> /sack)
cement	1.0	$1 \times 94 = 94$	197	$\frac{94}{197} = 0.477$
sand	2.5	$2.5 \times 94 = 235$	164	$\frac{235}{164} = 1.433$
coarse	4.0	$4.0 \times 94 = 376$	168	$\frac{376}{168} = 2.238$
water				$\frac{5.5}{7.48} = 0.735$
				4.883

### Example 49.3

50 ft<sup>3</sup> of 1:2.5:4 (by weight) concrete are to be produced. The ingredients have the following properties.

The solid yield is 4.883 ft<sup>3</sup> of concrete per sack of cement. The yield with 6% air is

ingredient	SSD density (lbf/ft <sup>3</sup> )	mixture moisture (SSD basis)
cement	197	—
fine aggregate	164	5% excess (free moisture)
coarse aggregate	168	2% deficit (absorption)

5.5 gal of water are to be used per sack, and the mixture is to have 6% entrained air. What are the ideal order quantities expressed in tons?

$$\frac{4.883 \frac{\text{ft}^3}{\text{sack}}}{1 - 0.06} = 5.19 \text{ ft}^3/\text{sack}$$

The ideal number of one-sack batches required is

$$\frac{50 \text{ ft}^3}{5.19 \frac{\text{ft}^3}{\text{sack}}} = 9.63 \text{ sacks}$$

The required sand weight as ordered (not SSD) is

$$\frac{(9.63 \text{ sacks})(1 + 0.05) \left( 94 \frac{\text{lbf}}{\text{sack}} \right) (2.5)}{2000 \frac{\text{lbf}}{\text{ton}}} = 1.19 \text{ tons}$$

The required coarse aggregate weight as ordered (not SSD) is

$$\frac{(9.63 \text{ sacks})(1 - 0.02) \left( 94 \frac{\text{lbf}}{\text{sack}} \right) (4.0)}{2000 \frac{\text{lbf}}{\text{ton}}} = 1.77 \text{ tons}$$

From Table 49.2, water occupies 239.7 gallons per ton. The excess water contained in the sand is

$$(1.19 \text{ tons}) \left( \frac{0.05}{1 + 0.05} \right) \left( 239.7 \frac{\text{gal}}{\text{ton}} \right) = 13.58 \text{ gal}$$

The water needed to bring the coarse aggregate to SSD conditions is

$$(1.77 \text{ tons}) \left( \frac{0.02}{1 - 0.02} \right) \left( 239.7 \frac{\text{gal}}{\text{ton}} \right) = 8.66 \text{ gal}$$

The total water needed is

$$\left( 5.5 \frac{\text{gal}}{\text{sack}} \right) (9.63 \text{ sacks}) + 8.66 \text{ gal} - 13.58 \text{ gal} = 48.0 \text{ gal}$$

## 8. MIXING

Mixing coats the surface of all aggregate particles with cement paste and blends all the ingredients into a uniform, homogeneous mass. The mixing method depends on many factors, including the quantity of concrete required for the job, the location of the job, the availability of the ingredients, and transportation costs.

*Stationary mixers* are mixing units that are to be moved from one job site to another. Large stationary mixers can also be found in ready-mix plants, usually located off the job site. They are commonly available in sizes of mixing batches from 2 yd<sup>3</sup> to 12 yd<sup>3</sup> (0.6 m<sup>3</sup> to 9.1 m<sup>3</sup>). Total output per hour depends on the mixing and dispensing time per batch, as well as the storage capacity for raw materials.

*Mobile batcher mixers* are special trucks that proportion each batch by volume, feeding and continuously mixing aggregates, water, and cement in the mixer.

## 9. TRANSPORTING AND HANDLING

The homogeneity of the concrete mix must not change during transport and handling at the job site. To achieve the predetermined desired wet and hardened

properties, concrete should be transported to the job site without delay. With delays, the concrete may begin to set, making consolidation difficult and increasing the possibility of voids (also known as *honeycombs*) in the finished product. Delays also increase the possibility of *segregation*, which occurs when the coarse aggregate separates from the sand-cement mortar.

## 10. PLACING

Before placing concrete, forms must be clean and free from any foreign substances such as oil, ice, and snow. All surfaces must be moistened, especially in hot weather and when concrete is to be placed on subgrades. All reinforcing steel bars and other embedments should be secured in their place and be free from rust, scale, and oil.

Concrete should be placed in a manner that eliminates or minimizes segregation. It should not be dumped in piles and then leveled. Concrete should be placed continuously in horizontal layers.

## 11. CONSOLIDATION

Freshly placed concrete must be compacted to eliminate entrapped air, rock pockets, and voids. Consolidation can be done manually or mechanically, depending on the workability of concrete, the shape and size of formwork, and the spacing between reinforcing bars. Workable concrete can be consolidated easily by hand-rodding, while stiff mixtures with low water-cement ratios must be consolidated using mechanical methods such as vibration.

Vibration is the most common technique for consolidating concrete. Vibration can be applied internally or externally. Both types of vibration are characterized by the amplitude and frequency of vibration (expressed in vibrations per minute (vpm)). Internal vibration is normally used to consolidate concrete in columns, beams, and slabs. External vibration is accomplished by using vibrating tables, surface vibrators such as vibratory screeds, plate vibrators, or vibratory hand floats or trowels. External vibration is used in cases of thin and heavily reinforced concrete members. Also it is used for stiff mixes where internal vibrators cannot be used.

## 12. CURING

The strength that concrete achieves depends on the *curing process*. During curing, the temperature and humidity must be controlled. Concrete strength increases with age as long as moisture and favorable temperatures are present for hydration of the cement. Therefore, concrete should be kept saturated or nearly saturated until the chemical reaction between water and cement is completed. Loss of water will reduce the hydration process and cause the concrete to shrink and crack.

There are three primary ways of keeping concrete moist and at a favorable temperature. (a) Water can be

copiously applied to make it available to meet the hydration demands. Flat surfaces can be ponded or immersed. Vertical and horizontal surfaces can be sprayed or fogged. Saturated fabric coverings such as cotton mats, burlap, and rugs can be placed over the concrete. (b) The mixing water can be prevented from evaporating by sealing the surface. Impervious paper, plastic sheets, and membrane-forming curing compounds are commonly used. (c) The rate of strength development can be accelerated by providing heat. Live steam, heating coils, and electrically heated forms or pads are used.

### 13. HOT-WEATHER CONCRETING

Concrete should be mixed, transported, placed, and finished at a temperature that will not affect its properties in the fresh or hardened state. Hot weather will increase evaporation and water demand, decrease the slump, and increase the rate of setting. Counteracting these effects by adding more water to concrete will decrease strength and durability of concrete in the hardened state.

Previous studies have shown that increasing the concrete temperature from 50°F to 100°F (10°C to 38°C) would require an additional 33 lbf of water per cubic yard (20 kg per cubic meter) just to maintain a 3 in (75 mm) slump. This additional water would decrease the compressive strength by 12–15%. Such a loss of strength could disqualify the concrete mix.

Rather than increase the water, an effort is made to limit the temperatures at which the concrete is placed. Concrete having a temperature between 50°F and 60°F (10°C and 16°C) is generally considered ideal, but placement in this temperature range is not always possible. However, many specifications require that concrete be placed when its temperature is less than 85–90°F (29–32°C).

### 14. COLD-WEATHER CONCRETING

Concrete temperature has a direct effect on the strength and workability of concrete. Therefore, in cold weather, steps should be taken to ensure a safe and desirable temperature for concrete during mixing, placing, finishing, and curing.

Publication ACI 306R defines *cold weather* as a period of more than three consecutive days in which the average daily air temperature is less than 40°F (4°C) and the air temperature is not greater than 50°F (10°C) for more than one-half of any 24-hour period. The *average daily air temperature* is the arithmetic average of the highest and the lowest temperatures occurring during the time period from midnight to midnight. Even during periods that are not defined as cold weather but when freezing temperatures can exist, it is good practice to take appropriate measures to protect concrete surfaces. At such temperatures, the rate of cement hydration decreases,

delaying the strength development. Not only must concrete be delivered at the proper temperature, but the temperature of the forms, reinforcing steel, and ground must be considered. Concrete should not be placed on frozen concrete or on frozen ground.

The mix temperature at the time of pouring can be raised by heating the ingredients. Water is easily heated, but it is not advisable to exceed a temperature of 140–180°F (60–82°C), as the concrete may *flash set* (i.e., harden suddenly). Aggregate can also be steam-heated prior to use.

## 15. FORMWORK

*Formwork* refers to the system of boards, ties, and bracing required to construct the mold in which wet concrete is placed. Formwork must be strong enough to withstand the weight and pressure created by the wet concrete and must be easy to erect and remove.

### Types of Forms

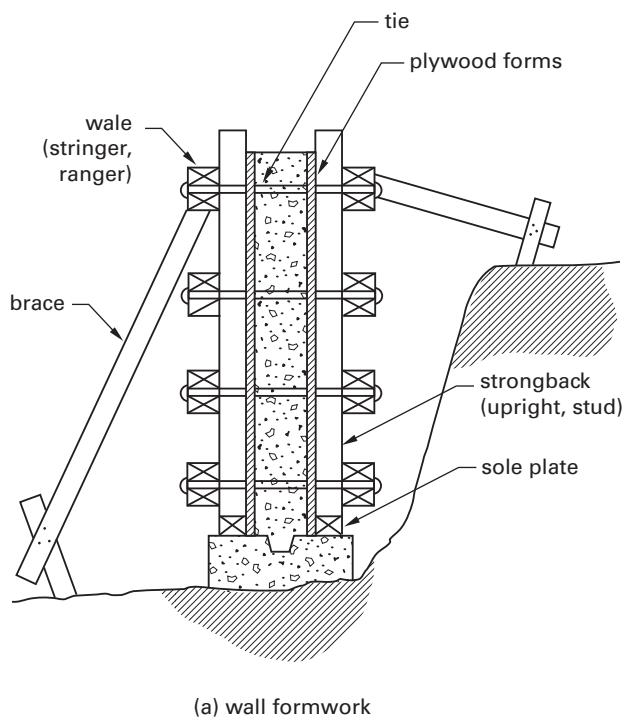

Forms are constructed out of a variety of materials. Unless the concrete is finished in some way, the shape and pattern of the formwork will affect the appearance of the final product. Wood grain, knotholes, joints, and other imperfections in the form will show in their negative image when the form is removed. Plywood is the most common forming material. It is usually  $\frac{3}{4}$  in (19 mm) thick and is coated on one side with oil, a water-resistant glue, or plastic to prevent water from penetrating the wood and to increase the reusability of the form. Oil on forms also prevents adhesion of the concrete so the forms are easier to remove. The plywood is supported with solid wood framing, which is braced or shored as required. Figure 49.1 shows two typical wood-framed forms.

Prefabricated steel forms are often used because of their strength and reusability. They are often employed for forming one-way joist systems, waffle slabs, round columns, and other special shapes.

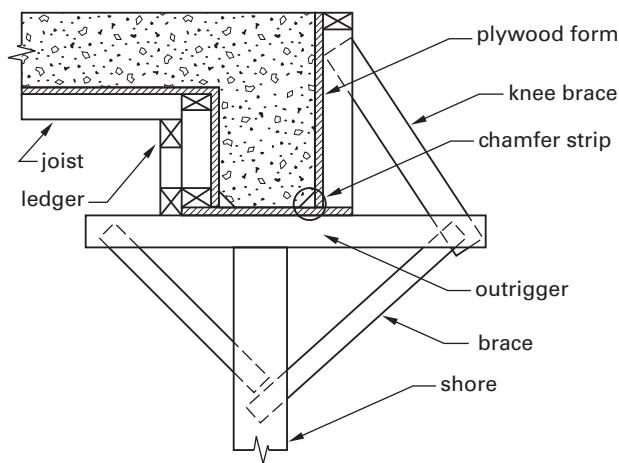

Other types of forms include glass-fiber reinforced plastic, hardboard, and various kinds of proprietary systems. Plastic forms are manufactured with a variety of patterns embedded in them. These patterns are transferred to the concrete and constitute the final surface. Special form liners can also be used to impart a deeply embossed pattern.

For exposed architectural surfaces, a great deal of consideration must be given to the method and design of the formwork because the pattern of joints and form ties will be visible. Joints are often emphasized with rustication strips, continuous pieces of neoprene, wood, or other material that when removed shows a deep reveal in the concrete.

*Form ties* are metal wires or rods used to hold opposite sides of the form together and also to prevent their collapse. When the forms are removed, the wire remains

**Figure 49.1** Concrete Framework

(a) wall formwork

(b) beam/slab formwork

in the concrete, and the excess is twisted or cut off. Some form ties are threaded rods that can be unscrewed and reused. Tie holes are made with cone-shaped heads placed against the concrete form. When these are removed, a deep, round hole is left that allows the tie to be cut off below the surface of the concrete. These holes can remain exposed as a design feature or can be patched with grout.

### Special Forms

Most formwork is designed and constructed to remain in place until the concrete cures sufficiently to stand on its own. However, with *slip forming*, the formwork moves as

the concrete cures. Slip forming is used to form continuous surfaces such as curbs and gutters, open channels, tunnels, and high-rise building cores. The entire form is constructed along with working platforms and supports for the jacking assembly. In vertical slip forming, the form moves continuously at about 6–12 in (150–300 mm) per hour. Various types of jacking systems are used to support the form as it moves upward. With horizontal slip forming, as would be used in roadway construction, speeds of 200–300 ft/hr (60–90 m/h) are possible.

*Flying forms* are large fabricated sections of framework that are removed, once the concrete has cured, to be reused in forming an identical adjacent section. They are often used in buildings with highly repetitive units, such as hotels and apartments. After forming the floor for a hotel, for example, the form assembly is slid outside the edge of the building where it is lifted by crane to the story above. Once that floor is poured, the process is repeated.

### Economy in Formwork

Because one of the biggest expenses for cast-in-place concrete is formwork, the overall cost can be minimized by following some basic guidelines. To begin with, forms should be reusable as much as possible. This implies uniform bay sizes, beam depths, column widths, opening sizes, and other major elements. Slab thicknesses should be kept constant without offsets, as should walls. Of course, structural requirements will necessitate variations in many elements, but it is often less expensive to use a little more concrete to maintain a uniform dimension than to form offsets.

### Accuracy Standards

Because of the nature of the material and forming methods, concrete construction cannot be perfect; there are certain tolerances that are industry standards. Construction attached to concrete must be capable of accommodating these tolerances. Per ACI 301 Table 4.3.1, ACI 117, and ACI 347R, for columns, piers, and walls, the maximum variation in plumb is plus or minus  $\frac{1}{4}$  in (6 mm) in any 10 ft (3050 mm) length. The same tolerance applies for horizontal elements such as ceilings, beam soffits, and slab soffits. Architectural surfaces and surfaces that will be tiled may have smaller tolerances.

The maximum variation out of plumb for the total height of the structure is 1 in (25 mm) for interior columns and  $\frac{1}{2}$  in (13 mm) for corner columns for buildings up to 100 ft (30 m) tall, while the maximum variation for the total length of the building is plus or minus 1 in (25 mm). Elevation control points for slabs on grade can vary up to  $\frac{1}{2}$  in (13 mm) in any 10 ft (3050 mm) bay and plus or minus  $\frac{3}{4}$  in (19 mm) for the total length of the structure.

For elevated, formed slabs the tolerance is plus or minus  $\frac{3}{4}$  in (19 mm). Finished concrete floors can be specified anywhere from plus or minus  $\frac{1}{8}$  in (3 mm) in 10 ft (3 m) for very flat slabs to plus or minus  $\frac{1}{2}$  in (13 mm) for bullfloated slabs.

## 16. LATERAL PRESSURE ON FORMWORK

Formwork must be strong enough to withstand hydraulic loading from the concrete during curing. The hydraulic load is greatest immediately after pouring. As the concrete sets up, it begins to support itself, and the lateral force against the formwork is reduced. ACI 347 predicts the maximum lateral pressure for various types of concretes, pour rates, and applications. ACI 347 Sec. 2.2.2 ascribes a liquid-like, zero shear stress property to concrete by defining the pressure,  $p$ , from wet concrete as Eq. 49.2. For rapidly filled columns,  $h$  is taken as the full height of the pour as long as the pour is finished before the concrete starts to stiffen. When concrete is pumped from the base of the form, an allowance of 25% should be added to account for *pump surge pressure* [ACI 347 Sec. 2.2.2.3].

$$p = \rho gh \quad [\text{SI}] \quad 49.2(a)$$

$$p = \gamma h = \frac{\rho gh}{g_c} \quad [\text{U.S.}] \quad 49.2(b)$$

Equation 49.2 would imply that the pressure can be infinitely high by making  $h$  infinite. In reality, the pressure is practically limited by pour and setup (i.e., curing) rates. In the absence of experimental data appropriate to the job, ACI 347 Sec. 2.2.2.1 prescribes the pressure for which formwork should be designed by specifying the maximum pressure,  $p_{\max}$ , that the formwork is expected to experience.

In these maximum pressure calculations, walls are distinguished from columns. An element is considered to be a column if no plan dimension exceeds 6.5 ft (2 m). An element is considered to be a wall if at least one plan dimension exceeds 6.5 ft (2 m).

With concrete that has a slump of 7 in (175 mm) or less and is placed with internal vibration, Eq. 49.3 can be used for columns filled to a depth of 4 ft (1.2 m) or less and for walls when filled to a depth of 14 ft (4.2 m) or less with a placement rate of 7 ft/hr (2.1 m/h) or less.

$$p_{\max,\text{kPa}} = 30C_w \leq C_w C_c \left( 7.2 + \frac{785R_{\text{m/h}}}{T_{\circ\text{C}} + 17.8^\circ} \right) \leq \rho gh$$

$$\begin{bmatrix} \text{columns: } h \leq 1.2 \text{ m} \\ \text{walls: } h \leq 4.2 \text{ m} \\ R \leq 2.1 \text{ m/h} \end{bmatrix} \quad [\text{SI}] \quad 49.3(a)$$

$$p_{\max,\text{psf}} = 600C_w \leq C_w C_c \left( 150 + \frac{9000R_{\text{ft/hr}}}{T_{\circ\text{F}}} \right) \leq \gamma h$$

$$\begin{bmatrix} \text{columns: } h \leq 4 \text{ ft} \\ \text{walls: } h \leq 14 \text{ ft} \\ R \leq 7 \text{ ft/hr} \end{bmatrix} \quad [\text{U.S.}] \quad 49.3(b)$$

With concrete that has a slump of 7 in (175 mm) or less and is placed with internal vibration, Eq. 49.4 can be used for walls when filled to a depth exceeding 14 ft (4.2 m) with a placement rate of 7 ft/hr (2.1 m/h) or less, and for all walls with placement rates of 7 ft/hr to 15 ft/hr.

$$p_{\max,\text{kPa}} = 30C_w \leq C_w C_c$$

$$\times \left( 7.2 + \frac{1156 + 244R_{\text{m/h}}}{T_{\circ\text{C}} + 17.8^\circ} \right) \leq \rho gh$$

$$\begin{bmatrix} \text{walls: } h > 4.2 \text{ m, } R \leq 2.1 \text{ m/h} \\ \text{walls: } 2.1 \text{ m/h} < R \leq 4.5 \text{ m/h} \end{bmatrix} \quad [\text{SI}] \quad 49.4(a)$$

$$p_{\max,\text{psf}} = 600C_w \leq C_w C_c$$

$$\times \left( 150 + \frac{43,400 + 2800R_{\text{ft/hr}}}{T_{\circ\text{F}}} \right) \leq \gamma h$$

$$\begin{bmatrix} \text{walls: } h > 14 \text{ ft, } R \leq 7 \text{ ft/hr} \\ \text{walls: } 7 \text{ ft/hr} < R \leq 15 \text{ ft/hr} \end{bmatrix} \quad [\text{U.S.}] \quad 49.4(b)$$

In Eq. 49.3 and Eq. 49.4,  $C_w$  is the *unit weight coefficient* given in Table 49.4.

**Table 49.4** Values of the Unit Weight Coefficient,  $C_w$

unit weight,  $\gamma$ , (density,  $\rho$ ) of  
concrete

	$C_w$
<140 lbf/ft <sup>3</sup> (<2240 kg/m <sup>3</sup> )	$0.5 \left( 1 + \frac{\gamma_{\text{lbf/ft}^3}}{145} \right) \geq 0.8$ $\left( 0.5 \left( 1 + \frac{\rho_{\text{kg/m}^3}}{2320} \right) \geq 0.8 \right)$
140 lbf/ft <sup>3</sup> ≤ $\gamma \leq 150$ lbf/ft <sup>3</sup> (2240 kg/m <sup>3</sup> ≤ $\rho \leq 2400$ kg/m <sup>3</sup> )	1.0
> 150 lbf/ft <sup>3</sup> (> 2400 kg/m <sup>3</sup> )	$\frac{\gamma_{\text{lbf/ft}^3}}{145}$ $\left( \frac{\rho_{\text{kg/m}^3}}{2320} \right)$

In Eq. 49.3 and Eq. 49.4,  $C_c$  is the *chemistry coefficient* given in Table 49.5. As used in Table 49.5, a *retarder* includes any admixture that delays the setting of concrete, including low-, mid-, and high-range admixtures and superplasticizers.

**Table 49.5** Values of the Chemistry Coefficient,  $C_c$

cement type or blend	$C_c$
types I, II, and III without retarders	1.0
types I, II, and III with retarders	1.2

<i>w</i>	web

**1. INTRODUCTION**

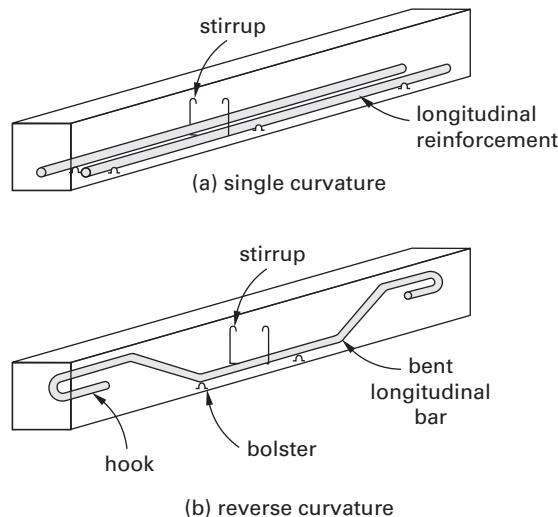

The design of reinforced concrete beams is governed by the provisions of the American Concrete Institute (ACI) code ACI 318. Many of the code equations are not homogeneous—the units of the result cannot be derived from those of the input. In particular, the quantity  $\sqrt{f_c}$  is treated as though it has units of  $\text{lbf/in}^2$ , even though that does not follow from the expression. Whenever nonhomogeneous equations appear in this chapter, the units listed in the nomenclature should be used.

**2. STEEL REINFORCING**

Figure 50.1 illustrates typical reinforcing used in a simply supported reinforced concrete beam. The straight longitudinal bars resist the tension induced by bending, and the *stirrups* resist the diagonal tension resulting from shear stresses. As shown in Fig. 50.1(b), it is also possible to bend up the longitudinal bars to resist diagonal tension near the supports. This alternative, however, is rarely used because the saving in stirrups tends to be offset by the added cost associated with bending the longitudinal bars. In either case, the stirrups are usually passed

underneath the bottom steel for anchoring. Prior to pouring the concrete, the horizontal steel is supported on *bolsters* (*chairs*), of which there are a variety of designs.

**Figure 50.1** Typical Reinforcement in Beams

**3. TYPES OF BEAM CROSS SECTIONS**

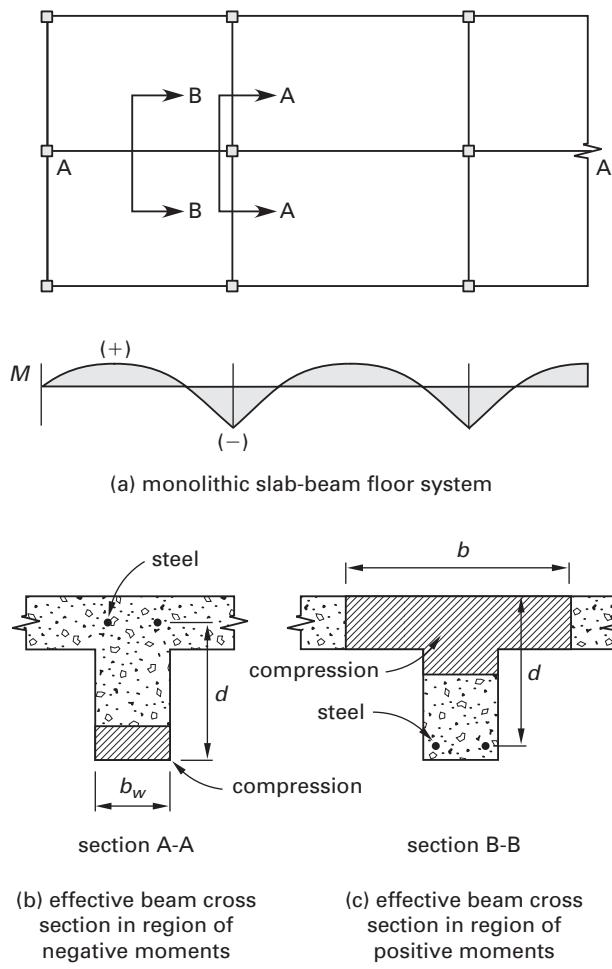

The design of reinforced concrete beams is based on the assumption that concrete does not resist any tensile stress. A consequence of this assumption is that the effective shape of a cross section is determined by the part of the cross section that is in compression. Consider the design of monolithic slab-and-girder systems. As Fig. 50.2 shows, moments are negative (i.e., there is tension on the top fibers) near the columns. The effective section in the region of negative moments is rectangular, as in Fig. 50.2(b). Elsewhere, moments are positive, and the effective section may be either rectangular or T-shaped, depending on the depth of the compressed region, as in Fig. 50.2(c).

Reinforced concrete sections can be singly or doubly reinforced. Doubly reinforced sections are used when concrete in the compression zone cannot develop the required moment strength. Doubly reinforced sections are also used to reduce long-term deformations resulting from creep and shrinkage.

Depending on the ratio of beam clear span to the depth of the cross section, beams may be considered “regular” or deep.

**4. ALLOWABLE STRESS DESIGN VERSUS STRENGTH DESIGN**

Structural members can be sized using two alternative design procedures. With the *allowable stress design method* (ASD), stresses induced in the concrete and the

**Figure 50.2** Slab-Beam Floor System

steel are estimated assuming that the behavior is linearly elastic. The member is sized so that the computed stresses do not exceed certain predetermined values. With the *strength design method* (SD), the actual stresses are not the major concern. Rather, a strength is provided that will support factored (i.e., amplified) loads. Although both methods produce adequate designs, strength design is considered to be more rational. This chapter only covers strength design provisions. ACI 318 no longer contains provisions for allowable stress design.

It is important to recognize that even though beam cross sections are sized on the basis of strength, the effects (i.e., moments, shears, deflections, etc.) of the factored loads are computed using elastic analysis.

ACI 318 contains two options for using strength design in the design of reinforced and prestressed concrete members: the “*unified*” methods in Chap. 9 (“Strength and Serviceability Requirements”) and the older App. C

(“Alternative Load and Strength Reduction Factors”).<sup>1,2</sup> These methods differ in how the factored loads are calculated, as well as specify different strength reduction factors,  $\phi$ .

Chapter 9 uses the following abbreviations for load types:  $D$ , dead load;  $L$ , live load;  $W$ , wind load;  $E$ , earthquake load;  $H$ , earth pressure;  $T$ , temperature, shrinkage, creep, and settlement loads;  $F$ , fluid load;<sup>3</sup>  $L_r$ , live roof load;  $S$ , snow load; and  $R$ , rain load.

Chapter 9 methods determine strength reduction factors on the basis of the strain conditions in the reinforcement farthest from the extreme compression face. The methods of Chap. 9 are consistent with ASCE/SEI7 and the IBC, which have diverged from the previous ACI 318 methods. The unified methods bring uniformity and eliminate many of the inconsistencies in the previous design requirements.

Appendix C uses only the following abbreviations for load types:  $D$ , dead load;  $L$ , live load;  $W$ , wind load;  $E$ , earthquake load;  $H$ , earth pressure; and  $T$ , temperature, shrinkage, creep, and settlement loads.

Appendix C methods determine strength reduction factors solely on the basis of the type of loading (axial, flexural, or both) on the section. From ACI 318 Sec. RC.9.1.1, the methods in App. C have “... evolved since the early 1960s and are considered to be reliable for concrete construction.”

Appendix C methods are not presented in this book.

## 5. SERVICE LOADS, FACTORED LOADS, AND LOAD COMBINATIONS

The objective in all designs is to ensure that the safety margin against any possible collapse under the service loads is adequate. In ACI 318, this margin is achieved by designing beam strength to be equal to or greater than the effect of the service loads amplified by appropriate load factors.

The term *service loads* designates the loads (forces or moments) that are expected to be actually imposed on a structure during its service life, and for design purposes are taken from building codes. The term *factored loads* designates the service loads increased by various amplifying *load factors*. The load factors depend both on the uncertainty of the various loads as well as on the load

<sup>1</sup>It is somewhat confusing that the method in Chap. 9 of ACI 318-2002 onward was previously in ACI 318-1999 App. C. In 2002, the two methods flip-flopped in location, with the older method being relegated to the appendix.

<sup>2</sup>ACI 318 App. C “Alternative Load and Strength Reduction Factors” is not related to the allowable stress “Alternate Design Method” in ACI 318-1999, which is no longer presented in ACI 318.

<sup>3</sup>Fluid loads are included with dead loads and share the same load function as  $D$ .

combination being considered. Load factors and load combinations are specified in ACI 318 Sec. 9.2. The factored loads are designated using the subscript  $u$  (ultimate). The moment and shear due to factored loads are  $M_u$  and  $V_u$ , respectively. These are also the *required strengths* in moment and shear, respectively.

According to ACI 318 Sec. 9.2, required strength  $U$  must be at least equal to the factored loads in Eq. 50.1 through Eq. 50.7.

When dead and live loads only are considered,

$$U = 1.4D \quad 50.1$$

$$U = 1.2D + 1.6L \quad 50.2$$

When dead and live loads and wind are considered,

$$U = 1.2D + 0.5W \quad 50.3$$

$$U = 1.2D + 1.0W + 1.0L \quad 50.4$$

$$U = 0.9D + 1.0W \quad 50.5$$

When earthquake forces are considered, the earthquake loading has a factor of 1.0, as it is derived from factored loads in the seismic code. Members must also satisfy the requirements of Eq. 50.1 and Eq. 50.2.

$$U = 1.2D + 1.0E + 1.0L \quad 50.6$$

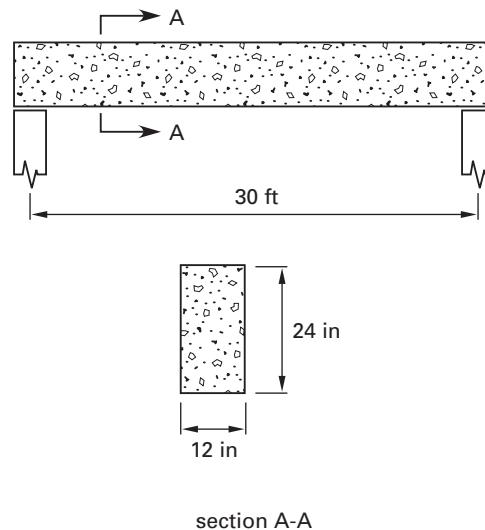

$$U = 0.9D + 1.0E \quad 50.7$$

The effect of one or more transient loads not acting simultaneously (i.e., the effects of live loads being zero in Eq. 50.2, live or wind loads being zero in Eq. 50.3, Eq. 50.4, and Eq. 50.5, and live or earthquake loads being zero in Eq. 50.6 and Eq. 50.7) needs to be investigated. The load factor on  $L$  in Eq. 50.4 and Eq. 50.6 can be reduced to 0.5 for all structures except garages, areas occupied as places of public assembly, and all areas where the live load is greater than 100 lbf/ft<sup>2</sup>.

A load factor of 1.2 applies to the maximum tendon jacking force in a post-tensioned anchorage zone [ACI 318 Sec. 9.2.7].

### Example 50.1

The simply supported beam shown is subjected to a dead load of 1.2 kips/ft and a live load of 0.8 kip/ft in addition to its own dead weight. What moment should be used to determine the steel reinforcement at the center of the beam?

### Solution

The specific weight of steel-reinforced concrete is approximately 150 lbf/ft<sup>3</sup>. The weight of the beam is

$$\frac{(12 \text{ in})(24 \text{ in})\left(150 \frac{\text{lbf}}{\text{ft}^3}\right)}{\left(12 \frac{\text{in}}{\text{ft}}\right)^2\left(1000 \frac{\text{lbf}}{\text{kip}}\right)} = 0.3 \text{ kip/ft}$$

The total dead load is

$$D = 1.2 \frac{\text{kips}}{\text{ft}} + 0.3 \frac{\text{kip}}{\text{ft}} \\ = 1.5 \text{ kips/ft}$$

From Eq. 50.2, the factored load is

$$w_u = 1.2D + 1.6L \\ = (1.2)\left(1.5 \frac{\text{kips}}{\text{ft}}\right) + (1.6)\left(0.8 \frac{\text{kip}}{\text{ft}}\right) \\ = 3.08 \text{ kips/ft}$$

For a uniformly loaded beam, the factored moment is maximum at the center of the beam and is

$$M_u = \frac{w_u L^2}{8} = \frac{\left(3.08 \frac{\text{kips}}{\text{ft}}\right)(30 \text{ ft})^2}{8} \\ = 346 \text{ ft-kips}$$

## 6. DESIGN STRENGTH AND DESIGN CRITERIA

ACI 318 uses the subscript  $n$  to indicate a “nominal” quantity. A *nominal value* can be interpreted as being in accordance with theory for the specified dimensions and

material properties. The nominal moment and shear strengths are designated  $M_n$  and  $V_n$ , respectively.

The *design strength* is the result of multiplying the *nominal strength* by a *strength reduction factor* (also known as a *capacity reduction factor*),  $\phi$ .

$$\text{design strength} = \phi(\text{nominal strength}) \quad 50.8$$

The design criteria for all sections in a beam are

$$\phi M_n \geq M_u \quad 50.9(a)$$

$$\phi V_n \geq V_u \quad 50.9(b)$$

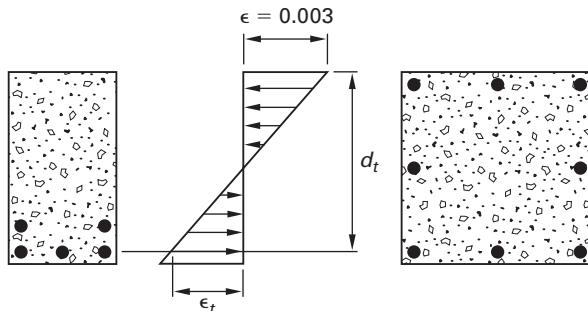

The following definitions are relevant to the unified design provisions. These definitions are used when determining strength reduction factors and design strengths. They can be found in ACI 318 Chap. 2.

*Net tensile strain*,  $\epsilon_t$ , is the tensile strain in the extreme tension steel at nominal strength, exclusive of strains due to effective prestress, creep, shrinkage, and temperature. The net tensile strain is caused by external axial loads and/or bending moments at a section when the concrete strain at the extreme compression fiber reaches its assumed limit of 0.003. Generally speaking, the net tensile strain can be used as a measure of cracking or deflection.

*Extreme tension steel* is the reinforcement (prestressed or nonprestressed) that is the farthest from the extreme compression fiber.

Figure 50.3 depicts the location of the extreme tension steel for two sections with different reinforcement arrangements, both of which assume the top fiber of the section is the extreme compression fiber. The distance from the extreme compression fiber to the centroid of the extreme tension steel is denoted in the illustration as  $d_t$ . The net tensile strain in the extreme tension steel due to the external loads can be determined from a strain compatibility analysis for sections with multiple layers of reinforcement. For sections with one layer of reinforcement, the net tensile strain can be determined from the strain diagram by using similar triangles.

**Figure 50.3** Location of Extreme Tension Steel and Net Tensile Strain at Nominal Strength

The *compression-controlled strain limit* is the net tensile strain corresponding to a balanced condition. The definition of a balanced strain condition, given in ACI 318 Sec. 10.3.2, is unchanged from previous editions of the code. (Also see Sec. 50.8.) A balanced strain condition exists in a cross section when tension reinforcement reaches the strain corresponding to its specified yield strength just as the concrete strain in the extreme compression fiber reaches its assumed limit of 0.003.

For grade 60 reinforcement and all prestressed reinforcement, ACI 318 Sec. 10.3.3 permits the compression-controlled strain limit to be taken equal to 0.002. For grade 60 bars, this limit is actually equal to  $f_y/E_s = 60,000 \text{ lbf/in}^2 / 29,000,000 \text{ lbf/in}^2 = 0.00207$ .  $f_y$  and  $E_s$  are the specified yield strength and modulus of elasticity of the nonprestressed reinforcement, respectively. For other grades of nonprestressed steel, the limit must be calculated from the ratio  $f_y/E_s$ .

A *compression-controlled section* is a cross section in which the net tensile strain is less than or equal to the compression-controlled strain limit. When the net tensile strain is small, a brittle failure condition is expected. In such cases, there is little warning of impending failure. Cross sections of compression members such as columns, subject to significant axial compression, are usually compression controlled.

A *tension-controlled section* is a cross section in which the net tensile strain is greater than or equal to 0.005. The net tensile strain limit of 0.005 applies to both nonprestressed and prestressed reinforcement and provides ductile behavior for most designs. When the net tensile strain is greater than or equal to 0.005, the section is expected to have sufficient ductility so that ample warning of failure in the form of visible cracking and deflection should occur. Cross sections of flexural members such as beams, if not heavily reinforced, are usually tension controlled.

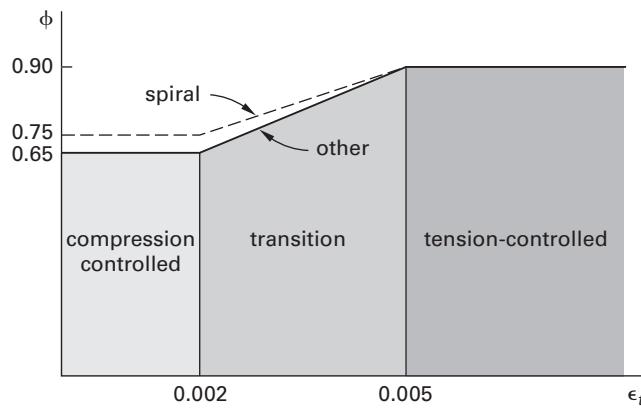

Some sections have a net tensile strain between the limits for compression-controlled and tension-controlled sections. An example of this is a section subjected to a small axial load and a large bending moment. These sections are called *transition sections*.

### Strength Reduction Factors

According to the unified design provisions, strength reduction factors are a function of the net tensile strain. ACI 318 Sec. 9.3.2 contains strength reduction factors for tension-controlled sections, compression-controlled sections, and sections in which the net tensile strain is between the limits for tension-controlled and compression-controlled sections. The variation in  $\phi$  with respect to  $\epsilon_t$  according to ACI 318 Sec. 9.3.2 is depicted in Fig. 50.4.

For compression-controlled sections,  $\phi$  is equal to 0.75 for members with spiral reinforcement conforming to ACI 318 Sec. 10.9.3 and is equal to 0.65 for other members in ACI 318 Sec. 9.3.2. For tension-controlled

**Figure 50.4** Variation of Strength Reduction Factors,  $\phi$ , with Net Tensile Strain  $\epsilon_t$  [ACI 318 Sec. 9.3.2]

sections,  $\phi$  is equal to 0.90 in ACI 318 Sec. 9.3.2. For sections that fall between these two limits, ACI 318 permits the strength reduction factor to be determined considering linear variation.

The following equations can be used to determine  $\phi$  in the transition region. For sections with spiral reinforcement,

$$\phi = 0.75 + 50(\epsilon_t - 0.002) \quad [\epsilon_t \leq 0.005] \quad [\text{ACI 318 Fig. R9.3.2}] \quad 50.10$$

For other sections,

$$\phi = 0.65 + \frac{250}{3}(\epsilon_t - 0.002) \quad [\epsilon_t \leq 0.005] \quad [\text{ACI 318 Fig. R9.3.2}] \quad 50.11$$

ACI 318 Fig. R9.3.2 contains equations to determine  $\phi$  as a function of the ratio  $c/d_t$ .  $c$  is the distance from the extreme compression fiber to the neutral axis at nominal strength.  $d_t$  is the distance from the compression fiber to the tension steel.

The nominal shear and torsional strengths must be reduced by

$$\phi = 0.75 \quad [\text{ACI 318 Sec. 9.3.2}] \quad 50.12$$

## 7. MINIMUM STEEL AREA

ACI 318 sets limits on the minimum and maximum areas of tension steel. The minimum area of tension steel is

$$A_{s,\min} = \frac{\sqrt{f'_c} b_w d}{4 f_y} \geq \frac{1.4 b_w d}{f_y} \quad [\text{SI}] \quad 50.13(a)$$

$$A_{s,\min} = \frac{3\sqrt{f'_c} b_w d}{f_y} \geq \frac{200 b_w d}{f_y} \quad [\text{U.S.}] \quad 50.13(b)$$

When the bending moment produces tension in the flange of a statically determinate T-beam, the value of

$A_{s,\min}$  calculated from Eq. 50.13 must be increased. For this condition, ACI 318 Sec. 10.5.2 requires that the minimum steel be taken as the smaller of what is calculated from either Eq. 50.13 (with  $b_w$  set equal to the width of the flange) or Eq. 50.14.

$$A_{s,\min} = \frac{\sqrt{f'_c} b_w d}{2 f_y} \quad [\text{SI}] \quad 50.14(a)$$

$$A_{s,\min} = \frac{6\sqrt{f'_c} b_w d}{f_y} \quad [\text{U.S.}] \quad 50.14(b)$$

Minimum steel provisions of Eq. 50.13 and Eq. 50.14 do not have to be followed if the area of steel provided exceeds the calculated amount required by at least 33% [ACI 318 Sec. 10.5.3].

## 8. MAXIMUM STEEL AREA

In a *ductile failure mode*, the steel yields in tension before the concrete crushes in compression. (The opposite would be a *brittle failure mode*.) The area of tension steel for which steel yielding occurs simultaneously with concrete crushing in compression is known as the *balanced steel area*,  $A_{sb}$ . An *under-reinforced beam* is defined as one having a steel area less than  $A_{sb}$ . An *over-reinforced beam* has more steel than  $A_{sb}$ .

The balanced steel area is

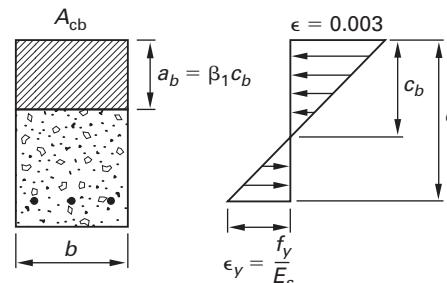

$$A_{sb} = \rho_{sb} bd = \frac{0.85 f'_c A_{cb}}{f_y} = \frac{0.85 f'_c a_b b}{f_y} \\ = \frac{0.85 f'_c \beta_1 c_b b}{f_y} \quad 50.15$$

Figure 50.5 illustrates that the compression area for balanced conditions,  $A_{cb}$ , extends from the most compressed fiber to a depth equal to  $a_b$ .

$$a_b = \beta_1 \left( \frac{600}{600 + f_y} \right) d \quad [\text{SI}] \quad 50.16(a)$$

$$a_b = \beta_1 \left( \frac{87,000}{87,000 + f_y} \right) d \quad [\text{U.S.}] \quad 50.16(b)$$

**Figure 50.5** Beam at Balanced Condition

The factor  $\beta_1$  is defined as

$$\beta_1 = 0.85 \quad [f'_c \leq 27.6 \text{ MPa}] \quad [\text{SI}] \quad 50.17(a)$$

$$\beta_1 = 0.85 \quad [f'_c \leq 4000 \text{ lbf/in}^2] \quad [\text{U.S.}] \quad 50.17(b)$$

$$\beta_1 = 0.85 - 0.05 \left( \frac{f'_c - 27.6}{6.9} \right) \geq 0.65 \quad [\text{SI}] \quad 50.17(c)$$

$$\beta_1 = 0.85 - 0.05 \left( \frac{f'_c - 4000}{1000} \right) \geq 0.65 \quad [\text{U.S.}] \quad 50.17(d)$$

Combining Eq. 50.15 and Eq. 50.16 with  $A_{cb} = a_b b$ , for rectangular sections, the balanced steel area is

$$A_{sb} = \rho_{sb} bd = \left( \frac{0.85\beta_1 f'_c}{f_y} \right) \left( \frac{600}{600 + f_y} \right) bd \quad [\text{SI}] \quad 50.18(a)$$

$$A_{sb} = \rho_{sb} bd = \left( \frac{0.85\beta_1 f'_c}{f_y} \right) \left( \frac{87,000}{87,000 + f_y} \right) bd \quad [\text{U.S.}] \quad 50.18(b)$$

Previous versions of ACI 318 ensured the steel would fail in tension before the concrete failed in compression (i.e., ductile failure) by limiting the maximum reinforcement to 75% of the balanced reinforcement. (This provision is still present in ACI 318 Sec. B10.3.3 of the alternative provisions.)

$$A_{s,\max} = 0.75 A_{sb} \quad [\text{alternative provisions only}] \quad 50.19$$

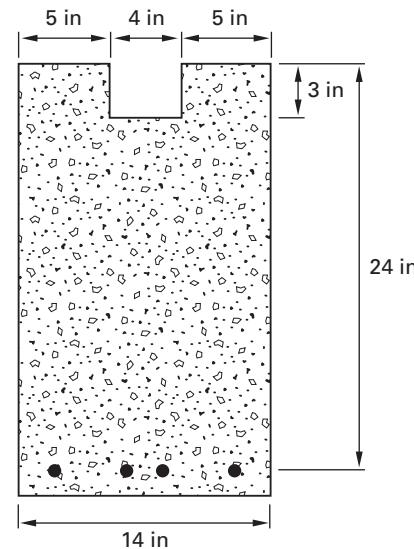

For unified design, the ductile failure is ensured by specifying a minimum tensile steel strain,  $\epsilon_{t,\min}$  of 0.004.

The unified design provisions limit the maximum reinforcement in a flexural member (with factored axial load less than  $0.1f'_c A_g$ ) to that which would result in a net tensile strain,  $\epsilon_t$ , not less than 0.004 [ACI 318 Sec. 10.3.5]. The fraction of the balanced reinforcement ratio equivalent to a steel strain of 0.004 depends on both the concrete ultimate compressive strength and the steel tensile yield strength. For a singly reinforced section with grade 60 reinforcement, this is equivalent to a maximum reinforcement ratio of  $0.714\rho_b$ . (By comparison, the ACI 318 App. B limit of  $\rho_{\max} = 0.75\rho_b$  results in a net tensile strain of 0.00376.) At the net tensile strain limit of 0.004, the strength reduction factor of ACI 318 Sec. 9.3.2,  $\phi$ , is reduced to 0.817 (as calculated from Eq. 50.11 with  $\epsilon_t = 0.004$ ).

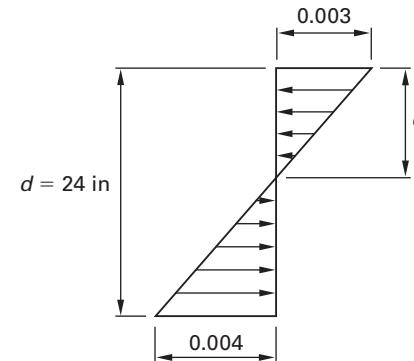

It is almost always advantageous to limit the net tensile strain in flexural members to a minimum of 0.005, which is equivalent to a maximum reinforcement ratio of  $0.63\rho_b$  [ACI 318 Sec. R9.3.2.2], even though the code permits higher amounts of reinforcement that produce lower net tensile strains. Where member size is limited and extra strength is needed, it is best to use compression reinforcement to limit the net tensile strain so that the section is tension controlled.

### Example 50.2

For the beam cross section shown, assume the centroid of the tension steel is at a depth of 24 in.  $f'_c = 4000 \text{ lbf/in}^2$ , and  $f_y = 60,000 \text{ lbf/in}^2$ . Calculate the maximum area of reinforcing steel that can be used.

*Solution Using ACI 318 Chap. 10*

The neutral axis depth,  $c$ , corresponding to minimum permissible  $\epsilon_t = 0.004$ , is

$$\frac{0.003}{0.003 + 0.004} = \frac{c}{24 \text{ in}} \\ c = \left( \frac{3}{7} \right) (24 \text{ in}) = 10.29 \text{ in}$$

The corresponding steel area is  $A_{s,\max}$ .

Equate the compressive and tensile forces.

$$\begin{aligned} & \left( (10 \text{ in})(0.85)(10.29 \text{ in}) \right. \\ & \quad \left. + (4 \text{ in})(0.85) \times (10.29 \text{ in} - 3 \text{ in}) \right) (0.85) \left( 4000 \frac{\text{lbf}}{\text{in}^2} \right) \\ & = A_{s,\max} \left( 60,000 \frac{\text{lbf}}{\text{in}^2} \right) \\ A_{s,\max} & = 6.36 \text{ in}^2 \end{aligned}$$

**Solution Using ACI 318 App. B**

This is not a rectangular beam, so the balanced steel area cannot be calculated from Eq. 50.18.

The depth of the equivalent rectangular stress block at balanced condition is obtained from Eq. 50.16(b) with  $\beta_1 = 0.85$ .

$$\begin{aligned} a_b &= \beta_1 \left( \frac{87,000}{87,000 + f_y} \right) d \\ &= (0.85) \left( \frac{87,000}{87,000 + 60,000} \right) (24 \text{ in}) \\ &= 12.07 \text{ in} \end{aligned}$$

The area  $A_{cb}$  corresponding to the depth  $a_b$  is

$$\begin{aligned} A_{cb} &= (10 \text{ in})(3 \text{ in}) + (14 \text{ in})(12.07 \text{ in} - 3 \text{ in}) \\ &= 156.98 \text{ in}^2 \end{aligned}$$

Substitute into Eq. 50.15.

$$\begin{aligned} A_{sb} &= \frac{0.85 f'_c A_{cb}}{f_y} = \frac{(0.85)(4000 \frac{\text{lbf}}{\text{in}^2})(156.98 \text{ in}^2)}{60,000 \frac{\text{lbf}}{\text{in}^2}} \\ &= 8.90 \text{ in}^2 \end{aligned}$$

The maximum steel permitted without the use of compression steel is given by Eq. 50.19.

$$\begin{aligned} A_{s,max} &= 0.75 A_{sb} = (0.75)(8.90 \text{ in}^2) \\ &= 6.67 \text{ in}^2 \end{aligned}$$

**9. STEEL COVER AND BEAM WIDTH**

The following details must be considered in the design of steel-reinforced concrete beams. The beam widths in Table 50.2 are derived from them.

- All steel, including shear reinforcement, must be adequately covered by concrete. A minimum of 1.5 in of cover is generally required. Table 50.1 provides more specific details.
- The minimum horizontal clear distance between bars is the larger of one bar diameter or 1 in [ACI 318 Sec. 7.6].
- The minimum vertical clear distance between steel layers is 1 in.
- Clear distance between bars must be  $4/3$  of the maximum aggregate size [ACI 318 Sec. 3.3.2(c)]. For typical  $3/4$  in aggregate, this is equivalent to a minimum clear distance of 1 in.
- Although it is not an ACI requirement, it is common practice to use a ratio of beam depth to width that satisfies Eq. 50.20.

$$1.5 \leq d/b \leq 2.5$$

$$50.20$$

(Multiply in by 25.4 to obtain mm.)

<sup>a</sup>Using no. 3 stirrups. If stirrups are not used, deduct 0.75 in.

<sup>b</sup>The minimum inside radius of a 90° stirrup bend is two times the stirrup diameter. An allowance has been included in the beam widths to achieve a full bend radius.

<sup>c</sup>For additional horizontal bars, the beam width is increased by adding the value in the last column.

**10. NOMINAL MOMENT STRENGTH OF SINGLY REINFORCED SECTIONS**

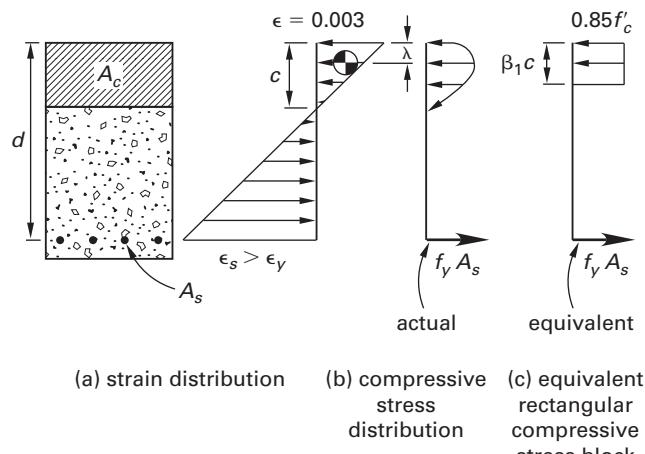

The moment capacity of a reinforced concrete cross section derives from the couple composed of the tensile force in the steel and the compressive force in the concrete. These forces are equal. The steel force is limited to the product of the steel area times the steel yield strength. Therefore, the nominal moment capacity is

$$M_n = f_y A_s (\text{lever arm}) \quad 50.21$$

The maximum nominal moment capacity will occur when the steel yields and the lever arm reaches a maximum value. However, since the true distribution of compressive forces at ultimate capacity is nonlinear, it is difficult to determine the lever arm length. To simplify the analysis, ACI 318 permits replacing the true nonlinear distribution of stresses with a simple uniform distribution where the stress equals  $0.85 f'_c$  [ACI 318 Sec. 10.2.7]. This is known as the *Whitney assumption*.

As shown in Fig. 50.6(c),  $\beta_1$  is the ratio of the depth of the equivalent rectangular stress block to the true depth of the neutral axis.

**Figure 50.6** Conditions at Maximum Moment

Most reinforced concrete beams are designed to be tensile-controlled. With strain varying linearly over the beam depth, the tensile steel strain for a given beam depth,  $d$ , and location of the neutral axis,  $c$ , at a maximum concrete strain of 0.003 is

$$\epsilon_t = 0.003 \left( \frac{d - c}{c} \right) \quad 50.22$$

The corresponding steel tensile stress (at maximum concrete strain) is

$$f_s = (600 \text{ MPa}) \left( \frac{d - c}{c} \right) \quad [\text{SI}] \quad 50.23(a)$$

$$f_s = \left( 87,000 \frac{\text{lbf}}{\text{in}^2} \right) \left( \frac{d - c}{c} \right) \quad [\text{U.S.}] \quad 50.23(b)$$

The reinforcement ratio,  $\rho$ , can be written in terms of the  $c/d$  ratio.

$$\rho = \frac{A_s}{bd} = 0.85\beta_1 \left( \frac{c}{d} \right) \left( \frac{f'_c}{f_y} \right) \quad 50.24$$

Equation 50.24 can be used with Fig. 50.4 to determine the failure mode of beams. For beams controlled by tensile failure,  $f_s = f_y$ ,  $\epsilon_t > 0.005$ , and  $c/d < 0.375$ . The beam strength will be limited by either tensile strength or shear. For beams controlled by compressive failure,  $f_s < f_y$ ,  $\epsilon_t < 0.002$ , and  $c/d > 0.6$ . The beam strength will be limited by either compressive strength or shear. A transition zone wherein beam strength can be limited by tensile strength, compressive strength, or shear exists between these two limits.

The nominal moment capacity can be computed for any singly reinforced section with the following procedure.

step 1: Compute the tension force.

$$T = f_y A_s \quad 50.25$$

step 2: Calculate the area of concrete that, at a stress of  $0.85f'_c$ , gives a force equal to  $T$ .

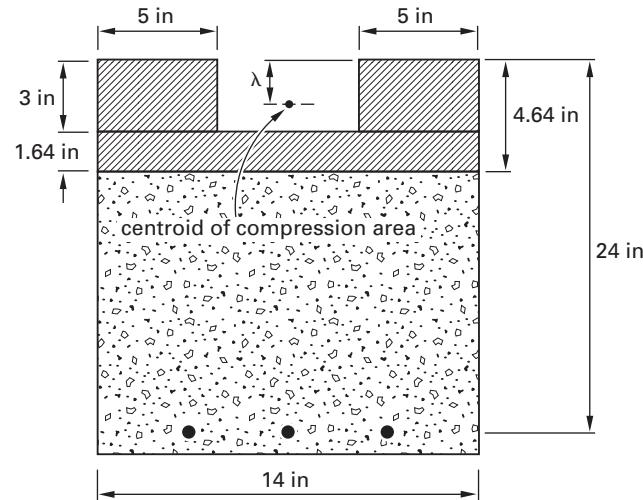

$$A_c = \frac{T}{0.85f'_c} = \frac{f_y A_s}{0.85f'_c} \quad 50.26$$

step 3: Locate the centroid of the area  $A_c$ . Designating the distance from the centroid of the compression region to the most compressed fiber as  $\lambda$ , calculate the nominal moment capacity.

$$M_n = A_s f_y (d - \lambda) \quad 50.27$$

### Example 50.3

The cross section of the beam shown is reinforced with 3.0 in<sup>2</sup> of steel. (The cross section and material properties of this example are the same as those used in Ex. 50.2.)  $f'_c = 4000 \text{ lbf/in}^2$  and  $f_y = 60,000 \text{ lbf/in}^2$ . Calculate the design moment capacity,  $\phi M_n$ .

### Solution

As part of the solution process, assume that the tension steel yields at the maximum moment. The area of concrete required to balance the steel force at yield is given by Eq. 50.26.

$$A_c = \frac{f_y A_s}{0.85f'_c} = \frac{\left( 60,000 \frac{\text{lbf}}{\text{in}^2} \right) (3 \text{ in}^2)}{(0.85)(4000 \frac{\text{lbf}}{\text{in}^2})}$$

$$= 52.94 \text{ in}^2$$

The thickness of the 14 in wide compression zone is

$$52.94 \text{ in}^2 = (2)(5 \text{ in})(3 \text{ in}) + (14 \text{ in})t$$

$$t = 1.64 \text{ in}$$

Sum moments of the areas about the top of the section and equate the sum to  $A_c\lambda$ .

$$(2)(5 \text{ in})(3 \text{ in})(1.5 \text{ in})$$

$$+ (1.64 \text{ in})(14 \text{ in})\left(3 \text{ in} + \frac{1.64 \text{ in}}{2}\right)$$

$$= (52.94 \text{ in}^2)\lambda$$

$$\lambda = 2.51 \text{ in}$$

The nominal moment capacity is obtained from Eq. 50.27.

$$M_n = A_s f_y (d - \lambda)$$

$$= \frac{(3 \text{ in}^2)\left(60,000 \frac{\text{lbf}}{\text{in}^2}\right)(24 \text{ in} - 2.51 \text{ in})}{(12 \frac{\text{in}}{\text{ft}})(1000 \frac{\text{lbf}}{\text{kip}})}$$

$$= 322.4 \text{ ft-kips}$$

The design moment capacity is

$$\phi M_n = (0.9)(322.4 \text{ ft-kips})$$

$$= 290 \text{ ft-kips}$$

Verify that the tensile steel yields at ultimate loading. Use the ACI alternative provisions. In Ex. 50.2, the balanced steel area was found to be  $8.90 \text{ in}^2$ .  $3 \text{ in}^2$  is less than the balanced area—and less than the maximum area—so the steel yields at ultimate loading.

Using unified design,

$$a = 4.64 \text{ in}$$

$$c = \frac{a}{\beta_1} = \frac{4.64 \text{ in}}{0.85}$$

$$= 5.46 \text{ in}$$

$$\epsilon_t = 0.003\left(\frac{d - c}{c}\right)$$

$$= (0.003)\left(\frac{24 \text{ in} - 5.46 \text{ in}}{5.46 \text{ in}}\right)$$

$$= 0.010$$

Since 0.010 is greater than 0.005, the section is tension controlled, and the tension reinforcement yields at ultimate loading.

## 11. BEAM DESIGN: SIZE KNOWN, REINFORCEMENT UNKNOWN

If the required strength,  $M_u$ , due to the factored loads is known or can be computed, beam design reduces to determining the amount of reinforcing steel required. Although formulas for determining reinforcing steel in rectangular cross sections can be derived, an iterative approach is sufficiently simple.

Equation 50.28 is derived by changing the  $\geq$  sign in Eq. 50.9(a) to an equality and substituting Eq. 50.27 for  $M_n$ .

$$A_s = \frac{M_u}{\phi f_y(d - \lambda)} \quad 50.28$$

Equation 50.28 is easily solved if a value for  $\lambda$  is first assumed. (A value of  $0.1d$  is typically a good estimate.) The design procedure consists of estimating  $\lambda$ , solving for  $A_s$  from Eq. 50.28, and checking the moment capacity for the selected steel using the actual associated  $\lambda$ .

If the values of the capacity,  $\phi M_n$ , and the demand,  $M_u$ , are not sufficiently close, the area of steel is adjusted (i.e., extrapolated) by multiplying it by  $M_u/(\phi M_n)$ . Even though the relationship between steel area and moment is linear only over small variations, this procedure seldom requires additional iterations because the adjusted steel area will be very close to the exact solution.

In actual practice, it is customary to provide the required steel area using at most two different bar sizes. For this reason, and because only a limited number of bar sizes is available, some excess steel is typically unavoidable.

### Example 50.4

The beam cross section in Ex. 50.2 and Ex. 50.3 is used in a simply supported beam having a span of 25 ft. The beam is subjected to a service dead load (which includes its own weight) of 1.2 kips/ft and a live load of 2.0 kips/ft.  $f'_c = 5000 \text{ lbf/in}^2$ , and  $f_y = 60,000 \text{ lbf/in}^2$ . Determine the required steel area for the maximum moment.

#### Solution

From Eq. 50.2, the factored load is

$$w_u = 1.2D + 1.6L$$

$$= (1.2)\left(1.2 \frac{\text{kips}}{\text{ft}}\right) + (1.6)\left(2.0 \frac{\text{kips}}{\text{ft}}\right)$$

$$= 4.64 \text{ kips/ft}$$

The maximum moment is

$$M_u = \frac{w_u L^2}{8} = \frac{\left(4.64 \frac{\text{kips}}{\text{ft}}\right)(25 \text{ ft})^2}{8}$$

$$= 362.5 \text{ ft-kips}$$

Estimate  $\lambda$ .

$$\begin{aligned}\lambda &= 0.1d = (0.1)(24 \text{ in}) \\ &= 2.4 \text{ in}\end{aligned}$$

From Eq. 50.28, assuming a tension-controlled section,

$$\begin{aligned}A_s &= \frac{M_u}{\phi f_y(d - \lambda)} \\ &= \frac{(362.5 \text{ ft-kips})(12 \frac{\text{in}}{\text{ft}})}{(0.9)(60 \frac{\text{kips}}{\text{in}^2})(24 \text{ in} - 2.4 \text{ in})} \\ &= 3.73 \text{ in}^2\end{aligned}$$

Compute  $M_n$  for this steel area. From Eq. 50.26,

$$\begin{aligned}A_c &= \frac{f_y A_s}{0.85 f'_c} = \frac{(3.73 \text{ in}^2) \left( 60 \frac{\text{kips}}{\text{in}^2} \right)}{(0.85) \left( 5 \frac{\text{kips}}{\text{in}^2} \right)} \\ &= 52.66 \text{ in}^2\end{aligned}$$

The thickness of the 14 in wide compression zone is

$$\begin{aligned}52.66 \text{ in}^2 &= (2)(5 \text{ in})(3 \text{ in}) + (14 \text{ in})t \\ t &= 1.62 \text{ in}\end{aligned}$$

Locate the centroid of the compression zone.

$$\begin{aligned}(10 \text{ in})(3 \text{ in})(1.5 \text{ in}) + (1.62 \text{ in})(14 \text{ in}) \left( 3 \text{ in} + \frac{1.62 \text{ in}}{2} \right) \\ = (52.66 \text{ in}^2)\lambda \\ \lambda &= 2.50 \text{ in}\end{aligned}$$

The nominal moment capacity obtained from Eq. 50.27 is

$$\begin{aligned}M_n &= A_s f_y (d - \lambda) \\ &= \frac{(3.73 \text{ in}^2) \left( 60 \frac{\text{kips}}{\text{in}^2} \right) (24 \text{ in} - 2.50 \text{ in})}{12 \frac{\text{in}}{\text{ft}}} \\ &= 401 \text{ ft-kips}\end{aligned}$$

Assuming a tension-controlled section, the design moment capacity is

$$\begin{aligned}\phi M_n &= (0.9)(401 \text{ ft-kips}) \\ &= 360.9 \text{ ft-kips}\end{aligned}$$

Since the design moment capacity (360.9 ft-kips) is slightly less than the factored moment (362.5 ft-kips), the "exact" steel area required is nominally larger than

the estimated value of 3.73 in<sup>2</sup>. The steel area is extrapolated as

$$\begin{aligned}A_{s,\text{new}} &= A_s \left( \frac{M_u}{\phi M_n} \right) = (3.73 \text{ in}^2) \left( \frac{362.5 \text{ ft-kips}}{360.9 \text{ ft-kips}} \right) \\ &= 3.75 \text{ in}^2\end{aligned}$$

The value of  $\phi M_n$  for this adjusted steel area is 362.6 ft-kips, essentially the same as  $M_u$ .

Check that the section is tension controlled. For  $A_s = 3.75 \text{ in}^2$ ,

$$\begin{aligned}A_c &= 52.94 \text{ in}^2 \\ t &= 1.64 \text{ in}\end{aligned}$$

The stress block depth is

$$a = 3 \text{ in} + 1.64 \text{ in} = 4.64 \text{ in}$$

From Eq. 50.17(d), with 5000 psi concrete,  $\beta_1 = 0.80$ .

The corresponding neutral axis depth is

$$\begin{aligned}c &= \frac{a}{\beta_1} = \frac{4.64 \text{ in}}{0.80} \\ &= 5.8 \text{ in}\end{aligned}$$

The net tensile strain is

$$\epsilon_t = (0.003) \left( \frac{24 \text{ in} - 5.8 \text{ in}}{5.8 \text{ in}} \right) = 0.0094$$

Since 0.0094 is greater than 0.005, the section is tension controlled.

## 12. BEAM DESIGN: SIZE AND REINFORCEMENT UNKNOWN

If beam size (i.e., cross section) and area of reinforcement are both unknown, there will not be a unique solution. In principle, the procedure involves first choosing a beam cross section and then sizing the steel in the usual manner. The beam is sized by (a) selecting a depth to ensure that deflections are not a problem and (b) selecting a width so that the ratio of depth to width is reasonable. (See Sec. 50.17.) Then, the steel is checked to see that the corresponding net tensile strain is not less than 0.004 and that the steel area is larger than or equal to the minimum value prescribed in ACI 318. (See Sec. 50.7.)

Portions of the design procedure can be streamlined for rectangular cross sections by deriving an explicit formula relating the nominal moment capacity to the relevant design parameters. For a rectangular cross section,

$$\lambda = \frac{A_c}{2b} \quad 50.29$$

Combining Eq. 50.27, Eq. 50.28, and Eq. 50.29,

$$M_n = A_s f_y d \left( 1 - \frac{A_s f_y}{1.7 f'_c b d} \right) \quad 50.30$$

A convenient form of Eq. 50.30 is obtained by expressing the steel area in terms of the *steel ratio* (also called the *reinforcement ratio*),  $\rho$ , which is defined as

$$\rho = \frac{A_s}{bd} \quad 50.31$$

Combining Eq. 50.30 and Eq. 50.31,

$$\begin{aligned} M_n &= \rho b d^2 f_y \left( 1 - \frac{\rho f_y}{1.7 f'_c} \right) \\ &= A_s f_y \left( d - \frac{A_s f_y}{1.7 f'_c b} \right) \end{aligned} \quad 50.32$$

The balanced reinforcement ratio is

$$\rho_{sb} = \left( \frac{0.85 \beta_1 f'_c}{f_y} \right) \left( \frac{600}{600 + f_y} \right) \quad [\text{SI}] \quad 50.33(a)$$

$$\rho_{sb} = \left( \frac{0.85 \beta_1 f'_c}{f_y} \right) \left( \frac{87,000}{87,000 + f_y} \right) \quad [\text{U.S.}] \quad 50.33(b)$$

The minimum steel is derived from Eq. 50.13.

$$\rho_{min} = \frac{\sqrt{f'_c}}{4f_y} \geq \frac{1.4}{f_y} \quad [\text{SI}] \quad 50.34(a)$$

$$\rho_{min} = \frac{3\sqrt{f'_c}}{f_y} \geq \frac{200}{f_y} \quad [\text{U.S.}] \quad 50.34(b)$$

**Table 50.3** Total Areas for Various Numbers of Bars ( $\text{in}^2$ )

(Multiply in by 25.4 to obtain mm.)

(Multiply in<sup>2</sup> by 645 to obtain mm<sup>2</sup>.)

(Multiply lbf/ft by 1.488 to obtain kg/m.)

\*No. 14 and no. 18 bars are typically used in columns only.

The following steps constitute a procedure for designing a beam with a rectangular cross section.

*step 1:* Select a value of  $\rho$  between the minimum and maximum values. The maximum value corresponds to a minimum steel strain of  $\epsilon_t = 0.004$  in unified design and is equal to  $0.714\rho_{sb}$  for 4000 psi concrete reinforced with 60 ksi bars. Common values are approximately half of the maximum permitted. It is widely held that values of  $pf_y/f'_c$  near 0.18 lead to economical beams. (Larger values will lead to smaller concrete cross sections.)

*step 2:* Calculate the required value of  $bd^2$  from Eq. 50.32.

*step 3:* Choose appropriate values of  $b$  and  $d$ . A good choice is to keep  $d/b$  between 1.50 and 2.5. For beams with a single layer of tension steel, the value of  $d$  is approximately equal to  $h - 2.5$  in. Furthermore, explicit computation of deflections can be avoided if a depth is chosen that is larger than a certain fraction of the span. (See Table 50.4.) The dimensions  $b$  and  $h$  are usually rounded to the nearest whole inch.

*step 4:* If the actual  $bd^2$  quantity is notably different from the  $bd^2$  calculated in step 2, use Eq. 50.32 to recalculate the associated  $\rho$  value.

*step 5:* Calculate the required steel area as

$$A_s = \rho bd \quad 50.35$$

*step 6:* Select reinforcing steel bars to satisfy the distribution and placement requirements of ACI 318. (Refer to Table 50.2 and Table 50.3.)

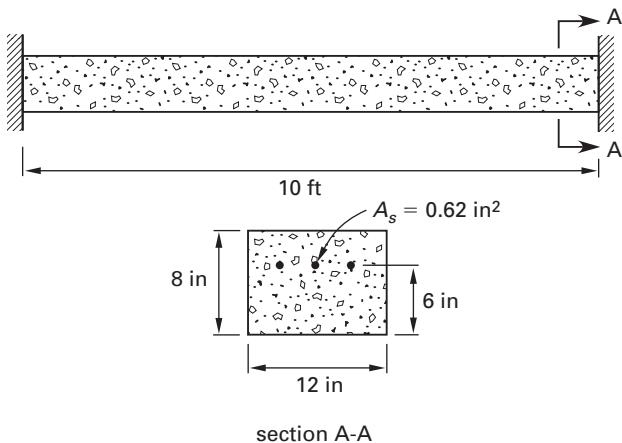

*step 7:* Design the shear reinforcement. (See Sec. 50.20.)

*step 8:* Check cracking requirements. (See Sec. 50.13.)

*step 9:* Check deflection. (See Sec. 50.15.)

**Example 50.5**

The span of a beam with the cross section shown is 10 ft, and the ends are built in.  $f'_c = 3500 \text{ lbf/in}^2$  and  $f_y = 40,000 \text{ lbf/in}^2$ . The maximum load is controlled by the capacity in the negative moment region. Based solely on flexural requirements, what is the maximum uniform live load the beam can carry?

*Solution*

The beam is rectangular, so Eq. 50.31 and Eq. 50.32 can be used to calculate  $M_n$ .

$$\begin{aligned}\rho &= \frac{A_s}{bd} \\ &= \frac{0.62 \text{ in}^2}{(12 \text{ in})(6 \text{ in})} \\ &= 0.00861\end{aligned}$$

From Eq. 50.32,

$$\begin{aligned}M_n &= \rho bd^2 f_y \left( 1 - \frac{\rho f_y}{1.7 f'_c} \right) \\ &= (0.00861)(12 \text{ in})(6 \text{ in})^2 \left( 40 \frac{\text{kips}}{\text{in}^2} \right) \\ &\times \left( 1 - \frac{(0.00861) \left( 40 \frac{\text{kips}}{\text{in}^2} \right)}{(1.7) \left( 3.5 \frac{\text{kips}}{\text{in}^2} \right)} \right) \\ &= 140.2 \text{ in-kips}\end{aligned}$$

For a beam fixed at both ends, the maximum negative moment occurs at the ends and is

$$M_u = \phi M_n = \frac{w_u L^2}{12}$$

Solve for the factored uniform load.

$$\begin{aligned}w_u &= \frac{12\phi M_n}{L^2} = \frac{(12)(0.9)(140.2 \text{ in-kips})}{(10 \text{ ft})^2 (12 \frac{\text{in}}{\text{ft}})} \\ &= 1.26 \text{ kips/ft}\end{aligned}$$

Using a unit weight of 150 lbf/ft<sup>3</sup> for the concrete, the weight of the beam is

$$\begin{aligned}w_d &= \frac{\left( 150 \frac{\text{lbf}}{\text{ft}^3} \right) (12 \text{ in})(8 \text{ in})}{\left( 1000 \frac{\text{lbf}}{\text{kip}} \right) \left( 12 \frac{\text{in}}{\text{ft}} \right)^2} \\ &= 0.10 \text{ kips/ft}\end{aligned}$$

Assume no additional dead load acts on the beam. The factored load is

$$\begin{aligned}w_u &= 1.26 \frac{\text{kips}}{\text{ft}} = 1.2D + 1.6L \\ &= (1.2) \left( 0.10 \frac{\text{kip}}{\text{ft}} \right) + 1.6w_l\end{aligned}$$

Solve for the maximum live load.

$$w_l = 0.71 \text{ kips/ft}$$

**Example 50.6**

Design a rectangular beam with only tension reinforcement to carry service moments of 34.3 ft-kips (dead) and 30 ft-kips (live).  $f'_c = 3500 \text{ lbf/in}^2$  and  $f_y = 40,000 \text{ lbf/in}^2$ . No. 3 bars are used for shear reinforcing. (Do not design stirrup placement.)

*Solution*

The factored moment is

$$\begin{aligned}M_u &= 1.2M_d + 1.6M_l \\ &= (1.2)(34.3 \text{ ft-kips}) + (1.6)(30 \text{ ft-kips}) \\ &= 89.16 \text{ ft-kips}\end{aligned}$$

Assuming a tension-controlled section,

$$\begin{aligned}M_n &= \frac{M_u}{\phi} \\ &= \frac{89.16 \text{ ft-kips}}{0.9} \\ &= 99.07 \text{ ft-kips}\end{aligned}$$

Select a reinforcement ratio  $\rho = 0.18f'_c/f_y$  to achieve a reasonably economical design.

$$\rho = \frac{(0.18)\left(3500 \frac{\text{lbf}}{\text{in}^2}\right)}{40,000 \frac{\text{lbf}}{\text{in}^2}} = 0.0158$$

Rearrange Eq. 50.32 to solve for  $bd^2$ .

$$\begin{aligned} bd^2 &= \frac{M_n}{\rho f_y \left(1 - \frac{\rho f_y}{1.7 f'_c}\right)} \\ &= \frac{(99.07 \text{ ft-kips})\left(12 \frac{\text{in}}{\text{ft}}\right)\left(1000 \frac{\text{lbf}}{\text{kip}}\right)}{(0.0158)\left(40,000 \frac{\text{lbf}}{\text{in}^2}\right)} \\ &\quad \times \left(1 - \frac{(0.0158)\left(40,000 \frac{\text{lbf}}{\text{in}^2}\right)}{(1.7)\left(3500 \frac{\text{lbf}}{\text{in}^2}\right)}\right) \\ &= 2104 \text{ in}^3 \end{aligned}$$

Choose  $d/b = 1.8$ .

$$\begin{aligned} d^3 &= (1.8)(2104 \text{ in}^3) = 3787 \text{ in}^3 \\ d &= 15.59 \text{ in} \\ b &= \frac{15.59 \text{ in}}{1.8} = 8.66 \text{ in} \end{aligned}$$

The total depth includes the effective depth (15.58 in), the diameter of the stirrup ( $3/8$  in), the cover (1.5 in), and half the diameter of the longitudinal bars. Assuming no. 8 bars, the theoretical depth is

$$\begin{aligned} h &= 15.58 \text{ in} + 0.375 \text{ in} + 1.5 \text{ in} + 0.5 \text{ in} \\ &= 17.955 \text{ in} \end{aligned}$$

The overall dimensions are typically rounded to the nearest inch. Select  $b = 9$  in and  $h = 18$  in. The actual  $d$  is  $h - 2.375$  in = 15.625 in.

It is appropriate to solve for the reinforcement ratio,  $\rho$ , corresponding to the final dimensions. This can be done with Eq. 50.32 (by solving a quadratic) and the actual value of  $bd^2$ .

$$\begin{aligned} bd^2 &= (9 \text{ in})(15.625 \text{ in})^2 \\ &= 2197.3 \text{ in}^3 \end{aligned}$$

The resulting value,  $\rho = 0.0151$ , is smaller than the initial value of 0.0158 because the dimensions were rounded up. For this low reinforcement ratio, the

section is going to be tension controlled. A formal check is unnecessary. The required steel area is

$$\begin{aligned} A_s &= \rho bd = (0.0151)(9 \text{ in})(15.625 \text{ in}) \\ &= 2.12 \text{ in}^2 \end{aligned}$$

Select three no. 8 bars, which gives a total area of 2.37 in<sup>2</sup>. Although this completes the first cycle of beam design, a check of required beam width from Table 50.2 shows that the reinforcement will not fit. The beam should be redesigned with either larger  $b$  or  $d$ , or both.

### 13. SERVICEABILITY: CRACKING

Flexural design procedures for reinforced concrete beams are based on strength. *Serviceability* considerations involve checking that deflections and crack widths are not excessive at service loads.

The low tensile strength of concrete makes cracking of concrete beams inevitable. It is possible, however, to keep the width of the cracks sufficiently small so that the tension steel remains protected by the *concrete cover*. Acceptable crack widths range from 0.006–0.016 in (0.15–0.41 mm), which clearly have no effect on the appearance of the member. While cracking reduces the stiffness of the beam, it has no significant effect on strength.

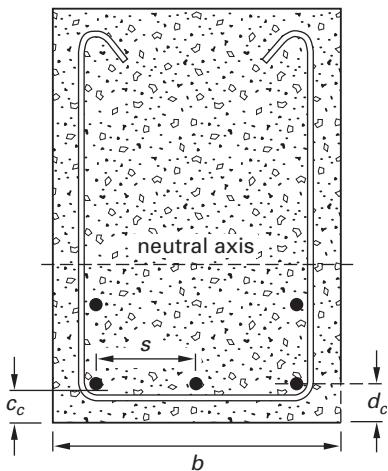

The basic goal in the control of cracking is to ensure that the elongation of the tension side of the beam is distributed between a large number of closely spaced small cracks instead of being taken up in a few widely spaced large cracks. If it is concluded that unacceptable cracking will occur, then smaller reinforcing bars must be used to redistribute the steel around a greater area.

Since the elongation of the tension steel is proportional to the stress acting on it, the potential importance of cracking is larger when high-strength steels are used. Experience has shown that cracking is usually not a problem for beams reinforced with steel bars having a yield strength equal to or less than 40,000 lbf/in<sup>2</sup> (276 MPa).

ACI 318 Chap. 10 provides a simplified approach for evaluating cracking in beams with reinforcement. The method does not deal directly with crack widths, but instead controls the spacing of the reinforcement layer closest to the tension face [ACI 318 Sec. 10.6.4].

$$s_{\max} = 15 \left( \frac{40,000}{f_s} \right) - 2.5 c_c \leq 12 \left( \frac{40,000}{f_s} \right) \quad 50.36$$

$f_s$  is the computed stress in the tension steel under service loads in psi. ACI 318 Sec. 10.6.4 permits this value to be calculated using linear elastic theory, or in lieu of an elastic analysis,  $f_s$  may be approximated as  $2/3 f_y$ . The parameters  $s$ ,  $c_c$ , and others are illustrated in Fig. 50.7.

**Figure 50.7** Parameters for Cracking Calculation

For the usual case of beams with grade 60 reinforcement, 2 in of clear cover to the main reinforcement, and with  $f_s = 40$  ksi (the maximum steel stress permitted) the maximum bar spacing is 10 in [ACI 318 Sec. R10.6.4].

#### 14. CRACKED MOMENT OF INERTIA

The *cracked moment of inertia*,  $I_{cr}$ , also referred to as the *transformed moment of inertia*, is the moment of inertia computed for the section under the assumption that the concrete carries no tension and behaves linearly in compression. Referring to Fig. 50.8, the procedure for computing  $I_{cr}$  is as follows.

*step 1:* Calculate the *modular ratio*,  $n$ , the ratio of the moduli of elasticity of the steel and the concrete. The modulus of elasticity for steel is almost always 29,000 kips/in<sup>2</sup> (200 GPa).

$$n = \frac{E_s}{E_c} \quad 50.37$$

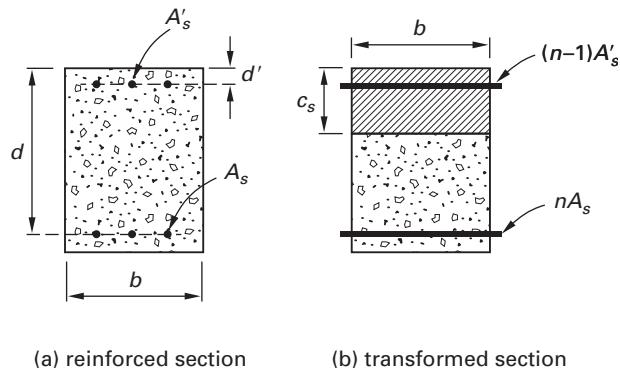

$$E_c = 4700\sqrt{f'_c} \quad [\text{SI}] \quad 50.38(a)$$

$$E_c = 57,000\sqrt{f'_c} \quad [\text{U.S.}] \quad 50.38(b)$$

*step 2:* Multiply the tension steel areas by  $n$  and the compression steel areas by  $n - 1$ . This converts the steel areas to equivalent concrete areas. (The “ $-1$ ” term for the compression steel accounts for the fact that the steel is replacing a concrete area.)

*step 3:* Determine the distance,  $c_s$ , to the neutral axis. All concrete below the neutral axis is assumed to be ineffective.

*step 4:* Calculate  $I_{cr}$  using the parallel axis theorem. The moments of inertia of the steel areas with respect to their local centroid are assumed to be negligible.

**Figure 50.8** Parameters for Cracked Moment of Inertia

There are many cases where the cross section is rectangular and singly reinforced. Closed-form expressions can be derived to simplify the computation of  $c_s$  and  $I_{cr}$ . Referring to Fig. 50.8,

$$\frac{bc_s^2}{2} = nA_s(d - c_s) \quad 50.39$$

This is a quadratic equation with the solution

$$c_s = \frac{nA_s}{b} \left( \sqrt{1 + \frac{2bd}{nA_s}} - 1 \right) \quad 50.40$$

Equation 50.40 can also be written in terms of the reinforcement ratio.

$$c_s = n\rho d \left( \sqrt{1 + \frac{2}{n\rho}} - 1 \right) \quad 50.41$$

The cracked moment of inertia for a rectangular, singly reinforced beam is

$$I_{cr} = \frac{bc_s^3}{3} + nA_s(d - c_s)^2 \quad 50.42$$

#### 15. SERVICEABILITY: DEFLECTIONS

Reinforced concrete beam deflections have two components: (a) an immediate deflection that occurs as a result of the strains induced by the applied loads, and (b) a long-term deflection that develops due to creep and shrinkage of the concrete. *Immediate (instantaneous) deflections*,  $\Delta_i$ , are computed using any available general method based on elastic linear response. However, the effect of cracking on the flexural stiffness of the beam must be considered.

Cracking takes place whenever the bending moment at a cross section exceeds the *cracking moment*,  $M_{cr}$ . Since moments from the applied loads vary along the beam length, certain portions of the beam will be cracked while others will be uncracked. This makes a rigorous

analysis that takes into account the actual variation of the flexural stiffness along the beam length essentially impractical. Therefore, ACI 318 provides a simplified method for obtaining an effective moment of inertia that is assumed to be constant along the entire beam length. The *effective moment of inertia*,  $I_e$ , is given by ACI 318 Sec. 9.5.2.3 as

$$I_e = \left( \frac{M_{cr}}{M_a} \right)^3 I_g + \left( 1 - \left( \frac{M_{cr}}{M_a} \right)^3 \right) I_{cr} \leq I_g \quad 50.43$$

The *cracking moment* is

$$M_{cr} = \frac{f_r I_g}{y_t} \quad 50.44$$

In Eq. 50.44,  $I_g$  is the *gross moment of inertia*,  $I_g = bh^3/12$ ,  $f_r$  is the *modulus of rupture* (i.e., the stress at which the concrete is assumed to crack), and  $y_t$  is the distance from the center of gravity of the gross section (neglecting reinforcement) to the extreme tension fiber. For a rectangular cross section,  $y_t = h/2$ . For stone or gravel concrete (normalweight concrete), the average modulus of rupture used for deflection calculations is

$$f_r = 0.7\lambda\sqrt{f'_c} \quad [\text{SI}] \quad 50.45(a)$$

$$f_r = 7.5\lambda\sqrt{f'_c} \quad [\text{U.S.}] \quad 50.45(b)$$

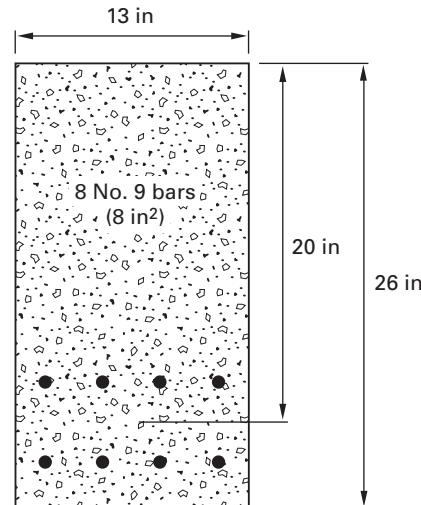

The *lightweight aggregate factor*,  $\lambda$ , is 0.75 for all-lightweight concrete, 0.85 for sand-lightweight concrete, and 1.0 for normalweight concrete. (See Table 48.2.)

Since cracking is not reversible,  $M_a$  should be taken as the largest bending moment due to service loads. In particular, if an immediate deflection due to the live load is desired, the deflection should be based on the live load, but  $I_e$  should be computed from Eq. 50.43 using the value of  $M_a$  corresponding to dead plus live load.

When a beam is continuous, the reinforcement will vary along the beam length. Then, the cracked inertia,  $I_{cr}$ , will also vary along the length. ACI 318 permits using the value of  $I_e$  that corresponds to the positive moment region (with  $M_a$  taken also as the maximum positive service moment), or  $I_e$  can be taken as the average of the values for the regions of maximum negative and maximum positive moment [ACI 318 Sec. 9.5.2.4].

### Example 50.7

The service moment on the beam shown is 100 ft-kips. The normalweight concrete compressive strength is 4000 lbf/in<sup>2</sup>, and the modular ratio is 8. Determine the (a) gross, (b) cracked, and (c) effective moments of inertia.

### Solution

(a) The gross moment of inertia is

$$I_g = \frac{bh^3}{12} = \frac{(13 \text{ in})(26 \text{ in})^3}{12} = 19,041 \text{ in}^4$$

(b) Since the section is rectangular, use Eq. 50.41 and Eq. 50.42. From Eq. 50.31, the reinforcement ratio is

$$\rho = \frac{A_s}{bd} = \frac{8 \text{ in}^2}{(13 \text{ in})(20 \text{ in})} = 0.0308$$

$$\begin{aligned} c_s &= n\rho d \left( \sqrt{1 + \frac{2}{n\rho}} - 1 \right) \\ &= (8)(0.0308)(20 \text{ in}) \left( \sqrt{1 + \frac{2}{(8)(0.0308)}} - 1 \right) \\ &= 9.95 \text{ in} \\ I_{cr} &= \frac{bc_s^3}{3} + nA_s(d - c_s)^2 \\ &= \frac{(13 \text{ in})(9.95 \text{ in})^3}{3} + (8)(8 \text{ in}^2)(20 \text{ in} - 9.95 \text{ in})^2 \\ &= 10,733 \text{ in}^4 \end{aligned}$$

(c) The modulus of rupture is given by Eq. 50.45.

$$\begin{aligned} f_r &= 7.5\lambda\sqrt{f'_c} = (7.5)(1.0)\sqrt{4000 \frac{\text{lbf}}{\text{in}^2}} \\ &= 474 \text{ lbf/in}^2 \quad (0.474 \text{ kips/in}^2) \end{aligned}$$

The cracking moment is given by Eq. 50.44.

$$M_{cr} = \frac{f_r I_g}{y_t} = \frac{\left(0.474 \frac{\text{kips}}{\text{in}^2}\right)(19,041 \text{ in}^4)}{(13 \text{ in})(12 \frac{\text{in}}{\text{ft}})} = 57.86 \text{ ft-kips}$$

$$\left(\frac{M_{cr}}{M_a}\right)^3 = \left(\frac{57.86 \text{ ft-kips}}{100 \text{ ft-kips}}\right)^3 = 0.194$$

The effective moment of inertia is given by Eq. 50.43.

$$I_e = \left(\frac{M_{cr}}{M_a}\right)^3 I_g + \left(1 - \left(\frac{M_{cr}}{M_a}\right)^3\right) I_{cr}$$

$$= (0.194)(19,041 \text{ in}^4) + (1 - 0.194)(10,733 \text{ in}^4)$$

$$= 12,345 \text{ in}^4$$

## 16. LONG-TERM DEFLECTIONS

Long-term deflection is caused by creep and shrinkage of the concrete. The long-term deformation develops rapidly at first and then slows down, being largely complete after approximately five years. As specified by ACI 318 Sec. 9.5.2.5, the *long-term deformation*,  $\Delta_a$ , is obtained by multiplying the immediate deflection produced by the portion of the load that is sustained by an amplification factor,  $\lambda$ . In computing the sustained part of the immediate deflection, judgment is required to decide what fraction of the prescribed service live load can be assumed to be acting continuously. The long-term deflection is taken as

$$\Delta_a = \lambda \Delta_i \quad 50.46$$

$$\lambda = \frac{i}{1 + 50\rho'} \quad 50.47$$

$\rho'$  is the compression steel ratio ( $A'_s / bd$ ) at midspan for simply supported and continuous beams, and at supports for cantilevers.  $i$  is an empirical factor that accounts for the rate of the additional deflection.  $i$  is 1.0 at three months, 1.2 at six months, 1.4 at one year, and 2 at five years or more.

The total deflection is the sum of the instantaneous plus the long-term deflections.

## 17. MINIMUM BEAM DEPTHS TO AVOID EXPLICIT DEFLECTION CALCULATIONS

For beams not supporting or attached to nonstructural elements sensitive to deflections, explicit deflection calculations are not required if the beam has been designed with a certain minimum thickness. The minimum thickness,  $h$ , is given in Table 50.4.

**Table 50.4** Minimum Beam Thickness Unless Deflections Are Computed ( $f_y = 60,000 \text{ lbf/in}^2$ )\*

construction	minimum $h$ (fraction of span length)
simply supported	$\frac{1}{16}$
one end continuous	$\frac{1}{18.5}$
both ends continuous	$\frac{1}{21}$
cantilever	$\frac{1}{8}$

\*Corrections are required for other steel strengths. See Eq. 50.48 and Eq. 50.49.

Source: ACI 318 Table 9.5(a)

The values in Table 50.4 apply to normalweight concrete reinforced with  $f_y = 60,000 \text{ lbf/in}^2$  (400 MPa) steel. The table values are multiplied by the adjustment factor in Eq. 50.48 for other steel strengths.

$$0.4 + \frac{f_y}{700} \quad [\text{SI}] \quad 50.48(a)$$

$$0.4 + \frac{f_y}{100,000} \quad [\text{U.S.}] \quad 50.48(b)$$

For structural lightweight concrete with a unit weight,  $w$ , between  $90 \text{ lbf/ft}^3$  and  $115 \text{ lbf/ft}^3$  ( $14.13 \text{ kN/m}^3$  and  $18.07 \text{ kN/m}^3$ ), multiply the table values by

$$1.65 - 0.0318w \geq 1.09 \quad [\text{SI}] \quad 50.49(a)$$

$$1.65 - 0.005w \geq 1.09 \quad [\text{U.S.}] \quad 50.49(b)$$

## 18. MAXIMUM ALLOWABLE DEFLECTIONS

When the minimum thicknesses of Table 50.4 are not used, or if the beam supports nonstructural elements that are sensitive to deformations, the deflections must be explicitly checked by computation. The limits prescribed by ACI 318 for the computed deflections are presented in Table 50.5.

The deflection limits in the first row (flat roofs) of Table 50.5 are not intended to safeguard against ponding. Ponding should be checked by deflection calculations, taking into consideration the added deflections due to accumulated ponded water and considering long-term effects of all sustained loads, camber, construction tolerances, and reliability of provisions for drainage.

## 19. DESIGN OF T-BEAMS

Although a beam can be specifically cast with a T-shaped cross section, that is rarely done. T-beam behavior

**Table 50.5** Maximum Allowable Computed Deflections

type of member	deflection to be considered	deflection limitation
flat roofs not supporting or attached to nonstructural elements likely to be damaged by large deflections	immediate deflection due to live load	$\frac{1}{180}$
floors not supporting or attached to nonstructural elements likely to be damaged by large deflections	immediate deflection due to live load	$\frac{1}{360}$
roof or floor construction supporting or attached to nonstructural elements likely to be damaged by large deflections	that part of the total deflection that occurs after attachment of the nonstructural elements	$\frac{1}{480}$
roof or floor construction supporting or attached to nonstructural elements not likely to be damaged by large deflections	that part of the total deflection that occurs after attachment of the nonstructural elements	$\frac{1}{240}$

Source: ACI 318 Table 9.5(b)

usually occurs in monolithic beam-slab (one-way) systems. The general beam design procedure presented earlier in this chapter applies to the design of T-beams. However, determining the width of the flange (i.e., the slab) that is effective in resisting compressive loads is code-sensitive. ACI 318 also specifies requirements pertaining to the distribution of the reinforcement.

The compressive stresses in the flange of a T-beam decrease with distance from the centerline of the web. ACI 318 specifies using an *effective width*, which is a width over which the compressive stress is assumed uniform.

It is assumed that a stress of  $0.85f'_c$  acting over the effective width,  $b_e$ , provides approximately the same compressive force as that realized from the actual variable stress distribution over the total flange width. The effective width of the flange for T- and L-shaped beams is illustrated in Fig. 50.9. The effective width in each case is the smallest value from the options listed [ACI 318 Sec. 8.12].

*case 1: Beams with flanges on each side of the web* [ACI 318 Sec. 8.12.2]

Effective width (including the compression area of the stem) for a T-beam may not exceed one-fourth of the beam's span length.

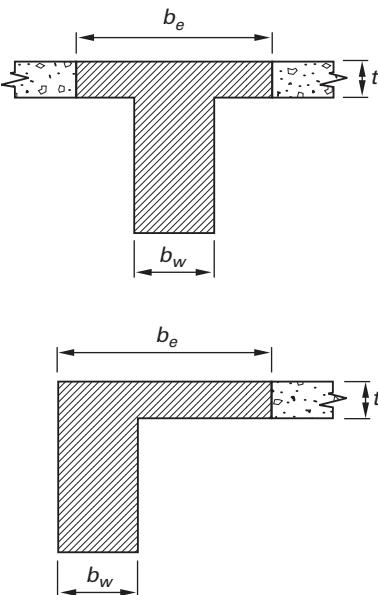

*case 2: Beams with an L-shaped flange* [ACI 318 Sec. 8.12.3]

Effective overhanging flange width (excluding the compression area of the stem) is the minimum of

one-twelfth of the beam's span length, or six times the slab's thickness, or one-half of the clear distance between beam webs

*case 3: Isolated T-beams* [ACI 318 Sec. 8.12.4]

If a T-beam is not part of a floor system but the T shape is used to provide additional compression area, the flange thickness must not be less than

**Figure 50.9** Effective Flange Width (one-way reinforced slab systems) (ACI 318 Sec. 8.12)

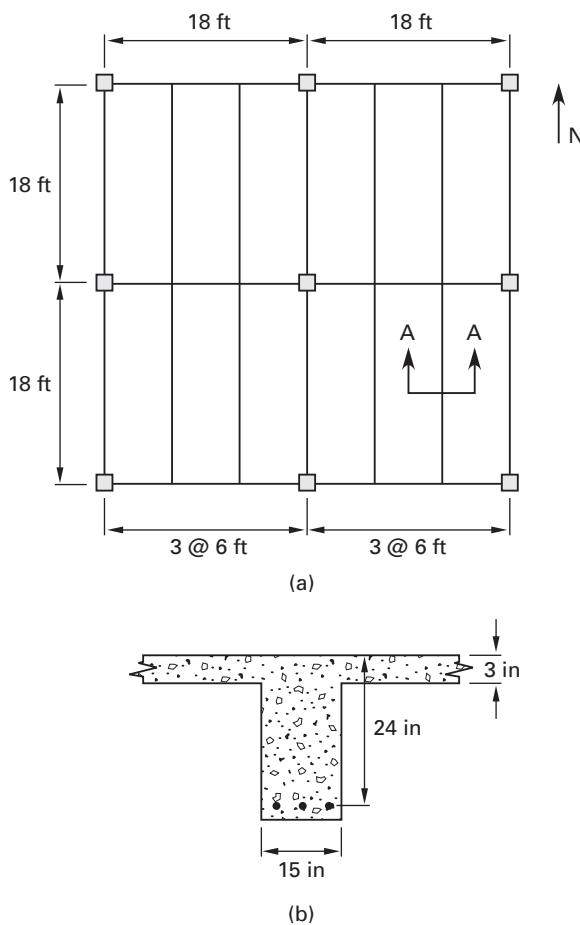

one-half of the width of the web. The effective width of the flange must not be more than four times the width of the web.

When a T-beam is subjected to a negative moment, the tension steel must be placed in the flange. ACI 318 Sec. 10.6.6 requires that this tension steel not all be placed inside the region of the web but that it be spread out into the flange over a distance whose width is the smaller of (a) the effective flange width or (b) one-tenth of the span. This provision ensures that cracking on the top surface will be distributed.

If the T-beam is an isolated member, loading will produce bending of the flange in the direction perpendicular to the beam span. Adequate transverse steel must be provided to prevent a bending failure of the flange.

**Example 50.8**

A monolithic slab-beam floor system is supported on a column grid of 18 ft on centers as shown. The dimensions of the cross section for the beams running in the north-south direction have been determined. The positive moments in the north-south beams are  $M_d = 200$  ft-kips, and  $M_l = 340$  ft-kips.  $f'_c = 3000$  lbf/in<sup>2</sup> and  $f_y = 50,000$  lbf/in<sup>2</sup>. Design the positive steel reinforcement.

**Solution**

The effective width of the flange is determined as the smallest of

$$\frac{L}{4} = \frac{(18 \text{ ft})(12 \frac{\text{in}}{\text{ft}})}{4} = 54 \text{ in} \quad [\text{controls}]$$

$$b_w + 16t = 15 \text{ in} + (16)(3 \text{ in}) = 63 \text{ in}$$

$$\text{beam spacing} = (6 \text{ ft})(12 \frac{\text{in}}{\text{ft}}) = 72 \text{ in}$$

The effective flange area is

$$(3 \text{ in})(54 \text{ in}) = 162 \text{ in}^2$$

The factored moment is

$$\begin{aligned} M_u &= 1.2M_d + 1.6M_l \\ &= (1.2)(200 \text{ ft-kips}) + (1.6)(340 \text{ ft-kips}) \\ &= 784 \text{ ft-kips} \end{aligned}$$

Estimate  $\lambda$  as  $(0.1)(24 \text{ in}) = 2.4 \text{ in}$ . The steel area required is given by Eq. 50.28. Assuming a tension-controlled section,

$$\begin{aligned} A_s &= \frac{M_u}{\phi f_y(d - \lambda)} = \frac{(784 \text{ ft-kips})(12 \frac{\text{in}}{\text{ft}})}{(0.9)(50 \frac{\text{kips}}{\text{in}^2})(24 \text{ in} - 2.4 \text{ in})} \\ &= 9.68 \text{ in}^2 \end{aligned}$$

The area of concrete in compression is given by Eq. 50.26.

$$\begin{aligned} A_c &= \frac{f_y A_s}{0.85 f'_c} = \frac{\left(50 \frac{\text{kips}}{\text{in}^2}\right)(9.68 \text{ in}^2)}{(0.85)(3 \frac{\text{kips}}{\text{in}^2})} \\ &= 189.80 \text{ in}^2 \end{aligned}$$

This area includes the flange plus a depth into the web of

$$\frac{189.80 \text{ in}^2 - 162 \text{ in}^2}{15 \text{ in}} = 1.85 \text{ in}$$

The centroid of the compressed area measured from the top is determined as follows.

$$\begin{aligned} (162 \text{ in}^2)(1.5 \text{ in}) + (189.80 \text{ in}^2 - 162 \text{ in}^2) \\ \times \left(3 \text{ in} + \frac{1.85 \text{ in}}{2}\right) &= (189.80 \text{ in}^2)\lambda \\ \lambda &= 1.86 \text{ in} \end{aligned}$$

The nominal moment capacity is given by Eq. 50.27.

$$\begin{aligned} M_n &= A_s f_y (d - \lambda) \\ &= \frac{(9.68 \text{ in}^2)(50 \frac{\text{kips}}{\text{in}^2})(24 \text{ in} - 1.86 \text{ in})}{12 \frac{\text{in}}{\text{ft}}} \\ &= 893 \text{ ft-kips} \end{aligned}$$

Assuming the section is tension controlled, the design moment capacity is

$$\begin{aligned} \phi M_n &= (0.9)(893 \text{ ft-kips}) \\ &= 804 \text{ ft-kips} \end{aligned}$$

Since the design moment capacity (804 ft-kips) is slightly larger than the factored moment (784 ft-kips), the steel area required is nominally smaller than the

estimated value of 9.68 in<sup>2</sup>. An incrementally better estimate of the steel area is

$$A_s = \left( \frac{784 \text{ ft-kips}}{804 \text{ ft-kips}} \right) (9.68 \text{ in}^2)$$

$$= 9.44 \text{ in}^2$$

Check that the section is tension controlled.

The stress block depth is

$$a = 3 \text{ in} + 1.85 \text{ in}$$

$$= 4.85 \text{ in}$$

The corresponding neutral axis depth is

$$c = \frac{a}{\beta_1} = \frac{4.85 \text{ in}}{0.85}$$

$$= 5.71 \text{ in}$$

The net tensile strain is

$$\epsilon_t = (0.003) \left( \frac{24 \text{ in} - 5.71 \text{ in}}{5.71 \text{ in}} \right)$$

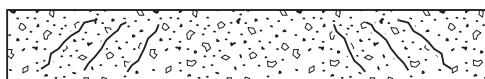

$$= 0.0096 > 0.005$$

Therefore, the section is tension controlled. The tension reinforcement ratio by definition is below the maximum allowed. Since the tension reinforcement ratio is relatively high, the minimum steel requirement is not checked explicitly. The design is adequate. Since the required steel is high, two layers may be required.

## 20. SHEAR STRESS

In addition to producing bending moments, beam loads also produce shear forces. Shear forces induce *diagonal tension stresses* that lead to diagonal cracking. The typical pattern of cracks induced by shear forces is depicted in Fig. 50.10. If a diagonal crack forms and the beam does not contain *shear reinforcement*, failure will occur abruptly. In order to have ductile beams (where the controlling mechanism is the ductile yielding of the tension steel), shear reinforcement is designed conservatively.

**Figure 50.10** Typical Pattern of Shear Cracks

The maximum shear at a given location does not necessarily result from placing the live load over the complete beam. For a simple beam, for example, the shear at the centerline is zero if the live load is placed over the full span. If only half the span is loaded, the shear from live load at the center will equal  $w_l L/8$ .

A *shear envelope* is a plot of the maximum shear that can occur at any given section, allowing for a variable position of the live load. In practice, the construction of the exact shear envelope is usually unnecessary since an approximate envelope obtained by connecting the maximum possible shear at the supports with the maximum possible value at the center of the spans is sufficiently accurate. Of course, the dead load shear must be added to the live load shear envelope.

In the design of beams, it is customary to call out the span length as the distance from the centerline of supports. Although the shear computed is largest immediately adjacent to a reaction, shears corresponding to locations that are within the support width are not physically meaningful. Furthermore, for the typical case where the beam is supported from underneath, the compression induced by the reaction increases the *shear strength* in the vicinity of the support.

ACI 318 Sec. 11.1.3 takes this enhanced strength into account by specifying that the region of the beam from a distance  $d$  to the face of the support can be designed for the same shear force that exists at a distance  $d$  from the support face. For this provision to apply, the reaction must induce compression in the member (i.e., the beam must not be hanging from a support, as in Fig. 50.11(b)), loads are applied at or near the top of the members, and there must be no concentrated loads acting within the distance  $d$ , as in Fig. 50.11(c). If concentrated loads exist within this distance, or if the reaction does not induce compression, it is necessary to provide for the actual shear forces occurring all the way to the face of the support.

## 21. SHEAR REINFORCEMENT

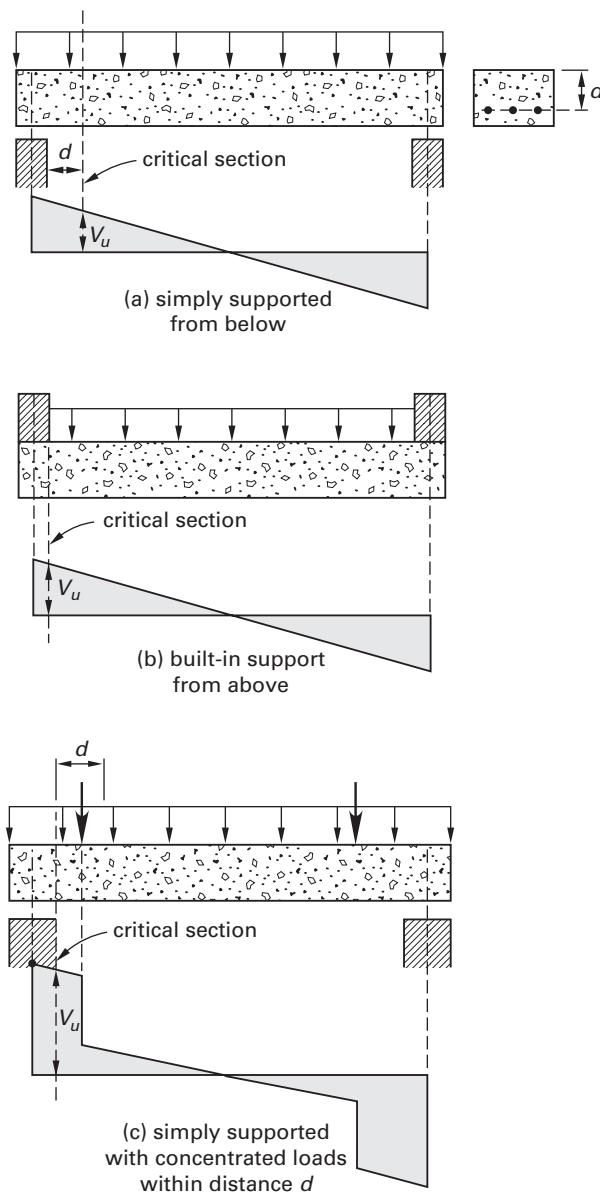

Shear reinforcement can take several forms. Vertical stirrups are used most often, but inclined stirrups are occasionally seen, as is welded wire fabric. Longitudinal steel that is bent up at 30° or more and enters the compression zone also contributes to shear reinforcement.

In seismically active regions, in order to increase the ductility of beams that are part of lateral load-resisting frames, the concrete in the compression zone must be adequately confined. This confinement is typically attained by providing closely spaced transverse reinforcement in the form of closed ties. These closed ties, which resist shear forces in the same way that stirrups do, are known as *hoops*.

The basic equation governing design for shear forces is Eq. 50.50. For shear,  $\phi = 0.75$ .

$$\phi V_n = V_u \quad 50.50$$

The beam's shear capacity,  $V_n$ , is determined semi-empirically as the sum of the concrete shear capacity,

**Figure 50.11 Locations of Critical Section**

$V_c$ , and the shear capacity that derives from the presence of shear reinforcement,  $V_s$ .

$$V_n = V_c + V_s \quad 50.51$$

(The term *nominal shear strength* is ambiguous in concrete design. The concrete shear strength,  $V_c$ , is often referred to as the *nominal concrete shear strength*. The sum of  $V_c + V_s$  is referred to as the *nominal beam shear strength*. Common usage attributes the term "nominal" to both.)

## 22. SHEAR STRENGTH PROVIDED BY CONCRETE

The shear capacity provided by the concrete,  $V_c$ , results from the strength in shear of the uncracked compression zone, a contribution from aggregate interlock across the cracks, and dowel action from the tension steel that crosses the diagonal crack. ACI 318 Sec. 11.2 provides two equations to calculate  $V_c$ . One equation is a refined equation that accounts for the effect of the moment and the amount of longitudinal steel on the shear strength.

$$V_c = \left( \frac{\lambda \sqrt{f'_c}}{7} + \frac{120}{7} \rho_w \left( \frac{V_u d}{M_u} \right) \right) b_w d \leq 0.29 \lambda \sqrt{f'_c} b_w d \quad [\text{SI}] \quad 50.52(a)$$

$$V_c = \left( 1.9 \lambda \sqrt{f'_c} + 2500 \rho_w \left( \frac{V_u d}{M_u} \right) \right) b_w d \leq 3.5 \lambda \sqrt{f'_c} b_w d \quad [\text{U.S.}] \quad 50.52(b)$$

The other equation is a simple equation computed solely from the strength of the concrete and the size of the cross section. In practice, the simpler equation is used. If the shear capacity is inadequate, the refined equation can be used.

$$V_c = \frac{1}{6} \lambda \sqrt{f'_c} b_w d \quad [\text{SI}] \quad 50.53(a)$$

$$V_c = 2 \lambda \sqrt{f'_c} b_w d \quad [\text{U.S.}] \quad 50.53(b)$$

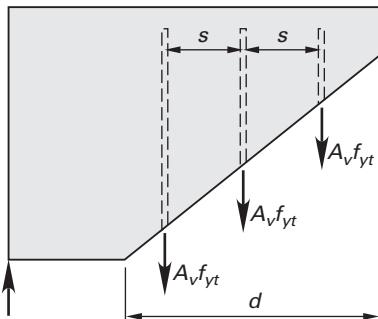

ACI 318 Sec. 8.13.8 permits an increase of 10% in the shear force that can be assigned to the concrete in the ribs of floor joist construction. (The term *joist construction* refers to closely spaced T-beams with tapered webs.) To qualify for the 10% increase in  $V_c$ , the ribs must be at least 4 in (10 cm) wide, have a depth of no more than 3.5 times the minimum width of the rib, and have a clear spacing not exceeding 30 in (76.2 cm).

For *circular members*, the area used to calculate  $V_c$  can be considered a rectangle with width equal to the circular diameter and effective depth,  $d$ , of 0.8 times the circular diameter [ACI 318 Sec. 11.2.3].

## 23. SHEAR STRENGTH PROVIDED BY SHEAR REINFORCEMENT

The shear capacity provided by the steel reinforcement,  $V_s$ , is derived by considering a free-body diagram of the beam with an idealized diagonal crack at 45° and computing the vertical component of the force developed by the reinforcement intersecting the crack. It is assumed that all the steel is yielding when the strength is attained. For the typical case of vertical stirrups, as shown in Fig. 50.12, the shear capacity is

$$V_s = \frac{A_v f_y d}{s} \quad 50.54$$

**Figure 50.12** Contribution of Vertical Stirrups to Shear Capacity

The area  $A_v$  includes all of the legs in a single stirrup. For example, for the typical U-shaped stirrup,  $A_v$  is twice the area of the stirrup bar. For stirrups inclined at an angle  $\theta$  from the horizontal, ACI 318 Sec. 11.4.7.4 gives the shear strength contribution as

$$V_s = \frac{A_v f_{yt} (\sin \theta + \cos \theta) d}{s} \quad 50.55$$

If the shear reinforcement is provided by a single longitudinal bar or a single group of parallel bars all bent up at the same distance from the support, ACI 318 Sec. 11.4.7.5 gives the shear strength contribution as Eq. 50.56(b), where  $\theta$  is the angle between the member's bent-up reinforcement and its longitudinal axis.

$$V_s = A_v f_y \sin \theta \leq 0.25 \sqrt{f'_c} b_w d \quad [\text{SI}] \quad 50.56(a)$$

$$V_s = A_v f_y \sin \theta \leq 3 \sqrt{f'_c} b_w d \quad [\text{U.S.}] \quad 50.56(b)$$

## 24. SHEAR REINFORCEMENT LIMITATIONS

In order to control the diagonal compressive stresses in the concrete resulting from shear, ACI 318 limits the maximum shear that can be assigned to the shear reinforcement [ACI 318 Sec. 11.4.7.9].

$$V_s \leq \frac{2}{3} \sqrt{f'_c} b_w d \quad [\text{steel only}] \quad [\text{SI}] \quad 50.57(a)$$

$$V_s \leq 8 \sqrt{f'_c} b_w d \quad [\text{steel only}] \quad [\text{U.S.}] \quad 50.57(b)$$

The maximum total shear force permitted depends on whether Eq. 50.52 or Eq. 50.53 is used to compute the concrete contribution. For the common case where  $V_c$  is computed with the simple equation, the maximum shear force,  $V_u$ , resisted by both the concrete and steel is a combination of Eq. 50.53 and Eq. 50.57.

$$V_{u,\max} = \left( \frac{2}{3} + \frac{\lambda}{6} \right) \phi \sqrt{f'_c} b_w d \quad [\text{concrete and steel}] \quad [\text{SI}] \quad 50.58(a)$$

$$V_{u,\max} = (8 + 2\lambda) \phi \sqrt{f'_c} b_w d \quad [\text{concrete and steel}] \quad [\text{U.S.}] \quad 50.58(b)$$

## 25. STIRRUP SPACING

Whenever stirrups are required, ACI 318 Sec. 11.4.4 and Sec. 11.4.5 specify that the spacing,  $s$ , must not be larger than calculated in Eq. 50.59 and Eq. 50.60. This maximum spacing ensures that at least one stirrup crosses each potential diagonal crack. The second limit in Eq. 50.60, which applies when the shear is high, ensures that at least two stirrups cross each potential shear crack.

$$s_{\max} = \min\{60 \text{ cm or } d/2\} \quad [V_s \leq \frac{2}{3} \sqrt{f'_c} b_w d] \quad [\text{SI}] \quad 50.59(a)$$

$$s_{\max} = \min\{24 \text{ in or } d/2\} \quad [V_s \leq 4 \sqrt{f'_c} b_w d] \quad [\text{U.S.}] \quad 50.59(b)$$

$$s_{\max} = \min\{30 \text{ cm or } d/4\} \quad [V_s > \frac{2}{3} \sqrt{f'_c} b_w d] \quad [\text{SI}] \quad 50.60(a)$$

$$s_{\max} = \min\{12 \text{ in or } d/4\} \quad [V_s > 4 \sqrt{f'_c} b_w d] \quad [\text{U.S.}] \quad 50.60(b)$$

Though not specified by the code, the minimum practical spacing is about 3 in (76 mm). If stirrups need to be closer than 3 in (76 mm), a larger bar size should be used. It is common to place the first stirrup at a distance of  $s/2$  from the face of the support, but not closer than 2 in (51 mm). However, the first stirrup can be placed a full space from the face.

When a diagonal crack forms, the stress transfers from the concrete to the stirrups. To ensure that the stirrups have sufficient strength (i.e., a minimum strength of at least  $0.75 \sqrt{f'_c}$ , but no less than 50 lbf/in<sup>2</sup> (340 kPa)), ACI 318 Sec. 11.4.6.3 requires all stirrups to have a minimum area of

$$A_{v,\min} = \frac{1}{8} \sqrt{f'_c} \left( \frac{b_w s}{f_{yt}} \right) \geq \frac{b_w s}{3 f_{yt}} \quad [\text{SI}] \quad 50.61(a)$$

$$A_{v,\min} = 0.75 \sqrt{f'_c} \left( \frac{b_w s}{f_{yt}} \right) \geq \frac{50 b_w s}{f_{yt}} \quad [\text{U.S.}] \quad 50.61(b)$$

## 26. NO-STIRRUP CONDITIONS

If the shear force is low enough, the concrete in the compression zone will be able to resist it without the need for shear reinforcement. Logically, shear reinforcement is not needed if  $\phi V_c > V_u$ . However, per ACI 318 Sec. 11.4.6.1, this criterion can be used on a beam (without slab) only if the depth,  $h$ , of the beam is less than or equal to 10 in (254 mm). For a beam integral with slab, the criterion can be applied only if the depth,  $h$ , of the beam (a) is not larger than 2.5 times the flange thickness, (b) is not greater than one-half the width of the

web, and (c) is not greater than 24 in (610 mm). In all other cases, ACI 318 is more conservative by a factor of two. Shear reinforcement can be eliminated only in regions of the beam where

$$\frac{\phi V_c}{2} \geq V_u \quad 50.62$$

## 27. SHEAR REINFORCEMENT DESIGN PROCEDURE

The following procedure will design shear reinforcement for an entire beam. Some steps can be omitted when designing for a limited portion of the beam.

*step 1:* Determine the shear envelope for the factored loads. If Eq. 50.52 is to be used to compute  $V_c$ , the moment diagram is also needed. The shear at any section is  $V_u$ .

*step 2:* Calculate  $V_c$ , generally using the simple equation.

*step 3:* Determine the portions of the beam where the factored shear is less than or equal to  $\phi V_c/2$ . A graphical representation of the shear envelope drawn to scale can be helpful in locating these regions. Stirrups are not required in these regions.

*step 4:* Use Eq. 50.54 to compute the capacity,  $V_{s,\min}$ , provided by minimum shear reinforcement. Minimum reinforcement is obtained by setting the spacing of the stirrups to the largest amount allowed by Eq. 50.59 and  $A_v$  to the smallest bar choice that will satisfy Eq. 50.61.

*step 5:* Add  $V_c$  from step 2 to  $V_{s,\min}$  from step 4 to obtain the shear capacity of the beam with minimum shear reinforcement. Use this minimum reinforcement in regions where  $\phi V_c/2 < V_u < \phi(V_c + V_{s,\min})$ .

*step 6:* Calculate the spacing of stirrups for the regions of the beam where  $V_u > \phi(V_c + V_{s,\min})$ . At any location, the shear reinforcement needs to supply a strength given by

$$V_{s,\text{req}} = \frac{V_u}{\phi} - V_c \quad 50.63$$

The maximum value permitted for  $V_{s,\text{req}}$  is given by Eq. 50.57. If the value computed in Eq. 50.63 exceeds this limit, adequate shear strength cannot be obtained with shear reinforcement. Either the section size or the concrete strength (or both) must be increased.

*step 7:* Calculate the spacing derived from Eq. 50.64. The spacing from Eq. 50.64 must not exceed the limits presented in Eq. 50.59 and Eq. 50.60.

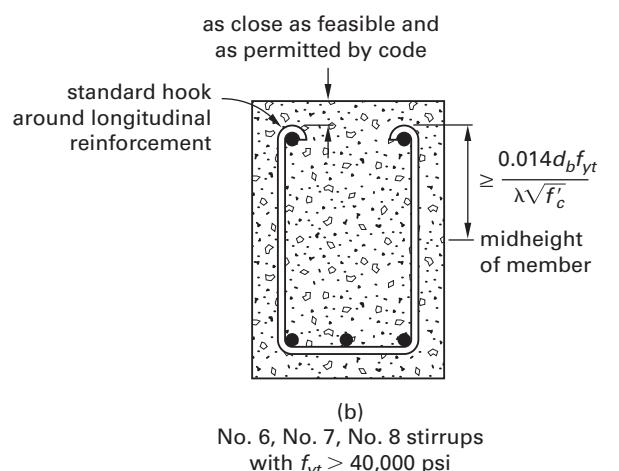

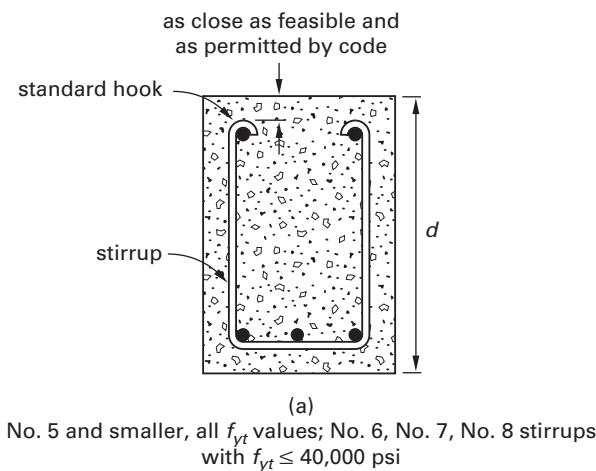

$$s = \frac{A_v f_{yt} d}{V_{s,\text{req}}} \quad 50.64$$

## 28. ANCHORAGE OF SHEAR REINFORCEMENT

ACI 318 requires that the shear reinforcement extend into the compression and tension regions as far as cover requirements and proximity to other bars permit. In order to develop its full capacity, shear reinforcement must be anchored at both ends by one of two means.

In a *U-shaped stirrup*, one end of the steel is bent around the longitudinal steel, anchoring that end. For no. 5 or smaller stirrups and for stirrups constructed of no. 6, no. 7, or no. 8 bars with  $f_{yt} \leq 40,000 \text{ lbf/in}^2$  (276 MPa), the other end may be considered to be developed if it is wrapped with a *standard hook* around longitudinal reinforcement [ACI 318 Sec. 12.13.2.1]. (See Fig. 50.13.)

**Figure 50.13** Anchorage Requirements for Shear Reinforcement (ACI 318 Sec. 12.13.2)

For no. 6, no. 7, or no. 8 stirrups with  $f_{yt} > 40,000 \text{ psi}$  (276 MPa), the other end may be considered to be developed if it has a standard hook around longitudinal reinforcement plus an *embedment distance* between

midheight of the member and the outside of the hook given by Eq. 50.65 [ACI 318 Sec. 12.13.2.2].

$$\text{embedding length} \geq \frac{0.17 d_b f_{yt}}{\lambda \sqrt{f'_c}} \quad [\text{SI}] \quad 50.65(a)$$

$$\text{embedding length} \geq \frac{0.014 d_b f_{yt}}{\lambda \sqrt{f'_c}} \quad [\text{U.S.}] \quad 50.65(b)$$

## 29. DOUBLY REINFORCED CONCRETE BEAMS

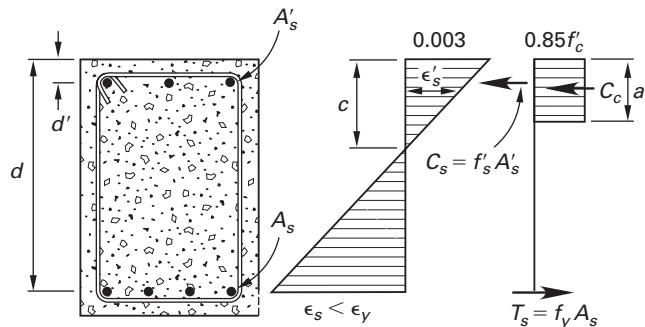

In singly reinforced beams, steel is used to withstand only tensile forces. There are instances, however, where it is appropriate to use steel reinforcement to resist compressive forces. The most common situation where a doubly reinforced beam is needed is when the moment capacity of the singly reinforced section, with the maximum area of steel permitted, is not sufficient to carry the applied moment. In such cases, steel can be provided in excess of the maximum allowed for a singly reinforced section if the added tensile force is balanced by steel in compression. Another less common reason for using compression steel is to control long-term deformations. Indeed, the factor  $\lambda$ , which determines the increase in deflection due to creep and shrinkage, decreases as the percentage of compression steel in the section increases. (See Eq. 50.47.) Sections that have steel in the tension and the compression regions are referred to as *doubly reinforced beams*.

There are also situations where cross sections are doubly reinforced as a result of detailing, not as a result of needing compression steel for strength. For example, in the negative moment region of a typical monolithic beam-slab system the tension steel is at the top of the section, but compression steel is always present regardless of whether it is needed. This is because ACI 318 requires that a certain fraction of the steel used for the positive moment be extended into the support. (ACI 318 Sec. 12.11.1 requires that at least one-third of the reinforcement from a section of maximum moment be extended at least 6 in (15 cm) into a simple support. If the member is continuous, at least one-fourth of the reinforcement from the section of maximum positive moment must extend at least 6 in (15 cm) into the support.) ACI 318 Sec. 7.13 contains requirements for structural integrity that often mandate positive reinforcement at the supports. In moderate to high seismic applications, top as well as bottom reinforcement is mandated at every section.

## 30. STRENGTH ANALYSIS OF DOUBLY REINFORCED SECTIONS

Figure 50.14 illustrates a *doubly reinforced concrete section* and the profile of strains and stresses when the flexural capacity is attained. The following iterative

**Figure 50.14** Parameters for Doubly Reinforced Beam

procedure calculates the nominal moment capacity of a doubly reinforced beam section with a known shape and reinforcement.

*step 1:* Compute the tension force in the steel as  $T_s = f_y A_s$ .

*step 2:* Estimate the stress in the compression steel. (Since the analysis process is iterative,  $f'_s = 0$  is a valid first estimate.)

*step 3:* Calculate the area of concrete,  $A_c$ , which at a stress of  $0.85 f'_c$  carries a compressive force equal to  $T_s - A'_s f'_s$ .

$$A_c = \frac{f_y A_s - f'_s A'_s}{0.85 f'_c} \quad 50.66$$

The depth of the equivalent compressed area is  $a$ . The actual neutral axis is at  $c = a/\beta_1$ , where  $\beta_1$  is given by Eq. 50.17.

*step 4:* Compute the strain in the compression steel as

$$\epsilon'_s = \left( \frac{0.003}{c} \right) (c - d') \quad 50.67$$

*step 5:* Compute the stress in the compression steel as

$$f'_s = E_s \epsilon'_s \leq f_y \quad 50.68$$

*step 6:* Compare the stress assumed in step 2 with the value computed in step 5. If they differ significantly (say, by more than 10%), replace the assumed value with the result from Eq. 50.68 and repeat steps 3 through 5. If they are reasonably close (say, within 10%), go to step 7.

*step 7:* Locate the centroid of the area  $A_c$ .

*step 8:* The nominal moment capacity is the sum of the concrete-steel couple and the steel-steel couple. (Equation 50.69 is the general form of Eq. 50.27 for singly reinforced sections with  $f'_s = 0$  and  $A'_s = 0$ .)

$$M_n = (A_s f_y - A'_s f'_s)(d - \lambda) + A'_s f'_s(d - d') \quad 50.69$$

### 31. DESIGN OF DOUBLY REINFORCED SECTIONS

The design of a doubly reinforced beam begins by determining the difference between the applied moment and the maximum that can be carried with tension steel. This moment deficit must be provided by a couple formed by a force from additional tension steel ( $A_{s,\text{add}}f_y$ ) balanced with a force from compression steel ( $A'_s f'_s$ ). It should be noted that, at ultimate, while the steel added in tension will always yield, the compression steel may or may not yield.

The following procedure can be used to design a doubly reinforced beam.

*step 1:* Calculate the maximum area of tension steel permitted if the section is singly reinforced. (See Sec. 50.8.)

*step 2:* Calculate the moment capacity for the maximum steel area as singly reinforced. Designate this moment as  $M_{nc}$ . For a rectangular cross section,  $M_{nc}$  can be conveniently computed using Eq. 50.32.

*step 3:* The nominal moment deficit is

$$M'_n = \frac{M_u}{\phi} - M_{nc} \quad 50.70$$

*step 4:* Compute the area of tension steel,  $A_{s,\text{add}}$ , that must be added to the area computed in step 1.

$$A_{s,\text{add}} = \frac{M'_n}{f_y(d - d')} \quad 50.71$$

The total tension steel area is

$$A_s = A_{s,\text{max}} + A_{s,\text{add}} \quad 50.72$$

*step 5:* Compute the stress in the compression steel from Eq. 50.67 and Eq. 50.68. In these formulas, the depth of the neutral axis,  $c$ , is for the singly reinforced section with the area of steel in step 1.

*step 6:* Calculate the area of compression steel from Eq. 50.73.

$$A'_s = \left( \frac{f_y}{f'_s} \right) A_{s,\text{add}} \quad 50.73$$

*step 7:* Complete the design as for a singly reinforced section. (ACI 318 Sec. 7.11.1 requires that the compression steel be enclosed by ties or stirrups satisfying size and spacing limitations that are the same as for ties in columns.)

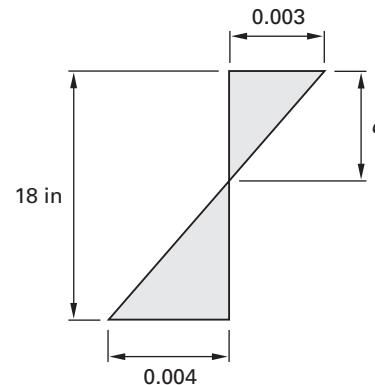

#### Example 50.9

The factored loads acting on a reinforced concrete beam produce a maximum design moment  $M_u = 275$  ft-kips.  $f'_c = 3000$  lb/in<sup>2</sup> and  $f_y = 60,000$  lb/in<sup>2</sup>. The width of

the beam is limited to 12 in, and the effective depth must not exceed 18 in. Design the reinforcing steel.

*Solution Using ACI 318 Chap. 10*

Determine if the moment that can be resisted with maximum steel as a singly reinforced section is larger than the applied moment,  $M_u$ .

Neutral axis depth,  $c$ , corresponding to minimum permissible  $\epsilon_t = 0.004$ , is

$$\begin{aligned} \frac{0.003}{0.003 + 0.004} &= \frac{c}{18 \text{ in}} \\ c &= \left(\frac{3}{7}\right)(18 \text{ in}) \\ &= 7.71 \text{ in} \end{aligned}$$

The corresponding steel area is  $A_{s,\text{max}}$ .

From a force equilibrium, as discussed in Sec. 50.10,

$$\begin{aligned} (12 \text{ in})(0.85)(7.71 \text{ in})(0.85) \left( 3000 \frac{\text{lbf}}{\text{in}^2} \right) \\ = A_{s,\text{max}} \left( 60,000 \frac{\text{lbf}}{\text{in}^2} \right) \\ A_{s,\text{max}} = 3.34 \text{ in}^2 \end{aligned}$$

The depth of the equivalent rectangular stress block is

$$\begin{aligned} a &= 0.85c = (0.85)(7.71 \text{ in}) \\ &= 6.55 \text{ in} \end{aligned}$$

The centroid of the compressed area is  $\lambda = (6.55 \text{ in})/2 = 3.28 \text{ in}$  from the top. The nominal moment capacity with maximum reinforcement is given by Eq. 50.27.

$$\begin{aligned} M_{nc} &= A_s f_y (d - \lambda) \\ &= \frac{(3.34 \text{ in}^2) \left( 60 \frac{\text{kips}}{\text{in}^2} \right) (18 \text{ in} - 3.28 \text{ in})}{12 \frac{\text{in}}{\text{ft}}} \\ &= 245.8 \text{ ft-kips} \end{aligned}$$

Since  $\phi M_{nc} < M_u$ , compression reinforcement is needed. Although  $\phi$  starts at 0.9, it is reduced to 0.817 at  $\epsilon = 0.004$ . The nominal moment deficit is

$$M'_n = \frac{M_u}{\phi} - M_{nc} = \frac{275 \text{ ft-kips}}{0.817} - 245.8 \text{ ft-kips} \\ = 90.8 \text{ ft-kips}$$

The area of tension steel,  $A_{s,\text{add}}$ , that must be added to the maximum permitted as a singly reinforced beam is

$$A_{s,\text{add}} = \frac{M'_n}{f_y(d - d')} = \frac{(90.8 \text{ ft-kips})(12 \frac{\text{in}}{\text{ft}})}{\left(60 \frac{\text{kips}}{\text{in}^2}\right)(18 \text{ in} - 2.5 \text{ in})} \\ = 1.17 \text{ in}^2$$

The total tension steel area is

$$A_s = 3.34 \text{ in}^2 + 1.17 \text{ in}^2 \\ = 4.51 \text{ in}^2$$

In order to find the required compression steel area, it is necessary to determine the strain at the level where the compression steel is to be placed when the beam is reinforced with  $A_{s,\text{max}}$ . In this problem, assume that the centroid of the compression steel is 2.5 in from the top of the section to account for 1.5 in of cover, the stirrup bar diameter, and half of a compression bar diameter.

Using Eq. 50.67 and Eq. 50.68,

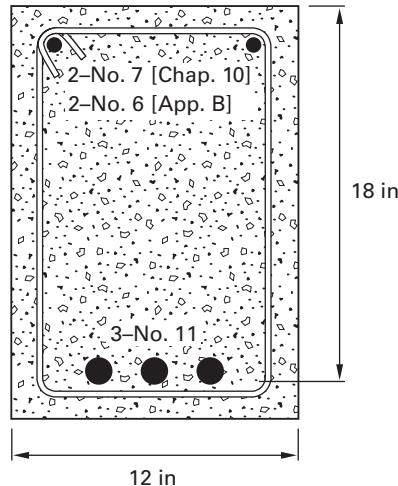

$$\epsilon'_s = 0.003 \left( \frac{c - d'}{c} \right) \\ = (0.003) \left( \frac{7.71 \text{ in} - 2.5 \text{ in}}{7.71 \text{ in}} \right) \\ = 0.00203$$

$$f'_s = E_s \epsilon'_s = \left( 29,000 \frac{\text{kips}}{\text{in}^2} \right) (0.00203) \\ = 58.9 \text{ kips/in}^2 \leq f_y$$

The compression steel area is

$$A'_s = \left( \frac{f_y}{f'_s} \right) A_{s,\text{add}} = \left( \frac{60 \frac{\text{kips}}{\text{in}^2}}{58.9 \frac{\text{kips}}{\text{in}^2}} \right) (1.17 \text{ in}^2) \\ = 1.19 \text{ in}^2$$

Put three no. 11 bars in the tension region, giving  $4.68 \text{ in}^2$  of reinforcement, which is marginally greater than the  $4.54 \text{ in}^2$  required. Put two no. 6 bars in the compression region, giving  $0.88 \text{ in}^2$  of area.

#### Solution Using ACI 318 App. B

Determine if the moment that can be resisted with maximum steel as a singly reinforced section is larger than the applied moment,  $M_u$ .

The balanced steel area is obtained from Eq. 50.18.

$$\beta_1 = 0.85$$

$$A_{sb} = \left( \frac{0.85\beta_1 f'_c}{f_y} \right) \left( \frac{87,000}{87,000 + f_y} \right) bd \\ = \left( \frac{(0.85)(0.85) \left( 3000 \frac{\text{lbf}}{\text{in}^2} \right)}{60,000 \frac{\text{lbf}}{\text{in}^2}} \right) \times \left( \frac{87,000}{87,000 + 60,000} \right) (12 \text{ in})(18 \text{ in}) \\ = 4.62 \text{ in}^2$$

The maximum amount of steel as a singly reinforced section is

$$A_s = (0.75)(4.62 \text{ in}^2) = 3.47 \text{ in}^2$$

The concrete area is given by Eq. 50.26.

$$A_c = \frac{f_y A_s}{0.85 f'_c} = \frac{\left( 60,000 \frac{\text{lbf}}{\text{in}^2} \right) (3.47 \text{ in}^2)}{(0.85) \left( 3000 \frac{\text{lbf}}{\text{in}^2} \right)} \\ = 81.6 \text{ in}^2$$

The depth of the equivalent rectangular stress block is

$$a = \frac{81.6 \text{ in}^2}{12 \text{ in}} = 6.8 \text{ in}$$

The centroid of the compressed area is  $\lambda = (6.8 \text{ in})/2 = 3.40 \text{ in}$  from the top. The nominal moment capacity with maximum reinforcement is given by Eq. 50.27.

$$M_{nc} = A_s f_y (d - \lambda)$$

$$= \frac{(3.47 \text{ in}^2) \left( 60 \frac{\text{kips}}{\text{in}^2} \right) (18 \text{ in} - 3.40 \text{ in})}{12 \frac{\text{in}}{\text{ft}}}$$

$$= 253.3 \text{ ft-kips}$$

Since  $\phi M_{nc} < M_u$ , compression reinforcement is needed. The nominal moment deficit is

$$M'_n = \frac{M_u}{\phi} - M_{nc} = \frac{275 \text{ ft-kips}}{0.9} - 253.3 \text{ ft-kips}$$

$$= 52.2 \text{ ft-kips}$$

The area of tension steel,  $A_{s,\text{add}}$ , that must be added to the maximum permitted as a singly reinforced beam is

$$A_{s,\text{add}} = \frac{M'_n}{f_y(d - d')}$$

$$= \frac{(52.2 \text{ ft-kips}) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{\left( 60 \frac{\text{kips}}{\text{in}^2} \right) (18 \text{ in} - 2.5 \text{ in})}$$

$$= 0.67 \text{ in}^2$$

The total tension steel area is

$$A_s = 3.47 \text{ in}^2 + 0.67 \text{ in}^2 = 4.14 \text{ in}^2$$

In order to find the required compression steel area, it is necessary to determine the strain at the level where the compression steel is to be placed when the beam is reinforced with  $A_{s,\text{max}}$ . In this problem, assume that the centroid of the compression steel is 2.5 in from the top of the section to account for 1.5 in of cover, the stirrup bar diameter, and half of a compression bar diameter.

The neutral axis depth is  $c = a/\beta_1 = 6.8 \text{ in}/0.85 = 8.0 \text{ in}$ . Using Eq. 50.67 and Eq. 50.68,

$$\epsilon'_s = 0.003 \left( \frac{c - d'}{c} \right) = (0.003) \left( \frac{8.0 \text{ in} - 2.5 \text{ in}}{8.0 \text{ in}} \right)$$

$$= 0.00206$$

$$f'_s = E_s \epsilon'_s = \left( 29,000 \frac{\text{kips}}{\text{in}^2} \right) (0.00206)$$

$$= 59.7 \text{ kips/in}^2 \leq f_y$$

The compression steel area is

$$A'_s = \left( \frac{f_y}{f'_s} \right) A_{s,\text{add}} = \left( \frac{60,000 \frac{\text{lbf}}{\text{in}^2}}{59,700 \frac{\text{lbf}}{\text{in}^2}} \right) (0.67 \text{ in}^2)$$

$$= 0.67 \text{ in}^2$$

Put three no. 11 bars in the tension region, giving  $4.68 \text{ in}^2$  of reinforcement. Put two no. 6 bars in the compression region, giving  $0.88 \text{ in}^2$  of area.

### 32. DEEP BEAMS

Deep beams are members loaded on one face and supported on the opposite face so that compression struts can develop between the loads and the supports. They have either (a) clear spans,  $l_n$ , equal to or less than four times the overall member depth,  $h$ ; or (b) regions loaded with concentrated loads within twice the member depth from the face of the support. The same definition applies for flexural design [ACI 318 Sec. 10.7.1] and for shear design [ACI 318 Sec. 11.7.1].

ACI 318 Sec. 11.8 states only that deep beams must be designed using nonlinear analysis as permitted in either ACI 318 Sec. 10.7.1 or App. A (strut and tie models).

Since the expected orientation of shear cracks in deep beams is more nearly vertical than in shallow beams, horizontal reinforcement as well as vertical reinforcement is required. ACI 318 Sec. 11.7.4.1 requires that the area of shear reinforcement perpendicular to the span,  $A_v$ , be not less than  $0.0025 b_w s$ , and that  $s$  may not exceed  $d/5$  and 12 in. ACI 318 Sec. 11.7.4.2 requires that the area of shear reinforcement parallel to the span,  $A_{vh}$ , may not be less than  $0.0025 b_w s_2$ , and  $s_2$  may not exceed  $d/5$  nor 12 in. ACI 318 Sec. 11.7.3 limits the shear strength,  $V_u$ , of deep beams to  $\phi 10 \sqrt{f'_c} b_w d$ .

### 1. INTRODUCTION

Slabs are structural elements whose lengths and widths are large in comparison to their thicknesses. Shear is generally carried by the concrete without the aid of shear reinforcement (which is difficult to place and anchor in shallow slabs). Longitudinal reinforcement is used to resist bending moments. Slab thickness is typically governed by deflection criteria or fire rating requirements.

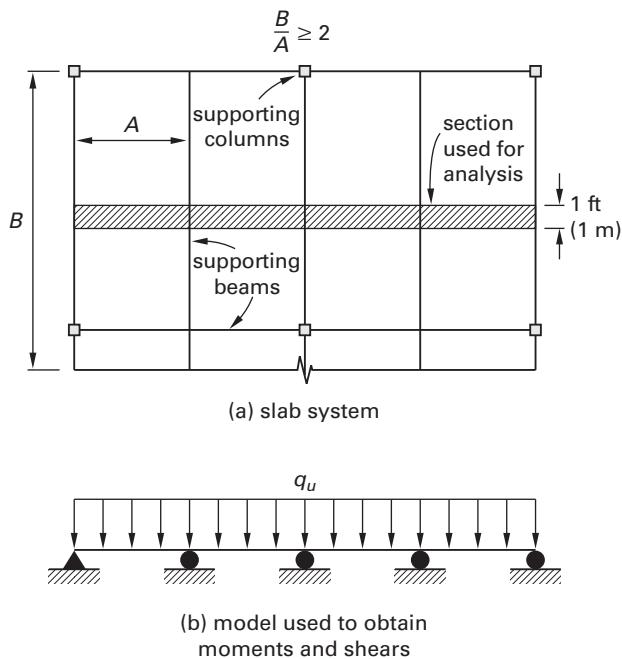

A primary issue associated with the design of slabs is the computation of the moments induced by the applied loads. Slabs are highly indeterminate two-dimensional structures, so an exact analysis to obtain the distribution of moments is impractical. Fortunately, moments can be obtained using simplified techniques. In fact, in many instances, slabs can be designed assuming that all the load is carried by moments in one direction only. These slabs are known as one-way slabs and are discussed in detail starting in Sec. 51.2. A practical approach for obtaining the distribution of moments in the more general two-dimensional case is presented starting in Sec. 51.8.

## 2. ONE-WAY SLABS

Floor slabs are typically supported on all four sides. If the slab length is more than twice the slab width, a uniform load will produce a deformed surface that has little curvature in the direction parallel to the long dimension. Given that moments are proportional to curvature, bending moments will be significant only in the short direction. Slabs designed under the assumption that bending takes place in only one direction are known as *one-way slabs*.

In one-way slabs, the internal forces are computed by taking a strip of unit width and treating it like a beam. The torsional restraint introduced by the supporting beams is typically neglected. For example, the moments per unit width in the short direction for the floor system shown in Fig. 51.1(a) would be obtained by analyzing the four-span continuous beam depicted in Fig. 51.1(b).

**Figure 51.1 One-Way Slab**

## 3. TEMPERATURE STEEL

Although one-way slabs are designed to be capable of carrying the full applied load by spanning in a single direction, ACI 318 Sec. 7.12 requires that reinforcement for shrinkage and temperature stresses be provided normal to the main flexural steel. This is known as *temperature steel*. Temperature steel is required only in structural slabs, not slabs cast against the earth and retaining wall footings. The minimum reinforcement ratio for shrinkage and temperature control (based on the gross area,  $bh$ ) is 0.0020 (grade 40 and grade 50 steel) and 0.0018 (grade 60 steel) [ACI 318 Sec. 7.12.2.1]. The minimum reinforcement ratio for steels with yield stresses exceeding 60 kips/in<sup>2</sup> (413.7 MPa) is

$$\rho_t = 0.0018 \left( \frac{413.7}{f_y} \right)$$

[SI] 51.1(a)

$$\rho_t = 0.0018 \left( \frac{60,000}{f_y} \right)$$

[U.S.] 51.1(b)

The minimum reinforcement ratio cannot be less than 0.0014.

Although slabs are typically designed for uniform loads, slabs also experience significant concentrated loads. Temperature steel makes one-way slabs less vulnerable to excessive cracking from moments parallel to the long dimension that are induced by such concentrated loads. In cases where restraint is significant, shrinkage and temperature effects can cause substantial internal forces and displacements. The amount of reinforcing steel required for shrinkage and temperature could exceed that required for flexure. Temperature steel must be spaced no farther apart than either five times the slab thickness or 18 in (46.0 cm) [ACI 318 Sec. 7.12.2.2].

Although no. 3 bars may be used, it is common practice to use no. 4 bars, which are stiffer and, therefore, bend less during construction handling and installation.

## 4. MINIMUM THICKNESS FOR DEFLECTION CONTROL

Deflections of one-way slabs can be computed using the procedures for beams. If the slab is not supporting or attached to partitions that are likely to be damaged by large deflections, the computation of deflections can be avoided if the thickness,  $h$ , equals or exceeds the values in Table 51.1.

**Table 51.1 Minimum One-Way Slab Thickness<sup>a,b</sup> (unless deflections are computed) ( $f_y = 60,000 \text{ lbf/in}^2$ )<sup>c</sup>**

construction	minimum thickness, $h$ (fraction of span length, $l$ ) <sup>d</sup>
simply supported	$\frac{l}{20}$
one end continuous	$\frac{l}{24}$
both ends continuous	$\frac{l}{28}$
cantilever	$\frac{l}{10}$

<sup>a</sup>ACI 318 Table 9.5(a)

<sup>b</sup>For normalweight concrete that is reinforced with  $f_y = 60,000 \text{ lbf/in}^2$  (413.7 MPa) steel.

For slabs built integrally with supports, the minimum depth can be based on the clear span [ACI 318 Sec. 8.9.3]. For slabs that are not built integrally with supports, the span length (for the purposes of this table) equals the clear span plus the thickness of the slab but need not exceed the centerline-to-centerline distance [ACI 318 Sec. 8.9.1].

<sup>c</sup>Corrections are required for other steel strengths. See Eq. 50.48 and Eq. 50.49.

## 5. ANALYSIS USING ACI COEFFICIENTS

Although the shear and moments in one-way slabs can be computed using standard indeterminate structural

analysis, ACI 318 Sec. 8.3.3 specifies a simplified method that can be used when the following conditions are satisfied: (a) There are two or more spans. (b) Spans are approximately equal, with the longer of two adjacent spans not longer than the shorter by more than 20%. (c) The loads are uniformly distributed. (d) The ratio of live to dead loads is no more than 3. (e) The slab has a uniform thickness.

## 6. SLAB DESIGN FOR FLEXURE

The procedure for selecting steel reinforcement is identical to that for beams, except that moments per unit width are used. Designating the required area of steel per unit (1 ft (1 m)) width as  $A_{sr}$  and the area of one bar as  $A_b$ , the spacing of the reinforcement,  $s$ , is given by Eq. 51.2. The maximum spacing for the main steel is three times the slab thickness but no more than 18 in (46 cm) [ACI 318 Sec. 7.6.5]. The smallest bar size typically used for flexural resistance is no. 4. Table 51.2 can be used to select the steel reinforcement if the steel area per foot of width is known.

$$s = \left( \frac{A_b}{A_{sr}} \right) \left( 12 \frac{\text{in}}{\text{ft}} \right) \quad 51.2$$

Although the design procedures for beams and slabs are similar, there are some differences. (a) From ACI 318 Sec. 7.7.1, the specified cover for the steel is  $\frac{3}{4}$  in (19 mm) when size no. 11 or smaller bars are used. For no. 14 and no. 18 bars, the specified cover is 1.5 in (38 mm). (b) The minimum steel ratio is equal to that used for shrinkage and temperature. The equations for minimum steel used in beams do not apply.

## 7. SLAB DESIGN FOR SHEAR

Due to the small thickness, shear reinforcement is difficult to anchor and is seldom used in one-way slabs. Because one-way slabs are wide members, the requirement for no shear reinforcement is  $\phi V_c \geq V_u$ . As in beams, the critical section for shear is at a distance,  $d$ , from the face of the support if the support induces compression in the vertical direction.

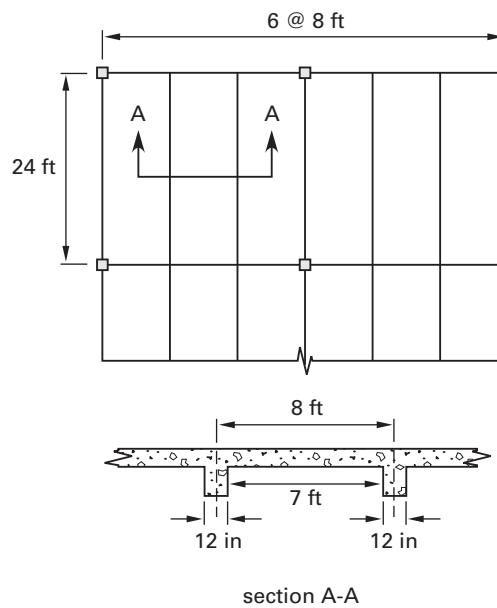

**Table 51.2** Average Steel Area per Foot of Width ( $\text{in}^2/\text{ft}$ )

bar size number	nominal diameter (in)	spacing of bars (in)															
		2	$2\frac{1}{2}$	3	$3\frac{1}{2}$	4	$4\frac{1}{2}$	5	$5\frac{1}{2}$	6	7	8	9	10	12		
3	0.375	0.66	0.53	0.44	0.38	0.33	0.29	0.26	0.24	0.22	0.19	0.17	0.15	0.13	0.11		
4	0.500	1.18	0.94	0.78	0.67	0.59	0.52	0.47	0.43	0.39	0.34	0.29	0.26	0.24	0.20		
5	0.625	1.84	1.47	1.23	1.05	0.92	0.82	0.74	0.67	0.61	0.53	0.46	0.41	0.37	0.31

(Multiply in by 25.4 to obtain mm.)  
(Multiply in<sup>2</sup> by 645 to obtain mm<sup>2</sup>.)

## Example 51.1

A floor system with columns on a 24 ft grid is shown. Beams in the north-south direction spaced at 8 ft on centers are used to create one-way slab action. The floor is subjected, in addition to its own weight, to dead and live loads of 20 lbf/ft<sup>2</sup> and 50 lbf/ft<sup>2</sup>, respectively.  $f'_c = 3000 \text{ lbf/in}^2$  and  $f_y = 60,000 \text{ lbf/in}^2$ . No. 4 bars are used for flexural reinforcement, and no. 3 bars are to be used for temperature steel. Select the thickness of the slab and design the flexural reinforcement.

### Solution

Begin by determining the required thickness. The clear span is 7 ft. From Table 51.1, for an edge panel,

$$h \geq \frac{l}{24} = \frac{(7 \text{ ft}) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{24} = 3.5 \text{ in} \quad [\text{use } 4 \text{ in}]$$

(The interior panels could be made thinner than the edge panels.)

The slab weight is

$$\frac{(150 \text{ lbf}) (4 \text{ in})}{12 \frac{\text{in}}{\text{ft}}} = 50 \text{ lbf/ft}^2$$

The factored load is

$$\begin{aligned} q_u &= 1.2D + 1.6L \\ &= (1.2) \left( 50 \frac{\text{lbf}}{\text{ft}^2} + 20 \frac{\text{lbf}}{\text{ft}^2} \right) + (1.6) \left( 50 \frac{\text{lbf}}{\text{ft}^2} \right) \\ &= 164 \text{ lbf/ft}^2 \quad (0.164 \text{ kip/ft}^2) \end{aligned}$$

Next, obtain the factored moments using moment coefficients with Eq. 47.43 and shear coefficients with Eq. 47.44. Consider a 1 ft wide strip.

The exterior negative moment is

$$\frac{M}{l_2} = \frac{q_u l_n^2}{24} = \frac{\left( 0.164 \frac{\text{kip}}{\text{ft}^2} \right) (7 \text{ ft})^2}{24} = 0.335 \text{ ft-kip/ft}$$

The interior negative moment is

$$\frac{M}{l_2} = \frac{q_u l_n^2}{12} = \frac{\left( 0.164 \frac{\text{kip}}{\text{ft}^2} \right) (7 \text{ ft})^2}{12} = 0.670 \text{ ft-kip/ft}$$

The positive moment in the exterior span is

$$\frac{M}{l_2} = \frac{q_u l_n^2}{14} = \frac{\left( 0.164 \frac{\text{kip}}{\text{ft}^2} \right) (7 \text{ ft})^2}{14} = 0.574 \text{ ft-kip/ft}$$

The positive moment in the interior spans is

$$\frac{M}{l_2} = \frac{q_u l_n^2}{16} = \frac{\left( 0.164 \frac{\text{kip}}{\text{ft}^2} \right) (7 \text{ ft})^2}{16} = 0.502 \text{ ft-kip/ft}$$

The maximum shear is

$$\frac{V_u}{l_2} = \frac{1.15 q_u l_n}{2} = \frac{(1.15) \left( 0.164 \frac{\text{kip}}{\text{ft}^2} \right) (7 \text{ ft})}{2} = 0.660 \text{ kip/ft}$$

Compute the effective depth. Using no. 4 bars,

$$\begin{aligned} d &= h - \text{cover} - \frac{d_b}{2} \\ &= 4 \text{ in} - 0.75 \text{ in} - \frac{0.5 \text{ in}}{2} \\ &= 3 \text{ in} \end{aligned}$$

Check the shear capacity. The lightweight aggregate factor,  $\lambda$ , is 1.0 for normalweight concrete.

$$\begin{aligned} V_c &= 2\lambda\sqrt{f'_c} b_w d = \frac{(2)(1.0)\sqrt{3000 \frac{\text{lbf}}{\text{in}^2}} (12 \frac{\text{in}}{\text{ft}}) (3 \text{ in})}{1000 \frac{\text{lbf}}{\text{kip}}} \\ &= 3.94 \text{ kips/ft} \\ \phi V_c &= (0.75)(3.94 \text{ kips}) \\ &= 2.96 \text{ kips/ft} > 0.660 \text{ kip/ft} \quad [\text{OK}] \end{aligned}$$

Design the flexural reinforcement. The interior negative moment is the largest. This will require the steel to be placed nearer to the top surface than the bottom surface in this region (if not on both surfaces). As with beams, initially estimate  $\lambda$ , the distance from the centroid of the compressed area to the external compression area.

$$\begin{aligned} \lambda &= 0.1d = (0.1)(3 \text{ in}) \\ &= 0.3 \text{ in} \end{aligned}$$

The steel required to resist the maximum moment is

$$\begin{aligned} A_s &= \frac{M_u}{\phi f_y(d - \lambda)} \\ &= \frac{\left( 0.670 \frac{\text{ft-kip}}{\text{ft}} \right) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{(0.9) \left( 60 \frac{\text{kips}}{\text{in}^2} \right) (3 \text{ in} - 0.3 \text{ in})} \\ &= 0.0551 \text{ in}^2/\text{ft} \end{aligned}$$

From ACI 318 Sec. 7.12.2, the minimum steel will be  $0.0018bh = (0.0018)(12 \text{ in}/\text{ft})(4 \text{ in}) = 0.0864 \text{ in}^2/\text{ft}$ , which is larger than the steel required to resist the maximum moment. Therefore, the minimum steel controls at all locations. A value of  $\phi = 0.9$  for tension-controlled sections is fully justified when the reinforcement is so light.

The maximum bar spacing according to ACI 318 Sec. 7.6.5 is  $3h = (3)(4 \text{ in}) = 12 \text{ in}$ . Since the area of a no. 4 bar is  $0.2 \text{ in}^2$ , the maximum spacing controls. Use no. 4 bars on 12 in centers for positive and negative moments.

Temperature steel is required parallel to the long direction. Using no. 3 bars, the required spacing is

$$s = \left( \frac{A_b}{A_{sr}} \right) \left( 12 \frac{\text{in}}{\text{ft}} \right) = \left( \frac{0.11 \frac{\text{in}^2}{\text{in}^2}}{0.0864 \frac{\text{in}^2}{\text{ft}}} \right) \left( 12 \frac{\text{in}}{\text{ft}} \right)$$

$$= 15.27 \text{ in}$$

The maximum spacing for temperature steel is the minimum of five times the slab thickness:  $(5)(4 \text{ in}) = 20 \text{ in}$  or 18 in. Use no. 3 bars on 15 in centers in the long direction as temperature reinforcement.

## 8. TWO-WAY SLABS

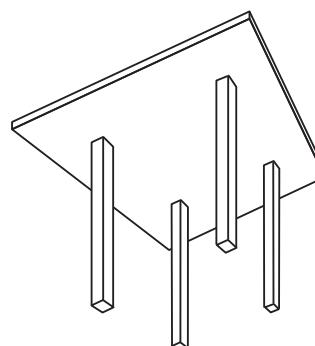

Slabs are classified as *two-way slabs* when the ratio of long-to-short sides is no greater than two. A two-way slab supported on a column grid without the use of beams is known as a *flat plate*. (See Fig. 51.2(a).) A modified version of a flat plate, where the shear capacity around the columns is increased by thickening the slab in those regions, is known as a *flat slab*. (See Fig. 51.2(b).) The thickened part of the flat plate is known as a *drop panel*. Another two-way slab often used without beams between column lines is a *waffle slab*. (See Fig. 51.2(c).) In a waffle slab, the forms used to create the voids are omitted around the columns to increase resistance to punching shear. A two-way slab system that is supported on beams is illustrated in Fig. 51.2(d).

The moments used to design the reinforcement in two-way slabs, whether with or without beams, are obtained in the same manner as for beams and one-way slabs: The slab system and supporting columns are reduced to a series of one-dimensional frames running in both directions. As Fig. 51.3 illustrates, the beams in the frames are wide elements whose edges are defined by cuts midway between the columns. In ACI 318, the dimensions associated with the direction in which moments are being computed are identified by the subscript 1 and those in the transverse direction by the subscript 2. Figure 51.3 also shows that the width of the wide beam is the average of the transverse panel dimensions on either side of the column line. For the edge frames, the width is half the width (centerline-to-centerline) of the first panel.

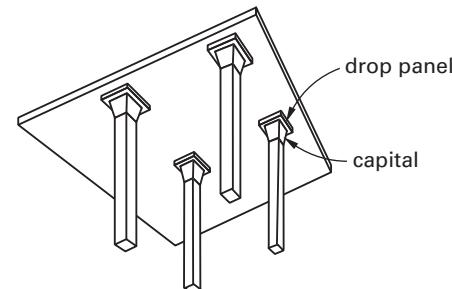

If the small effect of edge panels is neglected, and if the slab system is assumed to be uniformly loaded (from symmetry), the vertical shears and torques in the edges of the wide beams will be zero. There are two steps in the analysis of two-way slabs using the procedure in ACI 318: (a) calculating the longitudinal distribution of the moments (variation in the direction  $l_1$ ), and (b) distributing the moment at any cross section across the width of the wide beams.

ACI 318 provides two alternative methods for computing the longitudinal distribution of moments. In the *equivalent frame method* (EFM), the moments are

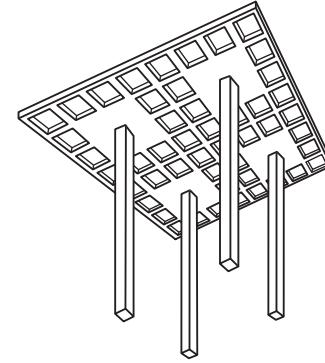

**Figure 51.2** Two-Way Slabs

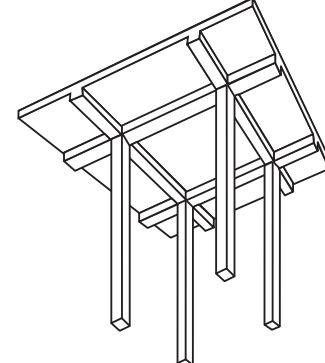

(a) flat plat

(b) flat sla

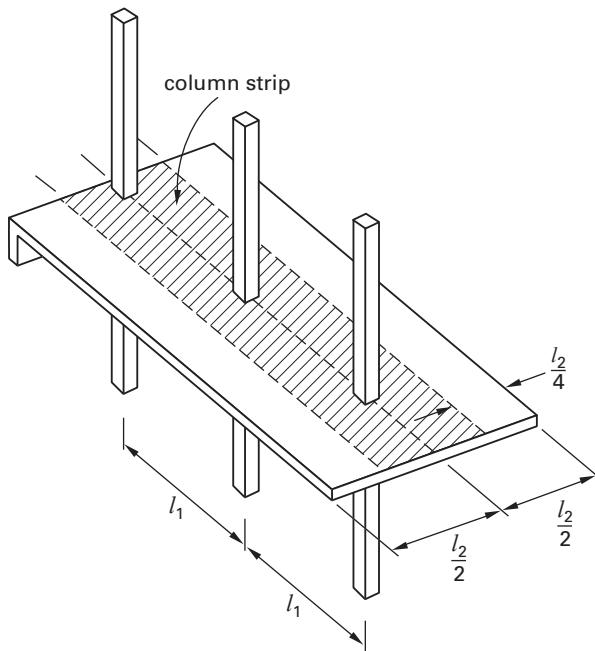

(c) waffle sla

(d) two-way slab with beams

obtained from a structural analysis of the wide beam frame. In this analysis, it is customary to treat the columns as fixed one level above and below the level being considered. (Special provisions that apply to the definition of the stiffnesses of the elements in the equivalent frame, and to other related aspects, are presented in ACI 318 Sec. 13.7.) In the second

**Figure 51.3** Wide Beam Frame (used in the analysis of two-way slabs)

alternative, known as the *direct design method* (DDM), the moments are obtained using a simplified procedure conceptually similar to that introduced for one-way slabs [ACI 318 Sec. 13.6].

The procedure to distribute the moment computed at any section of the wide beam across the width of the wide beam is not dependent on whether the EFM or the DDM is used.

## 9. DIRECT DESIGN METHOD

The DDM can be used when the following conditions are met: (a) There are a minimum of three spans in both directions. (b) Panels are rectangular with a ratio of long-to-short side (center-to-center of supports) of no more than two. (c) Successive span lengths do not differ by more than one-third of the longest span. (d) Columns are not offset by more than 10% of the span in the direction of the offset.<sup>1</sup> (e) The loading consists of uniformly distributed gravity loads. (f) The service live load does not exceed two times the dead load. (g) If beams are present, the relative stiffness in two perpendicular directions,  $\alpha_1 l_2^2 / \alpha_2 l_1^2$ , is not less than 0.2 nor greater than 5.0.

The following steps constitute the direct design method.

*step 1:* Divide the floor system in each direction into wide beams, as shown in Fig. 51.3.

<sup>1</sup>For design purposes, the moments are computed neglecting the column offsets. This procedure will lead to an adequate design if the column offset does not exceed the limit specified. For larger offsets, neither the DDM nor the EFM apply. It is customary in these cases to calculate the moments in the slab using a finite element model.

*step 2:* Calculate the total statical moment in each span from Eq. 51.3 [ACI 318 Sec. 13.6.2.2].

$$M_o = \frac{q_u l_2 l_n^2}{8} \quad [\text{ACI Eq. 13-4}] \quad 51.3$$

This moment is the maximum moment in a simple beam of span  $l_n$  that carries the total load ( $q_u l_2$ ). In Eq. 51.3, the span  $l_2$  refers to the width of the wide beam being considered.  $l_n$  is measured face-to-face of columns or other supports. However,  $l_n \geq 0.65l_1$ . For the computation of minimum thickness in two-way slabs,  $l_n$  is taken as the distance face-to-face of supports in slabs without beams and face-to-face of beams or other supports in other cases.

*step 3:* Divide the total moment,  $M_o$ , in each span into positive and negative moments. For interior spans, the negative factored moment is calculated as  $0.65M_o$ , and the positive factored moment is  $0.35M_o$ . The total moment in end (exterior) spans is distributed according to the coefficients in Table 51.3.

*step 4:* Divide the width of the wide beam into column-strip and middle-strip regions. A *column strip* is a design strip with a width on each side of the column centerline equal to  $0.25l_2$  or  $0.25l_1$ , whichever is less. A *middle strip* is a design strip bounded by two column strips.

*step 5:* Design the column strip for the fractions of the moment at each section according to Table 51.4.

*step 6:* Design the middle strip for the fractions of the moment at each section not assigned to the column strip.

## 10. FACTORED MOMENTS IN SLAB BEAMS

A “beam,” for the purpose of designing two-way slabs, is illustrated in Fig. 51.4. A beam includes the portion of the slab on each side extending a distance equal to the projection of the beam above or below the slab, whichever is largest, but not greater than four times the slab thickness.

The distribution of moments in two-way slabs depends on the relative stiffness of the beams (with respect to the slab without beams). ACI 318 designates this relative stiffness as  $\alpha$ , which is the ratio of the flexural stiffness of the beam to the flexural stiffness of a slab of width equal to that of the wide beam (i.e., the width of a slab bounded laterally by the centerlines of adjacent panels).

$$\alpha = \frac{E_{cb} I_b}{E_{cs} I_s} \quad 51.4$$

When beams are part of the column strip, they are proportioned to resist 85% of the column strip moment if  $\alpha_1 l_2 / l_1 \geq 1$ . For values of  $\alpha_1 l_2 / l_1$  between 0 and 1, linear interpolation is used to select the moment to be assigned to the beam, with zero percent assigned when

**Table 51.3** Distribution of Moments in Exterior Spans (fraction of  $M_o$ )

	exterior edge unrestrained	slab with beams between all supports	slabs without beams between interior supports		
			without edge beam	with edge beam	exterior edge fully restrained
interior negative factored moment	0.75	0.70	0.70	0.70	0.65
positive factored moment	0.63	0.57	0.52	0.50	0.35
exterior negative factored moment	0	0.16	0.26	0.30	0.65

**Table 51.4** Distribution of Moments in Column Strips<sup>a,b,c</sup> (fraction of moment at section,  $M_o$ )

(a) interior negative moment

$\frac{l_2}{l_1}$	0.5	1.0	2.0
$\alpha_1 \left( \frac{l_2}{l_1} \right) = 0$ (no beams)	0.75	0.75	0.75
$\alpha_1 \left( \frac{l_2}{l_1} \right) \geq 1$	0.90	0.75	0.45

(b) exterior negative moment

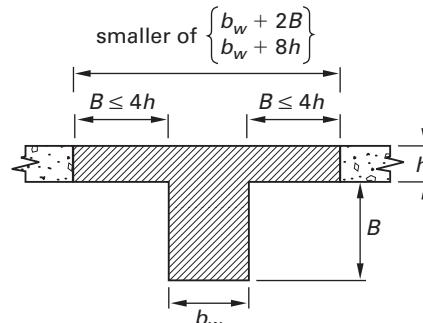

$\frac{l_2}{l_1}$	0.5	1.0	2.0
$\alpha_1 \left( \frac{l_2}{l_1} \right) = 0 \quad \beta_t = 0$	1.00	1.00	1.00
$\alpha_1 \left( \frac{l_2}{l_1} \right) = 0 \quad \beta_t \geq 2.5$	0.75	0.75	0.75
$\alpha_1 \left( \frac{l_2}{l_1} \right) \geq 1 \quad \beta_t = 0$	1.00	1.00	1.00
$\alpha_1 \left( \frac{l_2}{l_1} \right) \geq 1 \quad \beta_t \geq 2.5$	0.90	0.75	0.45

(c) positive factored moment

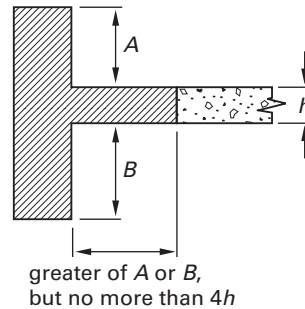

$\frac{l_2}{l_1}$	0.5	1.0	2.0
$\alpha_1 \left( \frac{l_2}{l_1} \right) = 0$ (no beams)	0.60	0.60	0.60
$\alpha_1 \left( \frac{l_2}{l_1} \right) \geq 1$	0.90	0.75	0.45

<sup>a</sup>Linear interpolation is used between the values shown.<sup>b</sup>Middle strips are designed for the fraction of the moment not assigned to the column strip.<sup>c</sup>Refer to ACI 318 Sec. 13.6.4.1, Sec. 13.6.4.2, and Sec. 13.6.4.3.

$\alpha_1 l_2 / l_1 = 0$ . The value of  $l_2$  in the previous expressions refers to the average of the values for the panels on either side of the column line (i.e., to the width of the wide beam).

**Figure 51.4** Two-Way Slab Beams (monolithic or fully composite construction) (ACI 318 Sec. 13.2.4)

(a) interior

(b) exterior

## 11. COMPUTATION OF RELATIVE TORSIONAL STIFFNESS

The distribution of the negative moment across the width of a slab at the exterior edge depends not only on the relative beam stiffness and the ratio  $l_2/l_1$ , but also on the stiffness in torsion of edge beams. ACI 318 uses the parameter  $\beta_t$  to quantify the relative torsional stiffness of the edge beam.

$$\beta_t = \frac{E_{cb} C}{2 E_{cs} I_s} \quad 51.5$$

$$C = \sum \left( 1 - 0.63 \left( \frac{x}{y} \right) \right) \left( \frac{x^3 y}{3} \right) \quad 51.6$$

The summation in Eq. 51.6 is taken over all of the separate rectangles that make up the edge beam (which is typically T-shaped, as illustrated in Fig. 51.4). The

division into separate rectangles that leads to the largest value of  $C$  should be used.

## 12. DEFLECTIONS IN TWO-WAY SLABS

Accurate estimates of deflections in two-way slabs are difficult to obtain. In practice, rather than attempting to calculate deflections accurately, two-way slabs should be sized to satisfy the minimum thickness values given in ACI 318 Sec. 9.5.3.

For slabs without beams or with beams that are only placed between exterior columns (i.e., slabs without beams between interior supports), minimum thickness is specified as the longest clear span (face-to-face of supports) divided by the values listed in Table 51.5. For the values in Table 51.5 for slabs with drop panels to be applicable, drop panels must project below the slab at least one-quarter of the slab thickness beyond the drop and must extend in each direction at least one-sixth the length of the corresponding span. The thickness of a slab without drop panels may not be less than 5 in. Slabs with drop panels may not be less than 4 in thick.

For the purpose of calculating minimum thickness in slabs with beams between interior supports, there are three possibilities [ACI 318 Sec. 9.5.3]. For  $\alpha_m \leq 0.2$ , the minimum thickness is computed from Table 51.5, neglecting the beams. For  $0.2 < \alpha_m \leq 2.0$ , the minimum thickness is given by Eq. 51.7, where  $\beta$  is the ratio of clear spans in the long-to-short directions.

$$h = \frac{l_n \left( 0.8 + \frac{f_y}{200,000} \right)}{36 + 5\beta(\alpha_m - 0.2)} \geq 5 \text{ in} \quad 51.7$$

For  $\alpha_m > 2.0$ , the minimum thickness is

$$h = \frac{l_n \left( 0.8 + \frac{f_y}{200,000} \right)}{36 + 9\beta} \geq 3.5 \text{ in} \quad 51.8$$

**Table 51.5** Minimum Thickness for Slabs Without Interior Beams (longest clear span divided by value given)

yield strength of reinforcement (lbf/in <sup>2</sup> )	without drop panels				with drop panels			
	exterior panels (in)		interior panels (in)		exterior panels (in)		interior panels (in)	
	without edge beams	with edge beams			without edge beams	with edge beams		
40,000	33	36	36		36	40	40	
60,000	30	33	33		33	36	36	
75,000	28	31	31		31	34	34	

(Multiply in by 25.4 to obtain mm.)

(Multiply lbf/in<sup>2</sup> by 0.00689 to obtain MPa.)

When the stiffness ratio  $\alpha$  of the edge beam is less than 0.8, the minimum thickness of the edge panel must be at least 10% larger than the value obtained from Eq. 51.7 and Eq. 51.8.

## 13. CONCRETE DECK SYSTEMS IN BRIDGES

*Deck slabs* are bridge components that support the wheel loads directly. The deck is supported by other components of the superstructure (generally concrete or steel girders) that transfer loads to the foundation through the substructure. Deck slabs generally have a sacrificial wearing surface that deteriorates over time due to the friction and impact with vehicular traffic.

Per AASHTO's *LRFD Bridge Design Specifications* (AASHTO *LRFD*) Sec. 9.7.1.1, the depth of a concrete deck (excluding any provisions for grinding, grooving, and sacrificial surface) must not be less than 7.0 in. Cantilever portions of the deck slab extending beyond the exterior girders must be designed for wheel loads and bridge railing impact loads.

### Empirical Design of Concrete Decks

AASHTO *LRFD* Sec. 9.7.2 allows empirical design of concrete decks if all the following conditions listed are satisfied.

- deck is fully cast-in-place and water cured
- deck is of uniform thickness, except for haunches at girder flanges
- stay-in-place concrete formwork is not used
- effective length of the deck does not exceed 13.5 ft
- ratio of effective length to design depth is not less than 6.0 and not more than 18.0
- specified 28-day strength of the deck concrete is not less than 4.0 ksi
- deck is supported by concrete and/or steel components
- deck is made composite using the supporting elements

- cross-frames or diaphragms are used throughout the cross-section at lines of support
- for decks supported by torsionally stiff units (e.g., box beams), the diaphragm spacing is not more than 25 ft

Four layers of reinforcement (two layers near each face of the slab) are provided in empirically designed concrete slabs. Main reinforcement is provided closest to the faces of the slab in the effective length direction. The direction of the secondary reinforcement is perpendicular to the main reinforcement. Per AASHTO *LRFD* Sec. 9.7.2.5, the minimum amount of reinforcement for each layer of steel must be 0.27 in<sup>2</sup>/ft for each bottom layer and 0.18 in<sup>2</sup>/ft for each top layer. The steel must be grade 60 or higher, and spacing cannot exceed 18 in.

### Traditional Design of Concrete Decks

The traditional design of concrete decks is based on flexure. The live load force effects in the slab are determined by analysis, and adequate primary reinforcement is provided to resist these forces. Secondary reinforcement is provided to resist stresses due to temperature and shrinkage.

### Stay-in-Place Formwork

*Stay-in-place formwork* is often used in deck construction. The formwork is designed to behave elastically and to prevent excessive sagging under construction loads. The formwork must be strong enough to carry the load

of self-weight, the deck concrete weight, and an additional 50 psf. AASHTO *LRFD* limits the stresses due to construction loads in the formwork to prevent failure of the formwork when vehicular loads are applied. In addition, deflection limits are specified for the formwork to ensure adequate cover for reinforcing steel.

### Precast Concrete Deck Slabs on Girders

Precast concrete slab panels can be used as decks in bridges. When these panels are used, an additional cast-in-place topping that acts as a wearing surface may be placed on-site. The panels can be either reinforced or prestressed and can be held in place by a combination of shear keys and/or transverse rods. AASHTO *LRFD* Sec. 9.7.5 allows the use of transversely joined and longitudinally post-tensioned precast decks.

Where the decks are subjected to deicing salts, transversely joined panels with shear keys are not recommended. The shear keys tend to crack under wheel loads and environmental effects, leading to the leaking of the shear keys and decreased load-carrying capacity.

Longitudinally post-tensioned precast panels represent alternatives to transversely joined panels with shear keys, since the deck becomes flexurally continuous. Additionally, if the ducts are grouted properly, longitudinally post-tensioned panels require little maintenance.

### 1. INTRODUCTION<sup>1</sup>

Columns are vertical members whose primary purpose is to transfer axial compression to lower members. In many practical situations, columns are subjected not only to axial compression but also to significant bending moments. Another factor sometimes increasing column loads is the *P-Δ* effect. The *P-Δ* effect refers to the increase in moment that results when the column sways, adding eccentricity. Columns where the *P-Δ* effect is significant are known as *long columns*. This chapter focuses on the design of *short columns* only, that is, columns where the *P-Δ* effect can be neglected. Only the case of uniaxial bending is covered in this chapter.

Columns that are part of braced structures are considered to be short columns if Eq. 52.1 holds. The quantity  $k_b l_u / r$  is the column's *slenderness ratio*.  $M_1$  is the smaller (in absolute value) of the two end moments acting on a column.  $M_2$  is the larger (in absolute value) of the two end moments acting on a column. The ratio  $M_1 / M_2$  is positive if the member is bent in single curvature, and it is negative if the member is bent in double curvature. The ratio  $M_1 / M_2$  cannot be less than -0.5. In Eq. 52.1, it is always conservative to take  $k_b = 1$  [ACI 318 Sec. 10.10.1].

$$\frac{k_b l_u}{r} \leq 34 - 12 \left( \frac{M_1}{M_2} \right) \leq 40 \quad 52.1$$

<sup>1</sup>Not specifically covered in this chapter are *pedestals*—upright compression members with ratios of unsupported height to average least lateral dimension not exceeding 3.

Columns that are part of unbraced structures are considered to be short columns if Eq. 52.2 holds.

$$\frac{k_u l_u}{r} \leq 22 \quad [k_u > 1] \quad 52.2$$

ACI 318 uses the notation  $k$  to represent the effective length factors,  $k_b$  and  $k_u$ , used in Eq. 52.1 and Eq. 52.2. For circular columns,  $r = d/4$ . For rectangular columns,  $r = 0.289h$ , but ACI 318 Sec. 10.10.1.2 permits the use of the approximation  $r = 0.30h$ .

If it cannot be determined by inspection whether a column is braced or unbraced, ACI 318 Sec. 10.10.1 permits a column to be considered braced against side-sway if the bracing elements in that story (typically shear walls and lateral braces) have a total stiffness resisting the lateral movement of that story which is at least 12 times the gross stiffness of the columns within that story.

Throughout this chapter, design specifications for transverse reinforcement are presented for the case where loads are applied at the column ends. If shear forces act between the ends or if the bending moments are significant, shear capacity is checked in a manner similar to that presented in Chap. 50 and in accordance with ACI 318 Sec. 11.2.2.2.

## 2. TIED COLUMNS

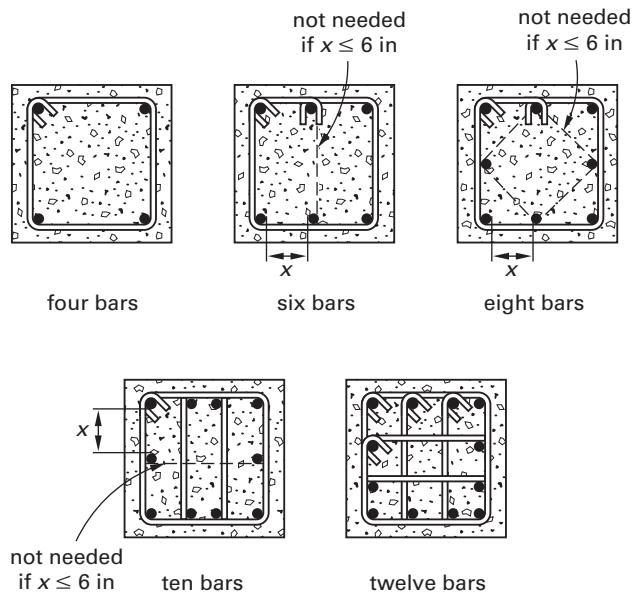

Reinforced concrete columns with transverse reinforcement in the form of closed ties or hoops are known as *tied columns*. Figure 52.1 illustrates a number of typical configurations.

The following construction details are specified by ACI 318 for tied columns.

- Longitudinal bars must have a clear distance between bars of at least 1.5 times the bar diameter, but not less than 1.5 in [ACI 318 Sec. 7.6.3].
- Ties must be at least no. 3 if the longitudinal reinforcement consists of bars no. 10 in size or smaller. For bars larger than no. 10, or when bundles are used in the longitudinal reinforcement, the minimum tie size is no. 4 [ACI 318 Sec. 7.10.5.1]. The maximum practical tie size is normally no. 5.
- The specified concrete cover must be at least 1.5 in over the outermost surface of the tie steel [ACI 318 Sec. 7.7.1].
- At least four longitudinal bars are needed for columns with square or circular ties [ACI 318 Sec. 10.9.2].
- The ratio of longitudinal steel area to the gross column area (given in Eq. 52.12) must be between 0.01 and 0.08 [ACI 318 Sec. 10.9.1]. The lower limit keeps the column from behaving like a plain concrete member. The upper limit keeps the column from being too congested.

$$0.01 \leq \rho_g \leq 0.08 \quad 52.3$$

**Figure 52.1** Types of Tied Columns

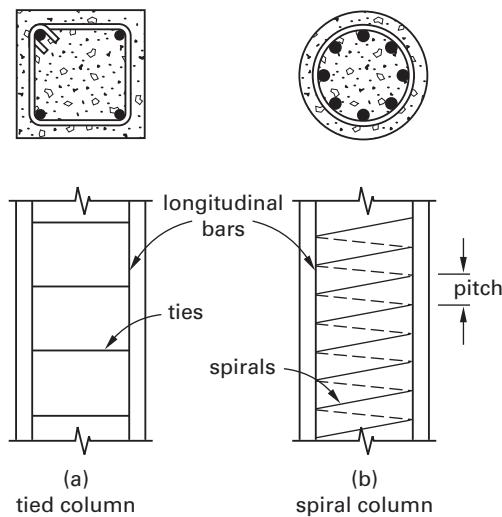

- Center-to-center spacing of ties must not exceed the smallest of 16 longitudinal bar diameters, 48 diameters of the tie, or the least column dimension [ACI 318 Sec. 7.10.5.2].
- Every corner and alternating longitudinal bar must be supported by a tie corner. The included angle of the tie cannot be more than 135° [ACI 318 Sec. 7.10.5.3]. (Tie corners are not relevant to tied columns with longitudinal bars placed in a circular pattern.)
- No longitudinal bar can be more than 6 in away from a bar that is properly restrained by a corner [ACI 318 Sec. 7.10.5.3].

## 3. SPIRAL COLUMNS

Reinforced concrete columns with transverse reinforcement in the form of a continuous spiral are known as *spiral columns*. (See Fig. 52.2.) The following construction details are specified by ACI 318 for spiral columns.

- Longitudinal bars must have a clear distance between bars of at least 1.5 times the bar diameter but not less than 1.5 in [ACI 318 Sec. 7.6.3].
- The minimum spiral wire diameter is  $\frac{3}{8}$  in [ACI 318 Sec. 7.10.4.2]. The maximum practical spiral diameter is  $\frac{5}{8}$  in.
- The clear distance between spirals cannot exceed 3 in or be less than 1 in [ACI 318 Sec. 7.10.4.3].
- The specified concrete cover should be at least 1.5 in from the outermost surface of the spiral steel [ACI 318 Sec. 7.7.1].
- At least six longitudinal bars are to be used for spiral columns [ACI 318 Sec. 10.9.2].

**Figure 52.2** Tied and Spiral Columns

- The ratio of the longitudinal steel area to the gross column area must be between 0.01 and 0.08 [ACI 318 Sec. 10.9.1].
- Splicing of spiral reinforcement is covered by ACI 318 Sec. 7.10.4.5.

ACI 318 also requires that the ratio of the volume of spiral reinforcement to the volume of the column core (concrete placed inside the spiral) be no less than the value in Eq. 52.4.  $A_c$  is the area of the core, measured to the outside surface of the spiral reinforcement, and  $A_g$  is the gross section area [ACI 318 Sec. 10.9.3].

$$\rho_s = 0.45 \left( \frac{A_g}{A_c} - 1 \right) \left( \frac{f'_c}{f_{yt}} \right) \quad 52.4$$

Once the spiral wire diameter is selected, the spiral pitch needed to satisfy Eq. 52.4 can be easily computed from Eq. 52.5, where  $A_{sp}$  is the area of the spiral wire, and  $D_c$  is the diameter of the core measured to the outside surface of the spiral.

$$s \approx \frac{4A_{sp}}{\rho_s D_c} \quad 52.5$$

The clear distance between the spirals is related to the spiral pitch,  $s$ , by Eq. 52.6, where  $d_{sp}$  is the diameter of the spiral wire.

$$\text{clear distance} = s - d_{sp} \quad 52.6$$

The design of spiral reinforcing consists of the following steps: (a) Select a wire size. (A starting estimate for a spiral wire size can be obtained from Table 52.1.) (b) Evaluate Eq. 52.4 and Eq. 52.5 to determine the required pitch. (c) Compute the clear spacing from Eq. 52.6. (d) Make sure the limit on clear spacing is satisfied.

**Table 52.1** Typical Spiral Wire Sizes\*

column diameter	spiral wire size (in)
up to 15 in, using no. 10 bars or smaller	$\frac{3}{8}$
up to 15 in, using bars larger than no. 10	$\frac{1}{2}$
16 in to 22 in	$\frac{1}{2}$
23 in and larger	$\frac{5}{8}$

(Multiply in by 25.4 to obtain mm.)

\*ACI 318 does not specify spiral wire size.

#### 4. DESIGN FOR SMALL ECCENTRICITY

The relative importance of bending and axial compression in the design of a column is measured by the *normalized eccentricity*. This parameter is defined as the ratio of the maximum moment acting on the column to the product of the axial load and the dimension of the column perpendicular to the axis of bending,  $M_u/P_u h$ .

Limits on normalized eccentricity are no longer part of ACI 318, but they can still be used to obtain approximate estimates of the maximum moment that will not affect the design for a given axial load. In an exact solution, the eccentricity limit will be a function of the percent of steel used and the type of reinforcement pattern. As described in Sec. 52.6 and ACI 318 Sec. R10.3.6, when the normalized eccentricity is less than approximately 0.1 for tied columns or 0.05 for spiral columns, the column can be designed without explicit consideration of flexural effects.

The design of a column for small eccentricity is based on Eq. 52.7. For tied columns, the following factors apply. ACI 318 Chap. 9 specifies  $\phi = 0.65$ , and the *strength factor*,  $\beta$ , is 0.80.

For spiral columns, ACI 318 Chap. 9 specifies  $\phi = 0.75$ , and  $\beta = 0.85$ . (ACI 318 does not actually use the symbol  $\beta$  as a parameter for columns. ACI 318 Sec. 10.3.6.1 prescribes the values without specifying a symbol.)

$$\phi\beta P_o \geq P_u \quad 52.7$$

In Eq. 52.7,  $P_o$  is the nominal axial load strength at zero eccentricity. The product  $\phi\beta P_o$  is known as the *design strength* for a column with small eccentricity. This strength is computed by assuming that, at the attainment of maximum capacity, the concrete is stressed to  $0.85f'_c$ , and the steel is stressed to  $f_y$ .

$$P_o = 0.85f'_c(A_g - A_{st}) + f_y A_{st} \quad 52.8$$

Although the nominal capacity,  $P_o$ , is the same for tied and spiral columns, their behaviors are different once the peak capacity is attained. In particular, while tied columns fail in a relatively brittle manner, spiral columns, having better confinement of the core, undergo significant deformation before significant deterioration of the load-carrying capacity ensues. ACI 318 takes into consideration the increased reliability of spiral columns

by providing higher values for  $\phi$  and  $\beta$ . The ultimate load,  $P_u$ , is determined by structural analysis.

$$P_u = 1.2(\text{dead load axial force}) + 1.6(\text{live load axial force}) \quad 52.9$$

The basic design expression for columns with small eccentricity is obtained by substituting Eq. 52.8 into Eq. 52.7. Passing  $\phi$  and  $\beta$  to the right-hand side,

$$0.85f'_c(A_g - A_{st}) + A_{st}f_y = \frac{P_u}{\phi\beta} \quad 52.10$$

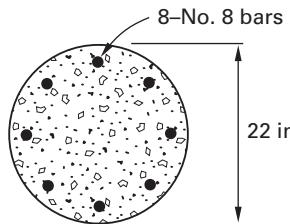

A convenient form of Eq. 52.10 is obtained by expressing the steel area as a function of the reinforcement ratio,  $\rho_g$ . If the column size is not known, a value of  $\rho_g$  between the limits of 0.01 and 0.08 is selected, and Eq. 52.11 is solved for the required gross column area,  $A_g$ . (Larger values of  $\rho_g$  decrease the gross column area. Typical starting values of  $\rho_g$  are approximately 0.02–0.025.) If the section size is known and only the steel reinforcement needs to be obtained, then the equation is solved for  $\rho_g$ , and the area of steel is obtained from Eq. 52.12.

$$A_g(0.85f'_c(1 - \rho_g) + \rho_g f_y) = \frac{P_u}{\phi\beta} \quad 52.11$$

$$\rho_g = \frac{A_{st}}{A_g} \quad 52.12$$

### Example 52.1

Calculate the design strength of the short spiral column shown. Assume the loading has a low eccentricity.  $f'_c = 3500 \text{ lbf/in}^2$ , and  $f_y = 40,000 \text{ lbf/in}^2$ .

*Solution*

The gross area of the column is

$$A_g = \frac{\pi D_g^2}{4} = \frac{\pi(22 \text{ in})^2}{4} = 380.1 \text{ in}^2$$

Since there are eight no. 8 bars, the area of steel is

$$A_{st} = (8)(0.79 \text{ in}^2) = 6.32 \text{ in}^2$$

Substitute into Eq. 52.8.

$$\begin{aligned} P_o &= 0.85f'_c(A_g - A_{st}) + f_y A_{st} \\ &= \left( (0.85) \left( 3500 \frac{\text{lbf}}{\text{in}^2} \right) (380.1 \text{ in}^2 - 6.32 \text{ in}^2) \right. \\ &\quad \left. + \left( 40,000 \frac{\text{lbf}}{\text{in}^2} \right) (6.32 \text{ in}^2) \right) \\ &\quad \times \left( \frac{1}{1000 \frac{\text{lbf}}{\text{kip}}} \right) \\ &= 1364.8 \text{ kips} \end{aligned}$$

The design strength is

$$\phi\beta P_o = (0.75)(0.85)(1364.8 \text{ kips}) = 870 \text{ kips}$$

### Example 52.2

Design a spiral column to carry a factored load of 375 kips. Use  $f'_c = 3000 \text{ lbf/in}^2$  and  $f_y = 40,000 \text{ lbf/in}^2$ .

*Solution*

Assume  $\rho_g = 0.02$ , which is within the allowable range.

Use Eq. 52.11 with a strength reduction factor of 0.75.

$$\begin{aligned} A_g &= \frac{P_u}{\phi\beta(0.85f'_c(1 - \rho_g) + \rho_g f_y)} \\ &= \frac{375 \text{ kips}}{(0.75)(0.85) \left( (0.85) \left( 3 \frac{\text{kips}}{\text{in}^2} \right) (1 - 0.02) \right. \\ &\quad \left. + (0.02) \left( 40 \frac{\text{kips}}{\text{in}^2} \right) \right)} \\ &= 178.3 \text{ in}^2 \end{aligned}$$

The outside diameter is

$$\begin{aligned} D_g &= \sqrt{\frac{4A_g}{\pi}} = \sqrt{\frac{(4)(178.3 \text{ in}^2)}{\pi}} \\ &= 15.07 \text{ in} \quad [\text{say } 15.25 \text{ in}] \end{aligned}$$

With 1.5 in of cover, the diameter of the core is

$$D_c = 15.25 \text{ in} - 3 \text{ in} = 12.25 \text{ in}$$

From Eq. 52.12, the area of steel is

$$\begin{aligned} A_{st} &= \rho_g A_g = (0.02)(178.3 \text{ in}^2) \\ &= 3.57 \text{ in}^2 \end{aligned}$$

ACI 318 requires at least six bars to be used. Several possibilities exist. For example, nine no. 6 bars or twelve no. 5 bars would both give the required area. Choose nine no. 6 bars after checking the clear spacing (not shown here).

The required spiral reinforcement ratio is obtained from Eq. 52.4. The area ratio is calculated from the ratio of the squared diameters.

$$\begin{aligned}\rho_s &= 0.45 \left( \frac{A_g}{A_c} - 1 \right) \left( \frac{f'_c}{f_{yt}} \right) \\ &= (0.45) \left( \left( \frac{15.25 \text{ in}}{12.25 \text{ in}} \right)^2 - 1 \right) \left( \frac{3000 \frac{\text{lbf}}{\text{in}^2}}{40,000 \frac{\text{lbf}}{\text{in}^2}} \right) \\ &= 0.0186\end{aligned}$$

Assume a  $\frac{3}{8}$  in spiral wire (cross-sectional area of  $0.11 \text{ in}^2$ ). The maximum pitch is obtained from Eq. 52.5.

$$\begin{aligned}s &= \frac{4A_{sp}}{\rho_s D_c} \\ &= \frac{(4)(0.11 \text{ in}^2)}{(0.0186)(12.25 \text{ in})} \\ &= 1.93 \text{ in}\end{aligned}$$

Use a spiral pitch equal to 1.75 in.

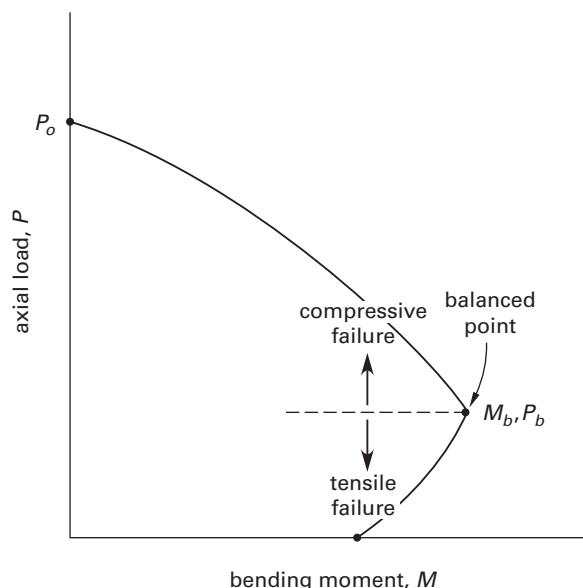

The clear space between spirals is  $1.75 \text{ in} - 0.375 \text{ in} = 1.375 \text{ in}$ . This is between 1 in and 3 in and satisfies ACI 318 Sec. 7.10.4.3.

## 5. INTERACTION DIAGRAMS

Based on approximate eccentricity limits, when the maximum moment acting on a column is larger than approximately  $0.1P_u h$  for tied columns or  $0.05P_u h$  for spiral columns, the design must account explicitly for the effect of bending. In practice, design of columns subjected to significant bending moments is based on interaction diagrams. An *interaction diagram* is a plot of the values of bending moments and axial forces corresponding to the strength (nominal or design) of a reinforced concrete section.

Figure 52.3 illustrates that, for small compressive loads, the moment capacity initially increases, then at a certain axial load it reaches a maximum and subsequently decreases, becoming zero when the axial load equals  $P_o$  from Eq. 52.8. The point in the interaction diagram where the moment is maximum is referred to as the *balanced point* because at that point, the yielding of the extreme tension reinforcement coincides with the attainment of a strain of 0.003 at the extreme compression fiber of concrete.

**Figure 52.3** Nominal Interaction Diagram

Points on a *nominal interaction diagram* are obtained from the following procedure. (Refer to Fig. 52.4 and Fig. 52.5.)

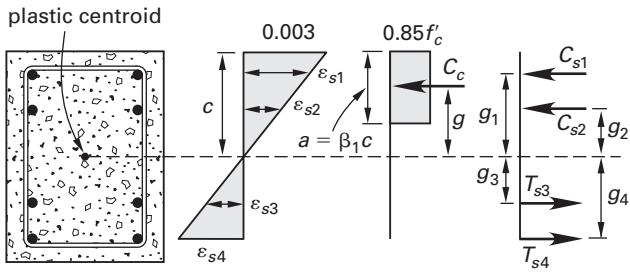

*step 1:* Assume an arbitrary neutral axis depth,  $c$ . (For  $c > c_b$ , points above the balanced point will be obtained.)

*step 2:* Calculate  $a = \beta_1 c$  and the associated area of concrete in compression,  $A_c$ . The force in the concrete is  $0.85f'_c A_c$ .

*step 3:* Compute the forces in the steel bars (or layers). This is done by computing the strain from the geometry of the strain diagram, obtaining the associated stress, and multiplying by the appropriate steel area.

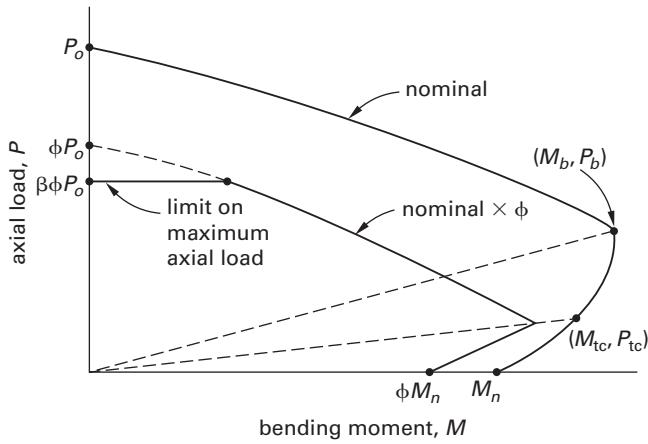

*step 4:* Compute the nominal axial load,  $P_n$ , as the sum of all the forces in the cross section. (For a sufficiently small neutral axis depth, the axial force resultant will be tensile. Although the portion of the interaction diagram corresponding to tension is not usually of interest, points on the negative side need not be discarded since they can help in drawing the interaction diagram.)

*step 5:* Compute the nominal moment,  $M_n$ , by summing moments of all the forces about the plastic centroid. The *plastic centroid* is the location of the resultant force when all of the concrete is compressed at  $0.85f'_c$  and all of the steel is yielding. This corresponds to the point where the line of action of  $P_o$  intersects the section. For the typical case of symmetrically reinforced rectangular or circular column sections, the plastic centroid coincides with the centroid of the section.

**Figure 52.4** Calculation of Points on a Nominal Interaction Diagram

$$P_n = C_c + C_{s1} + C_{s2} - T_{s3} - T_{s4}$$

$$M_n = C_c g + C_{s1} g_1 + C_{s2} g_2 + T_{s3} g_3 + T_{s4} g_4$$

**Figure 52.5** Relationship Between Nominal and Design Interaction Diagrams (per ACI 318 Chap. 9)

An approximate and conservative nominal interaction diagram can be sketched by drawing straight lines between the balanced point at  $(M_b, P_b)$  and  $(0, P_o)$ , and between  $(M_b, P_b)$  and the nominal moment capacity for pure bending.

A *design interaction diagram* can be constructed from the nominal interaction diagram in two steps: (a) Multiply by the appropriate values of  $\phi$ . (b) Limit the maximum allowable compression to  $\beta\phi P_o$ . Although  $\phi$  is constant (either 0.65 or 0.75 for most of the diagram), consistency with the design of beams requires that a transition to 0.9 be made as the axial load decreases to very low values.

In the typical case where  $f_y \leq 60,000 \text{ lbf/in}^2$  (457 GPa) and  $(h - d' - d_s)/h \geq 0.7$ , ACI 318 Sec. 9.3.2.2 indicates that the transition (which is a linear function of  $P_u$ ) begins when  $P_u = 0.1f'_c A_g$ . For other conditions, the transition starts at  $P_u = 0.1f'_c A_g$  or  $P_u = \phi P_b$ , whichever is smaller.

Alternatively, a transition is made in accordance with ACI 318 Sec. 9.3.2.2 between compression-controlled and tension-controlled sections. For sections in which the net tensile strain is between the limits for

compression-controlled and tension-controlled sections, the strength reduction factor is permitted to be linearly increased from that for compression-controlled sections (either 0.65 or 0.75) to 0.90 as the net tensile strain increases from the compression-controlled strain limit (which is equal to 0.002 in the typical case of  $f_y = 60,000 \text{ lbf/in}^2$ ) to 0.005.

Figure 52.5 illustrates the conversion of a nominal interaction diagram to the design interaction diagram per ACI 318 Chap. 9. Note that the balanced point and the point corresponding to the beginning of compression-controlled sections (those with  $\epsilon_t$  equal to 0.002) are the same. The subscript "tc" in the figure refers to the beginning of tension-controlled sections (those with  $\epsilon_t$  equal to 0.005).

## 6. DESIGN FOR LARGE ECCENTRICITY

Although interaction diagrams for columns with unusual shapes need to be drawn on a case-by-case basis, routine design of rectangular or circular columns is carried out using dimensionless interaction diagrams available from several sources. Typical dimensionless interaction diagrams are presented in App. 52.A through App. 52.R.

The use of dimensionless interaction diagrams is straightforward. Each diagram includes envelope lines (most of the diagrams have eight lines) and each line corresponds to a percentage of steel from the minimum of 1% to the maximum of 8%. Each diagram corresponds to a particular set of material properties and to a particular value of  $\gamma$  that is the ratio of the parallel distance between the outer steel layers to the gross section dimension perpendicular to the neutral axis. For practical purposes,  $\gamma$  can be estimated as  $(h - 5)/h$ , where  $h$  is in inches. For rectangular cross sections, there is also a need to determine if the steel is to be placed on the two faces parallel to the neutral axis or if a uniform distribution around the column is to be used. In this regard, it is worth noting that the circles represent only the reinforcing pattern, not the exact positioning.

The following procedure can be used to design short columns for large eccentricity using standard interaction diagrams.

*step 1:* If the column size is not known, an initial estimate can be obtained from Eq. 52.11 using an arbitrarily selected value of  $\rho_g$  between the limits allowed. Since the moment will increase the steel demand above that for no moment, a value of  $\rho_g$  somewhat smaller than the desired target should be selected.

*step 2:* Select the type of reinforcement pattern desired and estimate the value of  $\gamma$ . Choose the appropriate interaction diagram. Using a diagram for a  $\gamma$  value smaller than the actual leads to conservative results.

*step 3:* Evaluate the coordinates of  $P_u/\phi f'_c A_g$  and of  $P_u e/\phi f'_c A_g h$  (where  $P_u e = M_u$ ) and plot this point on the diagram, assuming a value of  $\phi$ . The dashed line corresponding to  $\epsilon_t = 0.002$  (compression-controlled section) and to  $\epsilon_t = 0.005$  (tension-controlled section) on the diagrams can be used as guides when assuming a value for the strength reduction factor. If the point is outside the last curve for  $\rho_g = 0.08$ , the section size is too small. In that case, the section size should be increased and this step repeated. If the point is inside the curve for  $\rho_g = 0.01$ , the section is oversized. In that case, the dimensions should be reduced and this step should be repeated.

*step 4:* Verify the assumed  $\phi$  value. In most cases, the section will turn out to be clearly compression controlled or tension controlled, and verification will involve no effort. In rare situations where this is not the case, calculate the strain in the extreme tension steel from a strain compatibility analysis for the selected size and arrangement of reinforcement. Determine the strength reduction factor on the basis of the magnitude of this strain and compare it to the value assumed in step 3. If the calculated and assumed values vary by more than a few percentage points, repeat the preceding steps based on the calculated strength reduction factor from this step.

Once the size and steel reinforcement are selected, the design is completed by selecting the transverse reinforcement. This step is carried out exactly the same way as in the case of columns with small eccentricity. Although seldom an issue in the design of columns, the adequacy of the cross section in shear should also be checked when significant bending moments exist.

$d$	diameter	in	m
$D$	dead load	lbf	N
$E$	modulus of elasticity	lbf/in <sup>2</sup>	Pa
$f'_c$	compressive strength of concrete	lbf/in <sup>2</sup>	Pa
$F$	lateral load	lbf	N
$h$	dimension perpendicular to the axis of bending	in	m
$h$	height	in	m
$I$	moment of inertia	in <sup>4</sup>	m <sup>4</sup>
$I_{se}$	moment of inertia of steel in a column	in <sup>4</sup>	m <sup>4</sup>
$k$	effective length factor	—	—
$l$	span length of flexural member, center-to-center of joints	in	m
$l_c$	height of column, center-to-center of joints	in	m
$l_u$	clear height of column	in	m
$L$	live load	lbf	N
$M_c$	amplified moment for braced conditions	ft-lbf	N·m
$M_1$	smaller (in absolute value) of the two end moments acting on a column	ft-lbf	N·m
$M_2$	larger (in absolute value) of the two end moments acting on a column	ft-lbf	N·m
$P$	axial load	lbf	N
$Q$	stability index	—	—
$r$	radius of gyration	in	m
$U$	required strength	lbf	N
$V$	shear force	lbf	N
$W$	wind load	lbf	N

## Symbols

$\beta_{dns}$	stiffness reduction factor reflecting long-term effects due to axial (non-sway) loading	—	—
---------------	---	---	---

$\beta_{ds}$	stiffness reduction factor reflecting long-term effects due to lateral (sway) loading	—	—
$\delta$	amplification factor	—	—
$\Delta$	building drift	in	m
$\Delta_o$	story drift	in	m
$\Psi$	relative stiffness parameter	—	—

## Subscripts

$b$	beam or braced
$c$	column or concrete
$f$	floor slab
$g$	gross
$ns$	no sway
$s$	sway or story
$u$	ultimate (factored) or unbraced
$w$	web

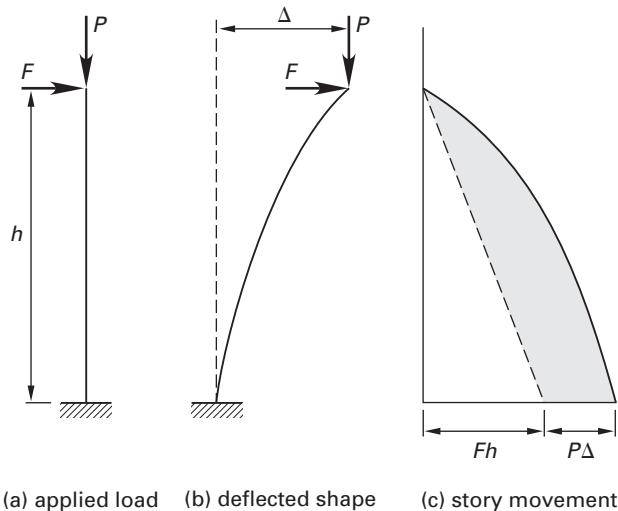

## 1. INTRODUCTION

A typical assumption used in the calculation of internal forces in structures is that the change in geometry resulting from deformations is sufficiently small to be neglected. This type of analysis, known as a *first-order analysis*, is an approximation that is often sufficiently accurate. There are other instances, however, where the changes in geometry resulting from the structural deformations have a notable effect and must be considered.

To illustrate how the deformations of a structure affect the internal forces, consider the cantilever column subjected to compressive and lateral loads shown in Fig. 53.1. The moment at the base of the column in a first-order solution is the product of the lateral load  $F$  times the height  $h$ . (The actual moment at the base, however, is  $Fh + P\Delta$ , where  $\Delta$  is the deflection at the tip of the cantilever due to the combined action of both  $F$  and  $P$ .) An unconservative design results if the moment  $P\Delta$  is significant (in comparison to  $Fh$ ) and is neglected in the design. Although the changes in geometry have an influence on the axial forces also, these effects are typically small and are neglected in design.

ACI 318 requires that the design of slender columns, restraining beams, and other supporting members be based on the factored loading from a second-order analysis, which must satisfy one of three potential analysis approaches: *nonlinear second-order analysis*, *elastic second-order analysis*, or *moment magnification*.

The nonlinear second-order analysis is too complex to be demonstrated here, and the elastic second-order analysis

**Figure 53.1** Effect of Deformation on Internal Forces

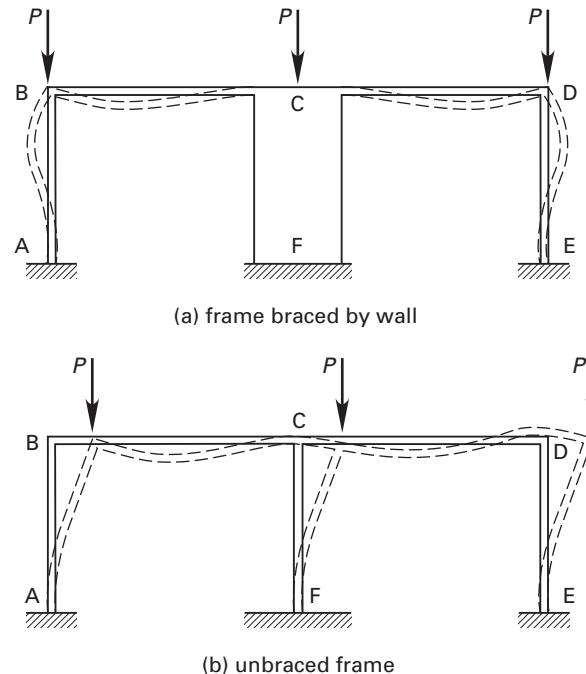

is briefly discussed in Sec. 53.4. In general, the computational effort and rigorous evaluation of second-order moments in large structures using these two methods is considered too involved for routine design and is typically performed using frame analysis software. However, a practical alternative to estimate the moments due to second-order effects is multiplying the first-order solution by appropriately defined moment magnification (or amplification) factors. This method is the third approach permitted by ACI 318 in its treatment of long columns. ACI 318 contains simplified criteria for determining when slenderness amplification factors do not have to be calculated. Regardless of the approach, ACI 318 restricts the total moment, including second-order effects, to no more than 1.4 times the moment due to first-order effects.

## 2. BRACED AND UNBRACED COLUMNS

A fundamental determination that has to be made in the process of computing the amplification factors for columns is whether the column is part of a braced (non-sway) or an unbraced (sway) structure. The magnitude of the vertical load required to induce buckling when sway is possible is typically much smaller than when sway is restrained.

Conceptually, a column is considered braced if its buckling mode shape does not involve translation of the end points. A structure may be braced even though *diagonal bracing* is not provided. For example, if the frame in Fig. 53.2(a) is assumed to be elastic and the vertical loading is progressively increased, columns AB and DE will eventually buckle without joint translation. Wall CF provides the necessary bracing in this case.

Because floor systems are essentially rigid against distortions in their own planes, it is not necessary for a wall to be located in the same plane of a column to provide adequate bracing. The only requirement is that the

**Figure 53.2** Braced and Unbraced Frames

arrangement of walls be such that significant torsional stiffness is provided so that the slab cannot rotate about a wall when any frame buckles.

When the wall is replaced by a column, however, buckling takes place with lateral translation of the joints, so the structure must be considered unbraced, as in Fig. 53.2(b).

There are instances where inspection is not sufficient to establish the distinction between braced and unbraced structures. For example, as the size of the wall CF in Fig. 53.2 is reduced, the condition changes from braced to unbraced. It is difficult to determine when the transition occurs. ACI 318 provides the following three quantitative methods to distinguish between braced and unbraced conditions. In particular, columns in any given level of a building can be treated as braced when one of the following criteria is satisfied.

1. The ratio of the moment from a second-order analysis to the first-order moment is less than or equal to 1.05 [ACI 318 Sec. 10.10.5.1].
2. The *stability coefficient*,  $Q$ , is less than or equal to 0.05.  $Q$  is given by Eq. 53.1 [ACI 318 Sec. 10.10.5.2].

$$Q = \frac{\sum P_u \Delta_o}{V_{us} l_c} \leq 0.05 \quad 53.1$$

$\sum P_u$  is the sum of the axial forces in the columns at the level in question,  $\Delta_o$  is the *story drift* (the relative displacement between the floor and the roof of the story),  $V_{us}$  is the shear force in the story, and  $l_c$  is the column height measured from centerline-to-centerline of the joints (essentially the same as the story height).

3. The sum of the lateral stiffness of the bracing elements in that story exceeds 12 times the gross lateral stiffness of all columns within that story [ACI 318 Sec. 10.10.1].

### 3. EFFECTIVE LENGTH

The buckling load of a column is dependent on how the ends are supported. The end-restraint conditions affect the column's *effective length*. The effective length is calculated as the product of an *effective length factor*,  $k$ , and the actual length of the column.

$$\text{effective length} = kl \quad 53.2$$

The effective length factor depends on the relative stiffness of the columns and beams at the ends of the column, and also on whether the column is part of a braced or an unbraced frame. ACI 318 uses the symbol  $k$  to identify the effective length factor for both braced and unbraced conditions. However, it is clearer to use  $k_b$  for the braced condition and  $k_u$  for unbraced condition.

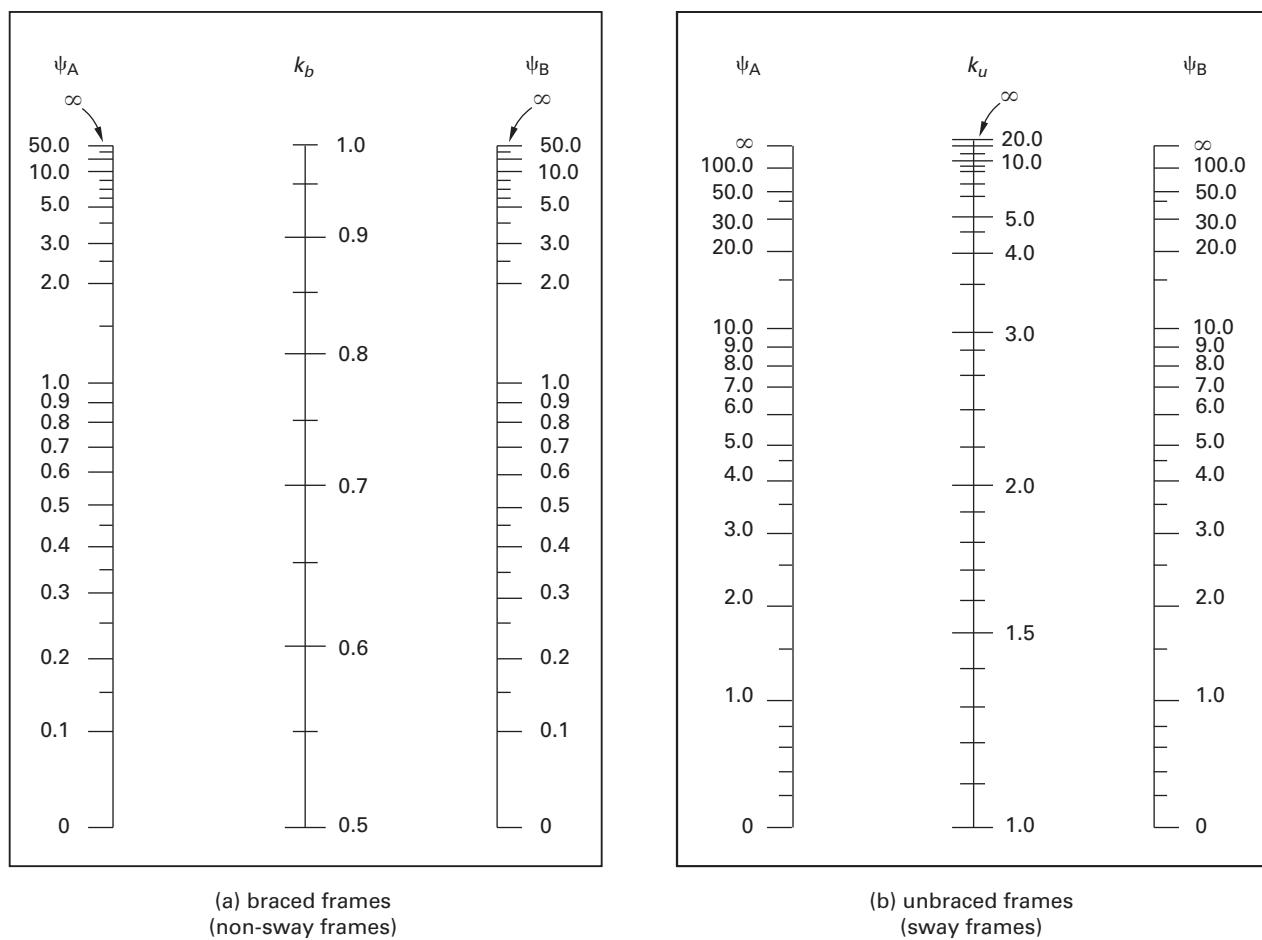

A convenient way to obtain the effective length factor is by using a *Jackson and Moreland alignment chart*, as shown in Fig. 53.3. The effective length is obtained by connecting the values of the relative stiffness parameter,  $\Psi$ , for each end of the column.

$$\Psi = \frac{\sum_{\text{columns}} \frac{EI}{l_c}}{\sum_{\text{beams}} \frac{EI}{l}} \quad 53.3$$

### 4. FRAME SECTION PROPERTIES (SECOND-ORDER ANALYSIS)

Cracks and other factors will reduce member strength and increase deformations. Since second-order moments depend on the actual deformations, it is important to use section properties that reflect the influence of cracking and the effect of the duration of the loads on the stiffness of the structure. ACI 318 Sec. 10.10.4 requires an analysis of such properties, but it permits use of the following values in the absence of a more detailed analysis.

**Figure 53.3** Effective Length Factors (Jackson and Moreland alignment chart)

These values represent assumed average values for a specific story within a frame, not an individual column. (Values for walls are also provided in ACI 318.)

modulus of elasticity of concrete	$57,000\sqrt{f'_c}$
area	$A_g$
moments of inertia of columns	$0.70I_g$
moments of inertia of beams	$0.35I_g$
moments of inertia of plates and slabs	$0.25I_g$

Alternatively, ACI 318 permits the moments of inertia for compression members to be calculated as

$$I = \left(0.80 + 25 \frac{A_{st}}{A_g}\right) \left(1 - \frac{M_u}{P_u h} - 0.5 \frac{P_u}{P_o}\right) I_g \quad 53.4$$

The moment of inertia calculated from Eq. 53.4 must be greater than  $0.35I_g$  and less than  $0.875I_g$ . The ultimate factored values  $P_u$  and  $M_u$  can be determined from either a specific load combination under consideration or the load combination that produces the smallest value of  $I$ .

For flexural members, the moments of inertia are

$$I = (0.10 + 25\rho) \left(1.2 - 0.2 \frac{b_w}{d}\right) I_g \quad 53.5$$

The value of  $I$  determined using Eq. 53.5 must be greater than  $0.25I_g$  and less than  $0.5I_g$ . For continuous flexural members,  $I$  may be calculated as the average of the values calculated at the critical positive and negative moment sections.

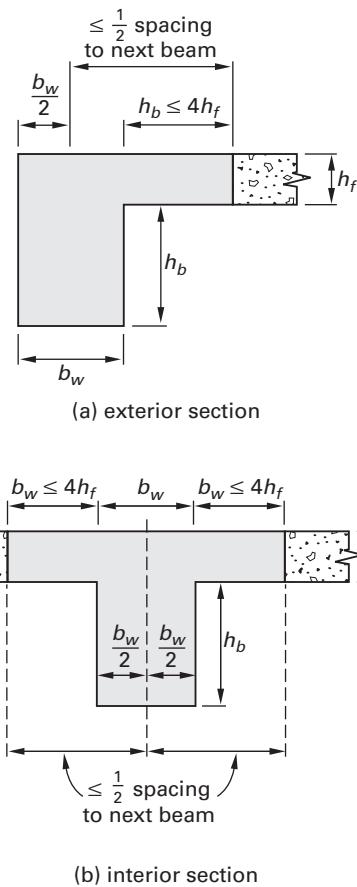

$I_g$  for T-beams and one-way beam-slab systems is computed using the effective flange width shown in Fig. 50.9 [ACI 318 Sec. 8.12].  $I_g$  for two-way beam-slab systems is computed using the effective flange width shown in Fig. 53.4 [ACI 318 Fig. R13.2.4].

For the unusual situation where a building is subjected to sustained lateral loads (e.g., from earth pressure), the moments of inertia are divided by the factor  $1 + \beta_{ds}$ .  $\beta_{ds}$  is defined as the ratio of the maximum factored sustained shear within a story to the total factored shear in that story. The maximum factored sustained shear and the total factored shear must be associated with the same load combination.  $\beta_{ds}$  must be less than or equal to 1.0.

## 5. EFFECTIVE FLEXURAL STIFFNESS: COLUMNS IN BRACED FRAMES

To evaluate the buckling load of a column, the effective length,  $kl_u$ , and the *flexural stiffness*,  $EI$ , are needed. This last term must include possible reductions due to cracking, nonlinear effects in the stress-strain curve and, in the case of sustained loads, the increase in curvatures that occurs as a result of creep deformations. ACI 318 Sec. 10.10.6 provides two formulas that provide conservative estimates of the flexural stiffness. Equation 53.7

**Figure 53.4 Effective Width of Two-Way Slab Sections Considered as Parts of Beams (ACI 318 Fig. R13.2.4)**

is typically used since it can be evaluated without knowing the steel reinforcement.

$$EI = \frac{0.2E_c I_g + E_s I_{se}}{1 + \beta_{dns}} \quad [\text{braced frames}] \quad 53.6$$

$$EI = \frac{0.4E_c I_g}{1 + \beta_{dns}} \quad [\text{braced frames}] \quad 53.7$$

In Eq. 53.6,  $I_{se}$  is the moment of inertia of the steel bars in a column cross section, calculated as the sum of the products of areas times the square of the distances to the centroidal axis.

$\beta_{dns}$  is a factor used to account for the reduction of stiffness of columns due to sustained axial (non-sway) loads within a story. Specifically,  $\beta_{dns}$  is the ratio of the maximum factored sustained axial load to the maximum factored axial load and must be less than or equal to 1.0. The maximum factored sustained axial load and the maximum factored axial load must be associated with the same load combination. Note that  $\beta_{dns}$  is similar to the factor  $\beta_{ds}$  (see Sec. 53.4). Both factors apply to a reduction in column stiffness due to sustained loads, but  $\beta_{dns}$  is used for axial (non-sway) loads and  $\beta_{ds}$  for lateral (sway) loads.

Equation 53.4 and Eq. 53.5 are intended to approximate the flexural stiffness of a single, highly loaded column. Alternatively, ACI 318 Sec. 10.10.6.1 allows  $EI$  for compression members to be calculated using the value of  $I$  obtained from Eq. 53.4 divided by  $(1 + \beta_{dns})$ .

## 6. BUCKLING LOAD

The column *buckling load* for a slender column is given by the Euler formula. The values of flexural stiffness and effective length previously determined in Sec. 53.3 and Sec. 53.5 must be used.

$$P_c = \frac{\pi^2 EI}{(kl_u)^2} \quad [\text{ACI 318 Eq. 10-13}] \quad 53.8$$

## 7. COLUMNS IN BRACED STRUCTURES (NON-SWAY FRAMES)

When the columns in a story are braced, the design is carried out using a factored axial load obtained from a first-order analysis and for a moment,  $M_c$ , given by Eq. 53.9 [ACI 318 Eq. 10-11].  $M_2$  is the larger factored end moment from a first-order solution.

$$M_c = \delta M_2 \quad 53.9$$

The *amplification factor* given by ACI 318 Sec. 10.10.6 is

$$\delta = \frac{C_m}{1 - \frac{P_u}{0.75P_c}} \geq 1.0 \quad 53.10$$

The buckling load,  $P_c$ , is obtained from Eq. 53.8 with  $k = k_b$  and  $EI$  given by either Eq. 53.6 or Eq. 53.7.

The parameter  $C_m$  is used to account for the shape of the first-order moment diagram. For columns with transverse loads between the endpoints,  $C_m = 1$ . For columns without transverse loads between the endpoints, Eq. 53.11 can be used. The quantity  $M_1/M_2$  is negative when the column is bent in double curvature. (When  $M_1 = M_2 = 0$ , use  $M_1/M_2 = 1$  [ACI 318 Sec. 10.10.6.4].)

$$C_m = 0.6 + 0.4 \left( \frac{M_1}{M_2} \right) \quad 53.11$$

ACI 318 Sec. 10.10.6.5 provides a minimum value for the moment  $M_2$ , as given by Eq. 53.12.

$$M_{2,\min,\text{in-lbf}} = P_{u,\text{lbf}}(0.6 + 0.03h_{\text{in}}) \quad 53.12$$

ACI 318 Sec. 10.10.1 specifies the conditions necessary to disregard slenderness effects in non-sway frames.

## 8. COLUMNS IN UNBRACED STRUCTURES (SWAY FRAMES)

Columns in unbraced structures should be designed for the axial load computed from a first-order analysis and

for the *amplified end moments*,  $M_1$  and  $M_2$ , which are computed as

$$M_1 = M_{1\text{ns}} + \delta_s M_{1s} \quad [\text{ACI 318 Eq. 10-18}] \quad 53.13$$

$$M_2 = M_{2\text{ns}} + \delta_s M_{2s} \quad [\text{ACI 318 Eq. 10-19}] \quad 53.14$$

The amplification factor or *moment magnifier*,  $\delta_s$ , is calculated from Eq. 53.15 and Eq. 53.16. If Eq. 53.15 yields a value of  $\delta_s$  that is greater than 1.5,  $\delta_s$  should be calculated using Eq. 53.16 or by performing a second-order analysis.  $Q$  is calculated from Eq. 53.1.

$$\delta_s = \frac{1}{1 - Q} \geq 1 \quad [\text{ACI 318 Eq. 10-20}] \quad 53.15$$

$$\delta_s = \frac{1}{1 - \frac{\sum P_u}{0.75 \sum P_c}} \geq 1.0 \quad [\text{ACI 318 Eq. 10-21}] \quad 53.16$$

The amplification factor,  $\delta_s$ , is not computed for a single given column, but rather for all the columns in a given story. This is because all of the columns in a story must buckle with sway if any one does.

The value of each of the buckling loads,  $P_c$  in Eq. 53.16, is obtained using Eq. 53.8 with the effective length factor taken as  $k_u$ .

While Eq. 53.13 and Eq. 53.14 give the amplified moments at the column ends in an unbraced structure, the moment may be even larger at some point along the height of the column. In fact, the moments within the column height cannot be obtained from the moments at the ends alone. The deflection of the column with respect to its chord affects the moments within the length.

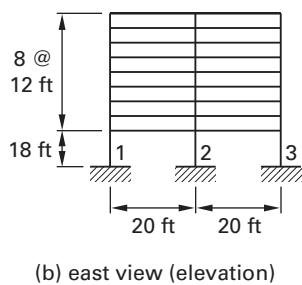

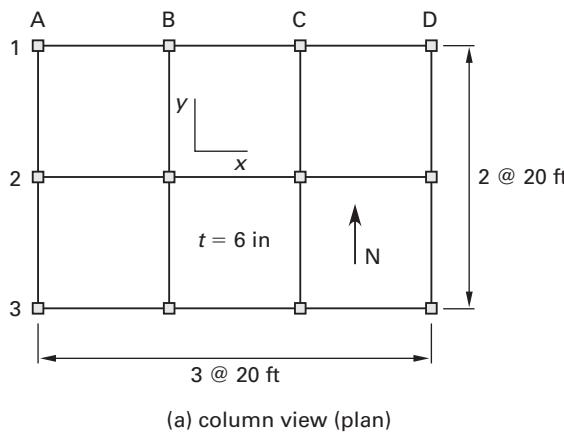

### Example 53.1

A nine-floor (eight floors above ground level) reinforced concrete building is supported on 20 in  $\times$  20 in columns located on a 20 ft  $\times$  20 ft rectangular grid. Concrete with a compressive strength of 4000 lbf/in<sup>2</sup> is used. The stories are 12 ft in height with the exception of the first story, which is 18 ft high. The first story column height can be taken as 17 ft. The effective length factor,  $k_u$ , for column B2 is 1.5. The slab thickness is 6 in. The actions in column B2 for dead load, live load, and wind loading in the N-S direction are as shown. The moments from the live load shown are obtained by positioning the live load on the panels located to the north of column B2 only. Moments in the E-W direction (about the  $y-y$  axis) are negligible.

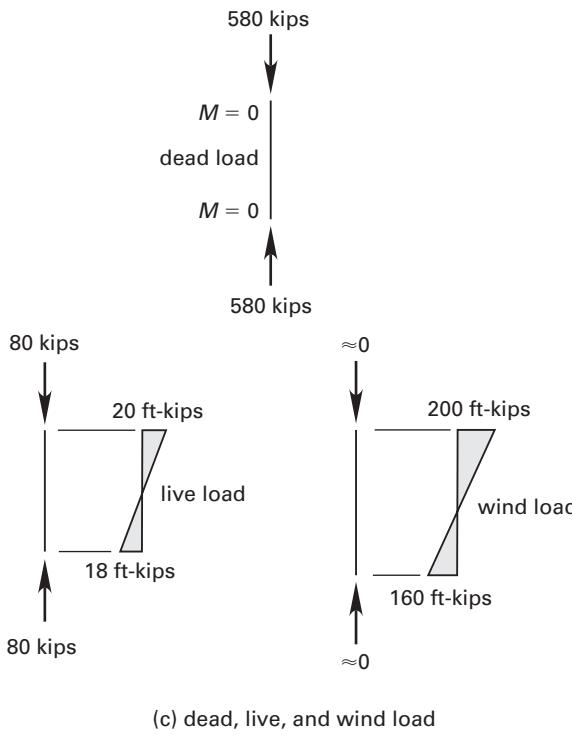

To account for the low probability of all stories above being fully loaded, the live load over all the stories above is assumed to be 40% of the nominal value for the purpose of computing the amplification  $\delta_s$  at level 1. To account for the fact that their effective lengths are longer as a result of having only one beam framing into their joints in the direction of the analysis, the critical load of the columns along axes 1-1 and 3-3 is assumed to be 0.75 times the critical load of the columns along

axis 2-2. The average dead load per floor is 150 lbf/ft<sup>2</sup>, and the basic (unreduced) floor live load is 50 lbf/ft<sup>2</sup>.

Compute the (a) design axial load and (b) amplified moments in the first level for column B2. Consider the load combination  $U = 1.2D + 1.0L + 1.0W$ .

(b) east view (elevation)

### Solution

(a) The design axial load is

$$\begin{aligned} P_u &= 1.2D + 1.0L + 1.0W \\ &= (1.2)(580 \text{ kips}) + (1.0)(80 \text{ kips}) + (1.0)(0 \text{ kips}) \\ &= 776 \text{ kips} \end{aligned}$$

(b) The absence of any lateral or diagonal bracing implies that the frame is considered unbraced and susceptible to sway. Check the slenderness using Eq. 52.2.

$$\frac{k_u l_u}{r} = \frac{(1.5)(17 \text{ ft})(12 \frac{\text{in}}{\text{ft}})}{(0.3)(20 \text{ in})} = 51 \quad [ > 22 ]$$

Therefore, slenderness effects may not be neglected. Use the moment magnification method.  $\sum P_u$  is the total factored load above the level in question. There are nine areas that contribute to loading.

$$\begin{aligned} \sum P_u &= \left( (1.2) \left( 0.15 \frac{\text{kip}}{\text{ft}^2} \right) + (1.0)(0.4) \left( 0.05 \frac{\text{kip}}{\text{ft}^2} \right) \right) \\ &\quad \times (9)(60 \text{ ft})(40 \text{ ft}) \\ &= 4320 \text{ kips} \end{aligned}$$

$\sum P_c$  is the sum of the buckling loads of all the columns in the level. Compute this for the columns along axis 2-2.

$$\begin{aligned} E_c &= \frac{57,000 \sqrt{4000 \frac{\text{lbf}}{\text{in}^2}}}{1000 \frac{\text{lbf}}{\text{kip}}} \\ &= 3605 \text{ kips/in}^2 \\ I_g &= \frac{bh^3}{12} = \frac{(20 \text{ in})(20 \text{ in})^3}{12} \\ &= 13,333 \text{ in}^4 \end{aligned}$$

For unbraced (sway) frames, ACI 318 Sec. 10.10.7.4 permits the flexural stiffness,  $EI$ , to be calculated using either Eq. 53.6 or Eq. 53.7. It is reasonable to assume that the lateral wind loads are generally of short duration and are not sustained. In this case,  $\beta_{ds} = 0$  [ACI 318 Sec. R10.10.7.4]. The flexural stiffness is

$$\begin{aligned} EI &= \frac{0.4E_c I_g}{1 + \beta_{ds}} = \frac{(0.4)(3605 \frac{\text{kips}}{\text{in}^2})(13,333 \text{ in}^4)}{1 + 0} \\ &= 19.23 \times 10^6 \text{ kips-in}^2 \end{aligned}$$

Substitute into Eq. 53.8. The buckling load is

$$P_c = \frac{\pi^2 EI}{(kl_u)^2} = \frac{\pi^2 (19.23 \times 10^6 \text{ kips-in}^2)}{\left((1.5)(17 \text{ ft})\left(\frac{12 \text{ in}}{\text{ft}}\right)\right)^2} \\ = 2027 \text{ kips}$$

Taking the reduction in axial loading into account,

$$\sum P_c = ((0.75)(8) + 4)(2027 \text{ kips}) = 20,270 \text{ kips}$$

Since the story drift is not given, the amplification factor is computed from Eq. 53.16.

$$\delta_s = \frac{1}{1 - \frac{\sum P_u}{0.75 \sum P_c}} = \frac{1}{1 - \frac{4320 \text{ kips}}{(0.75)(20,270 \text{ kips})}} \\ = 1.40$$

$$M_{1ns} = (1.0)(18 \text{ ft-kips}) = 18.0 \text{ ft-kips}$$

$$M_{2ns} = (1.0)(20 \text{ ft-kips}) = 20.0 \text{ ft-kips}$$

$$M_{1s} = (1.6)(160 \text{ ft-kips}) = 256.0 \text{ ft-kips}$$

$$M_{2s} = (1.6)(200 \text{ ft-kips}) = 320.0 \text{ ft-kips}$$

Using Eq. 53.13 and Eq. 53.14, the amplified moments at the column ends are

$$M_1 = M_{1ns} + \delta_s M_{1s} \\ = 18.0 \text{ ft-kips} + (1.40)(256.0 \text{ ft-kips}) \\ = 376 \text{ ft-kips}$$

$$M_2 = M_{2ns} + \delta_s M_{2s} \\ = 20.0 \text{ ft-kips} + (1.40)(320.0 \text{ ft-kips}) \\ = 468 \text{ ft-kips}$$

## 1. NONBEARING WALLS

Nonbearing walls support their own weight and, occasionally, lateral wind and seismic loads. The following minimum details are specified by ACI 318 for designing nonbearing walls.

### Minimum vertical reinforcement [ACI 318 Sec. 14.3.2]

1. 0.0012 times the gross concrete area for deformed no. 5 bars or smaller and  $f_y \geq 60,000$  psi (413 MPa)
2. 0.0015 times the gross concrete area for other deformed bars
3. 0.0012 times gross concrete area for smooth or deformed welded wire reinforcement not larger than W31 or D31

### Minimum horizontal reinforcement [ACI 318 Sec. 14.3.3]

1. 0.0020 times the gross concrete area for deformed no. 5 bars or smaller and  $f_y \geq 60,000$  psi (413 MPa)
2. 0.0025 times the gross concrete area for other deformed bars
3. 0.0020 times the gross concrete area for smooth or deformed welded wire reinforcement not larger than W31 or D31

### Number of reinforcing layers [ACI 318 Sec. 14.3.4]

1. Wall thickness  $> 10$  in (254 mm): two layers; one layer containing from  $\frac{1}{2}$  to  $\frac{2}{3}$  of the total steel placed not less than 2 in (51 mm) and not more than  $h/3$  from the exterior surface; the other layer placed

at a distance not less than  $\frac{3}{4}$  in (19 mm) and no more than  $h/3$  from the interior surface.

2. Wall thickness  $\leq 10$  in (254 mm): ACI 318 does not specify two layers of reinforcement.

*Spacing of vertical and horizontal reinforcement [ACI 318 Sec. 14.3.5]*

The spacing of vertical and horizontal reinforcement may not exceed three times the wall thickness or 18 in.

*Need for ties [ACI 318 Sec. 14.3.6]*

The vertical reinforcement does not have to be enclosed by ties unless (a) the vertical reinforcement is greater than 0.01 times the gross concrete area, or (b) the vertical reinforcement is not required as compression reinforcing.

*Thickness [ACI 318 Sec. 14.6.1]*

Thickness cannot be less than 4 in (102 mm) or  $\frac{1}{30}$  times the least distance between members that provide lateral support.

## 2. BEARING WALLS: EMPIRICAL METHOD

The majority of concrete walls in buildings are *bearing walls* (*load-carrying walls*). In addition to their own weights, bearing walls support vertical and lateral loads. There are two methods for designing bearing walls. They may be designed (a) by the ACI empirical design method, (b) by the ACI alternate design method, or (c) as compression members using the strength design provisions for flexure and axial loads. The minimum design requirements for nonbearing walls must also be satisfied for bearing walls.

The empirical method may be used only if the resultant of all factored loads falls within the middle third of the wall thickness. This is the case with short vertical walls with approximately concentric loads. ACI 318 Sec. 14.5.2 gives the empirical design equation as

$$P_u \leq \phi P_{n,w} \leq 0.55 \phi f'_c A_g \left( 1 - \left( \frac{k l_c}{32 h} \right)^2 \right) \quad 54.1$$

The strength reduction factor,  $\phi$ , is that for compression-controlled sections. The *effective length factor*,  $k$ , depends on the end conditions of the wall. According to ACI 318 Sec. 14.5.2,  $k = 0.8$  for walls braced at the top and bottom against lateral translation and restrained against rotation at the top and/or bottom.  $k = 1.0$  for walls braced at the top and bottom against lateral translation and not restrained against rotation at either end.  $k = 2.0$  for walls not braced against lateral translation.

Use of the ACI empirical equation is further limited to the following conditions. The wall thickness,  $h$ , must not be less than  $\frac{1}{25}$  times the supported length or height, whichever is shorter, nor may it be less than 4 in (102 mm). Exterior basement walls and foundation walls must be at least 7.5 in (191 mm) thick. The following

additional provisions apply to all walls designed by ACI 318 Chap. 14. (a) To be considered effective for beam reaction or other concentrated load, the length of the wall must not exceed the minimum of the center-to-center distance between reactions and the width of bearing plus four times the wall thickness [ACI 318 Sec. 14.2.4]. (b) The wall must be anchored to the floors or to columns and other structural elements of the building [ACI 318 Sec. 14.2.6].

## 3. BEARING WALLS: STRENGTH DESIGN METHOD

If the wall has a nonrectangular cross section (as in ribbed wall panels) or if the eccentricity of the force resultant is greater than one sixth of the wall thickness, the wall must be designed as a column subject to axial loading and bending [ACI 318 Sec. 14.5.1].

## 4. SHEAR WALLS

*Shear walls* are designed to resist lateral wind and seismic loads. Reinforced concrete walls have high in-plane stiffness, making them suitable for resisting lateral forces. The ductility provided by the reinforcing steel ensures a ductile-type failure. Ductile failure is the desirable failure mode because it gives warning and enough time for the occupants of the building to escape prior to total collapse.

## 5. DESIGN OF RETAINING WALLS

Retaining walls are essentially vertical cantilever beams, with the additional complexities of nonuniform loading and soil-to-concrete contact. The wall is designed to resist moments from the lateral earth pressure. The following procedure can be used to design the structural reinforcement.

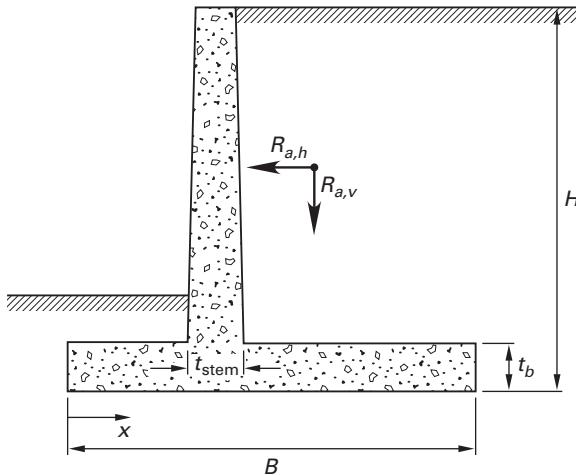

*step 1: Gather information needed to design the wall.  
(See Fig. 54.1.)*

$H$	wall height
$B$	base length
$t_b$	thickness of base
$b$	batter decrement (change in stem width per unit height)
$R_{a,h}$	horizontal active earth pressure resultant per unit wall width
$y_a$	height of the active earth pressure resultant
$R_{a,v}$	vertical active earth pressure resultant per unit wall width

*step 2: Select a reinforcement ratio to control deflections.*

$$\rho \approx 0.02$$

54.2

**Figure 54.1** Retaining Wall Dimensions (step 1)

*step 3:* Calculate a trial coefficient of resistance for the stem.

$$R_{u,\text{trial}} = \rho f_y \left( 1 - \left( \frac{\rho f_y}{(2)(0.85)f_c} \right) \right) \quad 54.3$$

*step 4:* Calculate the factored moment,  $M_{u,\text{stem}}$ , at the base of the stem per unit width,  $w$ , from the active earth pressure resultant. Include forces from surcharge loads, but disregard reductions from passive distributions.

$$M_{u,\text{stem}} = 1.6 R_{a,h} y_a \quad 54.4$$

*step 5:* Calculate the required stem thickness at the base. Since the ultimate moment is per unit, wall width,  $w$ , will be the width of that unit (e.g., 12 in for moments per foot or 1 m for moments per meter).  $\phi = 0.90$  for tension-controlled flexure. If  $\rho$  has been selected arbitrarily, the stem thickness will not be unique.

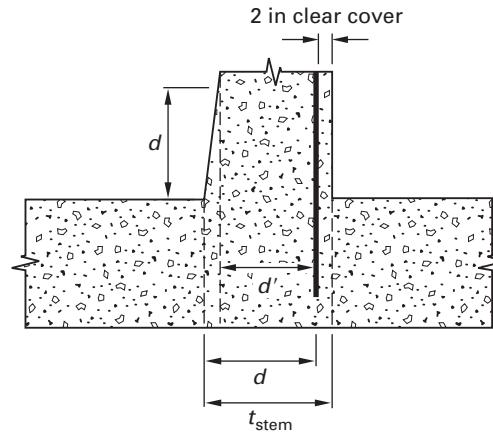

$$d = \sqrt{\frac{M_{u,\text{stem}}}{\phi R_u w}} \quad 54.5$$

2 in (51 mm) of cover is required for no. 6 bars or larger when exposed to earth or weather. (See Fig. 54.2.) The total thickness of the stem at the base is

$$t_{\text{stem}} = d + \text{cover} + \frac{1}{2}d_b \quad 54.6$$

*step 6:* Calculate the factored shear,  $V_{u,\text{stem}}$ , on the stem per unit width at the critical section. Include all of the active and surcharge pressure loading from the top of the retaining wall down to the critical section, a distance,  $d$ , from the base.

$$V_{u,\text{stem}} = 1.6 V_{\text{active}} + 1.6 V_{\text{surcharge}} \quad 54.7$$

**Figure 54.2** Base of Stem Details (step 5)

*step 7:* Calculate the unreinforced concrete shear strength for a unit wall width,  $w$ .  $\phi = 0.75$  for shear at the critical section a distance,  $d$ , from the bottom of the stem.  $d'$  is the thickness of the compression portion of the stem at a distance,  $d$ , from the bottom of the stem. (One-way shear is assumed.)  $d' = d$  when the batter decrement is zero. From ACI 318 Sec. 11.2.1.1,

$$\phi V_n = 2\phi w d' \lambda \sqrt{f'_c} \quad 54.8$$

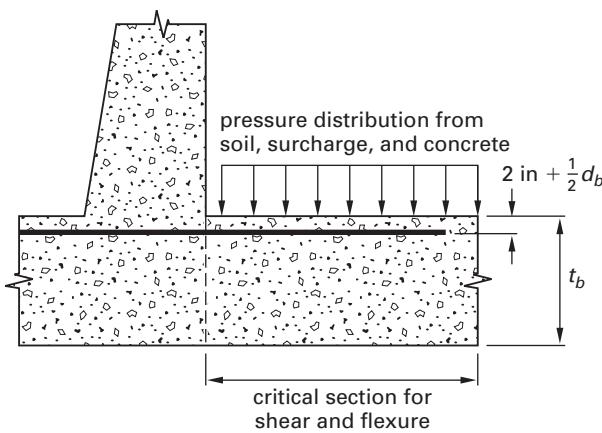

$\phi V_n$  is equivalent to  $\phi V_c$  since shear reinforcement is not provided. Note that Eq. 54.8 applies to normal weight concrete only. Necessary modifications to account for other concrete types are made using ACI 318 Sec. 11.9.5.

*step 8:* If  $\phi V_n \geq V_{u,\text{stem}}$ , the stem thickness is adequate. Otherwise, either the stem thickness must be increased or higher-strength concrete specified.

*step 9:* If the base design is not known, design the base heel as a cantilever beam. The procedure is similar to the previous steps. The critical section for shear checking is located at the face of the stem. (Since tension occurs in the heel, the critical section cannot be assumed to occur a distance,  $d$ , from the face of the stem. The entire heel contributes to  $V_u$  [ACI 318 Sec. 11.1.3]). Include shear for a unit width of base from the vertical active pressure, the surcharge, and the heel's self-weight. Disregard the upward pressure distribution as well as any effect the key has on the pressure distributions. (See Fig. 54.3.)

$$V_{u,\text{base}} = 1.2 V_{\text{soil}} + 1.2 V_{\text{heel weight}} + 1.6 V_{\text{surcharge}} \quad 54.9$$

$$M_{u,\text{base}} = 1.2 M_{\text{soil}} + 1.2 M_{\text{heel weight}} + 1.6 M_{\text{surcharge}} \quad 54.10$$

**Figure 54.3** Heel Details (step 9)

Since the base is cast against the earth, a specified cover of 3 in (76 mm) is required for reinforcing steel. If the base thickness,  $t_b$ , is significantly different from what was used to calculate  $M_u$ , a second iteration may be necessary.

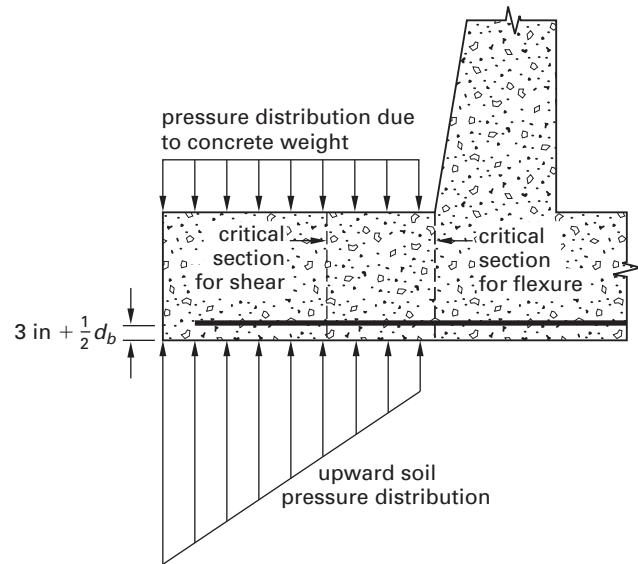

Complete the heel reinforcement design by calculating the development length. The distance from the face of the stem to the end of the heel reinforcement must equal or exceed the development length. The heel reinforcement must also extend a distance equal to the development length past the stem reinforcement into the toe.

**step 10:** The procedure for designing the toe is similar to that for the heel. The toe loading is assumed to be caused by the toe self-weight and the upward soil pressure distribution. The passive soil loading is disregarded. For one-way shear, the critical section is located a distance,  $d$ , from the outer face of the stem. For flexure, the critical section is at the outer face of the stem. (ACI 318 Sec. 9.2.1 specifies a factor of 1.2 for concrete and soil dead loads, and the factor is 1.6 for earth pressure. The toe soil pressure distribution is the result of the horizontal active earth pressure, so a factor of 1.6 is used.) It is likely that shear will determine the toe thickness. (See Fig. 54.4.)

$$V_{u,toe} = 1.6 V_{toe\ pressure} - 1.2 V_{toe\ weight} \quad 54.11$$

$$M_{u,toe} = 1.6 M_{toe\ pressure} - 1.2 M_{toe\ weight} \quad 54.12$$

An alternate interpretation, less conservative, is that the upward soil distribution is the result of two live loads, the active earth pressure, and the counteracting toe weight. This would result in forms of Eq. 54.11 and Eq. 54.12 that multiplied both terms by 1.7 or 1.6.

**Figure 54.4** Toe Details (step 10)

**step 11:** Calculate the reinforcement ratio,  $\rho$ , and the steel area,  $A_s$ . Select reinforcement to meet distribution requirements.

$$M_n = \frac{M_u}{\phi} = \rho f_y \left( 1 - \frac{\rho f_y}{(2)(0.85)f'_c} \right) bd^2 \quad 54.13$$

**step 12:** As the stem goes up, less reinforcement is required. Similar calculations should be performed at one or two other heights above the base to obtain a curve of  $M_u$  versus height. Select reinforcement to meet the moment requirements.

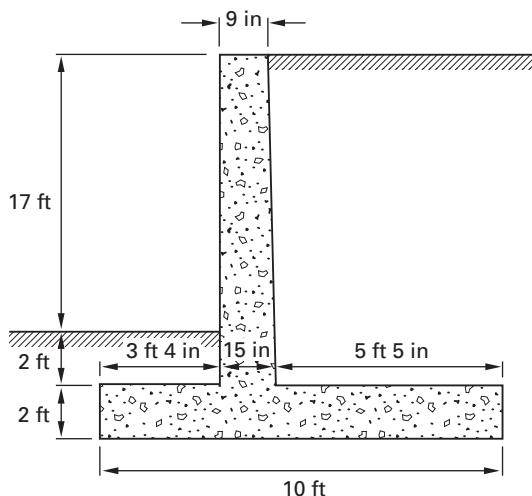

**step 13:** Check the development length of the stem reinforcement. (See Chap. 55.) The vertical stem height should be adequate without checking. However, it may be difficult to achieve full development in the base. The reinforcement can be extended into the key, if present. Otherwise hooks, bends, or smaller bars should be used.

**step 14:** Calculate the horizontal temperature and shrinkage reinforcement per unit width from the average stem thickness and the reinforcement ratios in ACI 318 Sec. 14.3.3. ACI 318 Sec. 14.3.4 requires that walls greater than 10 in (254 mm) thick have at least  $1/2$  and not more than  $2/3$  of this reinforcement placed in a layer on the exposed side. Allocate two-thirds of this reinforcement to the outside stem face, since that surface is alternately exposed to day and night temperature extremes. The remaining one-third should be located on the soil side of the stem, which is maintained at a more constant temperature by the insulating soil. Refer to ACI 318 Sec. 14.3.4 for specific face cover distances.

*step 15:* If the design assumed a drained backfill, provide for drainage behind the wall. Weep holes should be placed regularly.

### Example 54.1

The cantilever retaining wall shown supports 17 ft of earth above the toe of a cut. The backfill is level and has a unit weight of 100 lbf/ft<sup>3</sup>. The angle of internal friction is 35°. The allowable soil pressure under service loading is 5000 lbf/ft<sup>2</sup>. The coefficient of friction between the concrete and soil is 0.60. 3500 psi concrete and 60,000 psi steel are used. (a) What is the equivalent fluid pressure (density) behind the wall? (b) What is the active earth pressure resultant? (c) What is the overturning moment? (d) What is the resisting moment? (e) What is the factor of safety against overturning? (f) What is the factor of safety against sliding? (g) Is any part of the heel soil in tension? (h) What is the maximum pressure below the toe? (i) Specify the stem reinforcement. (j) Investigate the development length of the stem bars in the base. (k) Design the temperature steel for the stem. (l) Design the bending steel for the heel.

### Solution

(a) The active earth pressure coefficient is

$$k_a = \frac{1 - \sin \phi}{1 + \sin \phi} = \frac{1 - \sin 35^\circ}{1 + \sin 35^\circ} = 0.271$$

$$\begin{aligned}\gamma_{\text{equivalent}} &= k_a \gamma_{\text{soil}} \\ &= (0.271) \left( 100 \frac{\text{lbf}}{\text{ft}^3} \right) \\ &= 27.1 \frac{\text{lbf}}{\text{ft}^3}\end{aligned}$$

(b) The active height is

$$H = 17 \text{ ft} + 2 \text{ ft} + 2 \text{ ft} = 21 \text{ ft}$$

$$R_a = \frac{1}{2} k_a \gamma H^2$$

$$\begin{aligned}&= \frac{(0.5)(0.271) \left( 100 \frac{\text{lbf}}{\text{ft}^3} \right) (21 \text{ ft})^2}{1000 \frac{\text{lbf}}{\text{kip}}} \\ &= 5.976 \text{ kips/ft}\end{aligned}$$

(c) The overturning moment from the active resultant is

$$\begin{aligned}M_{\text{OT}} &= R_a y_a = R_a \left( \frac{H}{3} \right) \\ &= \left( 5.976 \frac{\text{kips}}{\text{ft}} \right) \left( \frac{21 \text{ ft}}{3} \right) \\ &= 41.83 \text{ ft-kips/ft}\end{aligned}$$

(d) Determine the weights per unit width (1 ft) and their moment arms (from the toe). Area 1 is the soil above the heel.

$$\begin{aligned}W_1 &= \frac{(5.5 \frac{\text{ft}}{12})(19 \text{ ft}) \left( 100 \frac{\text{lbf}}{\text{ft}^3} \right)}{1000 \frac{\text{lbf}}{\text{kip}}} \\ &= 10.29 \text{ kips/ft} \\ x_1 &= 10 \text{ ft} - \left( \frac{1}{2} \right) \left( 5.5 \frac{\text{ft}}{12} \right) = 7.29 \text{ ft} \\ M_1 &= W_1 x_1 = \left( 10.29 \frac{\text{kips}}{\text{ft}} \right) (7.29 \text{ ft}) \\ &= 75.01 \text{ ft-kips/ft}\end{aligned}$$

The other weights are found similarly.

area	weight (kips/ft)	moment arm (ft)	moment (ft-kips/ft)
1: heel soil	10.29	7.29	75.01
2: batter soil	0.48	4.42	2.12
3: batter stem	0.72	4.25	3.06
4: 9 in stem	2.14	3.71	7.92
5: base	3.0	5.00	15.0
totals	16.63 kips/ft		103.11 ft-kips/ft

(e) The factor of safety against overturning is

$$\begin{aligned}\text{FS}_{\text{OT}} &= \frac{M_R}{M_{\text{OT}}} = \frac{103.11 \frac{\text{ft-kips}}{\text{ft}}}{41.83 \frac{\text{ft-kips}}{\text{ft}}} \\ &= 2.46 \quad [> 1.5, \text{ so OK}]\end{aligned}$$

(f) The friction force resisting sliding is

$$R_{SL} = f \sum W_i = (0.60) \left( 16.63 \frac{\text{kips}}{\text{ft}} \right)$$

$$= 9.98 \text{ kips/ft}$$

$$FS_{SL} = \frac{9.98 \frac{\text{kips}}{\text{ft}}}{5.976 \frac{\text{kips}}{\text{ft}}}$$

$$= 1.67 \quad [> 1.5, \text{ so OK}]$$

(g) Locate the resultant from the toe.

$$x_R = \frac{M_R - M_{OT}}{\sum W_i}$$

$$= \frac{103.11 \frac{\text{ft-kips}}{\text{ft}} - 41.83 \frac{\text{ft-kips}}{\text{ft}}}{16.63 \frac{\text{kips}}{\text{ft}}}$$

$$= 3.685 \text{ ft}$$

Since the resultant acts in the middle third, there is no uplift on the footing. The heel soil is not in tension.

(h) The eccentricity is

$$\epsilon = \frac{10 \text{ ft}}{2} - 3.685 \text{ ft} = 1.31 \text{ ft}$$

Perform all calculations per foot of base width.

$$P = \sum W_i = 16.63 \text{ kips/ft}$$

$$A = 10 \text{ ft}^2/\text{ft}$$

$$M = (1.31 \text{ ft})(16.63 \text{ kips}) = 21.87 \text{ ft-kips/ft}$$

$$S = \frac{bh^2}{6} = \frac{(1 \text{ ft})(10 \text{ ft})^2}{6} = 16.67 \text{ ft}^3/\text{ft}$$

$$q = \frac{P}{A} \pm \frac{M}{S}$$

$$= \frac{16.63 \frac{\text{kips}}{\text{ft}}}{10 \frac{\text{ft}^2}{\text{ft}}} \pm \frac{21.87 \frac{\text{ft-kips}}{\text{ft}}}{16.67 \frac{\text{ft}^3}{\text{ft}}}$$

$$= 1.66 \text{ kips/ft}^2 \pm 1.31 \text{ kips/ft}^2$$

$$q_{\text{toe}} = 1.66 \frac{\text{kips}}{\text{ft}^2} + 1.31 \frac{\text{kips}}{\text{ft}^2} = 2.97 \text{ kips/ft}^2$$

$$q_{\text{heel}} = 1.66 \frac{\text{kips}}{\text{ft}^2} - 1.31 \frac{\text{kips}}{\text{ft}^2} = 0.35 \text{ kip/ft}^2$$

(i) Assume a 1 in diameter stem bar. Subtracting 2 in of cover for a formed surface, the effective depth of the wall is approximately

$$d \approx 15 \text{ in} - 2 \text{ in} - \frac{1 \text{ in}}{2} = 12.5 \text{ in}$$

The distance from the base to the critical stem section is also 12.5 in.

Calculate the factored shear at the critical section.

$$V_u = (1.6) \left( \frac{1}{2} \right) \gamma_{\text{equivalent}} L^2$$

$$= (1.6) \left( \frac{1}{2} \right) \left( 27.1 \frac{\text{lbf}}{\text{ft}^3} \right) \left( 21 \text{ ft} - 2 \text{ ft} - \frac{12.5 \text{ in}}{12 \frac{\text{in}}{\text{ft}}} \right)^2$$

$$= 6992 \text{ lbf/ft}$$

Assuming a 1 in diameter bar and considering the taper,

$$d' = 12.5 \text{ in} - \frac{\left( \frac{12.5 \text{ in}}{12 \frac{\text{in}}{\text{ft}}} \right) (15 \text{ in} - 9 \text{ in})}{17 \text{ ft} + 2 \text{ ft}}$$

$$= 12.2 \text{ in}$$

Use Eq. 54.8.

$$\phi V_n = 2\phi w d' \lambda \sqrt{f'_c}$$

$$= (2)(0.75)(12 \text{ in})(12.2 \text{ in})(1) \sqrt{3500 \frac{\text{lbf}}{\text{in}^2}}$$

$$= 12,992 \text{ lbf}$$

Since  $\phi V_n > V_u$ , the stem thickness is acceptable. The moment at the base of the stem is

$$M_u = (1.6) \left( \frac{1}{2} \right) \gamma_{\text{equivalent}} (H - t_b)^2 \left( \frac{H - t_b}{3} \right)$$

$$= (1.6) \left( \frac{1}{2} \right) \left( 27.1 \frac{\text{lbf}}{\text{ft}^3} \right) \left( \frac{(21 \text{ ft} - 2 \text{ ft})^3}{3} \right)$$

$$= 49,568 \text{ ft-lbf}$$

Estimate  $\lambda$ .

$$\lambda = 0.1d = (0.1)(12.5 \text{ in}) = 1.25 \text{ in}$$

$$\phi = 0.9 \text{ for beams in flexure}$$

Calculate the required stem steel.

$$\begin{aligned} A_s &= \frac{M_u}{\phi f_y(d - \lambda)} \\ &= \frac{(49,568 \text{ ft-lbf})(12 \frac{\text{in}}{\text{ft}})}{(0.90)(60,000 \frac{\text{lbf}}{\text{in}^2})(12.5 \text{ in} - 1.25 \text{ in})} \\ &= 0.98 \text{ in}^2 \quad [\text{per foot of wall}] \end{aligned}$$

This area can be provided with no. 9 bars at 12 in spacing.

(j) Check the development length. Refer to ACI 318 Sec. 12.2.2.  $\psi_t = 1$  (vertical bars),  $\psi_e = 1$  (uncoated), and  $\lambda = 1$  (normalweight concrete).

$$\begin{aligned} l_d &= \frac{d_b f_y \psi_t \psi_e}{20 \lambda \sqrt{f'_c}} \quad [\text{using no. 9 bars}] \\ &= \frac{(1.125 \text{ in})(60,000 \frac{\text{lbf}}{\text{in}^2})(1)(1)}{(20)(1)\sqrt{3500 \frac{\text{lbf}}{\text{in}^2}}} \\ &= 57 \text{ in} \end{aligned}$$

This is greater than the footing thickness. Either the footing thickness should be increased, hooks should be used on the ends of the stem bars, or a smaller-diameter bar should be used. A more sophisticated analysis can also be performed.

(k) Using 15 in as the stem thickness and assuming bars not larger than no. 5, conservatively the temperature steel required in the stem is

$$\begin{aligned} A_{s,\text{temperature}} &= 0.0020 b t_{\text{stem}} = (0.0020)(12 \text{ in})(15 \text{ in}) \\ &= 0.36 \text{ in}^2/\text{ft} \end{aligned}$$

Give two-thirds of this to the front face and one-third to the back face.

$$(\frac{2}{3})(0.36 \frac{\text{in}^2}{\text{ft}}) = 0.24 \text{ in}^2/\text{ft}$$

From Table 51.2, use no. 5 bars spaced at 12 in, or no. 4 bars spaced at 10 in.

$$(\frac{1}{3})(0.36 \frac{\text{in}^2}{\text{ft}}) = 0.12 \text{ in}^2/\text{ft}$$

From Table 51.2, use no. 4 bars spaced at 18 in, or no. 3 bars spaced at 10 in.

Place the temperature steel no closer than 2 in from the front face [ACI 318 Sec. 14.3.4].

(l) Disregard the soil pressure under the heel. Using ACI 318 Chap. 9, the factored uniform load above the heel is

$$\begin{aligned} w_u &= \frac{(1.2)(19 \text{ ft})(100 \frac{\text{lbf}}{\text{ft}^3}) + (2 \text{ ft})(150 \frac{\text{lbf}}{\text{ft}^3})}{1000 \frac{\text{lbf}}{\text{kip}}} \\ &= 2.64 \text{ kips/ft} \end{aligned}$$

Since the base is cast against earth, the bottom specified cover required is 3 in. The distance from the vertical stem steel to heel edge is

$$L = (5 \text{ ft } 5 \text{ in}) + 3 \text{ in} = 5 \text{ ft } 8 \text{ in} \quad (5.67 \text{ ft})$$

$$\begin{aligned} M_u &= \frac{1}{2} w_u L^2 = (\frac{1}{2})(2.64 \frac{\text{kips}}{\text{ft}})(5.67 \text{ ft})^2 \\ &= 42.4 \text{ ft-kips} \end{aligned}$$

The heel extension (from the stem's soil face) is

$$L = 5 \text{ ft } 5 \text{ in} \quad (5.42 \text{ ft})$$

$$V_u = w_u L = \left(2.64 \frac{\text{kips}}{\text{ft}}\right)(5.42 \text{ ft}) = 14.3 \text{ kips}$$

The heel flexural steel is located at the top. (See Fig. 54.3.) The top surface is not cast against the earth. The heel thickness is 2 ft. Assume a 1 in diameter bar will be used. The heel depth is

$$\begin{aligned} d &= t_{\text{heel}} - \text{top cover} - \frac{d_b}{2} \\ &= (2 \text{ ft})(12 \frac{\text{in}}{\text{ft}}) - 2 \text{ in} - \frac{1 \text{ in}}{2} \\ &= 21.5 \text{ in} \end{aligned}$$

$$\begin{aligned} \phi V_n &= 2\phi bd\sqrt{f'_c} \\ &= \frac{(2)(0.75)(12 \text{ in})(21.5 \text{ in})\sqrt{3500 \frac{\text{lbf}}{\text{in}^2}}}{1000 \frac{\text{lbf}}{\text{kip}}} \\ &= 22.9 \text{ kips} \quad [> V_u = 14.3 \text{ kips, so OK}] \end{aligned}$$

Solve for the required flexural steel using Eq. 54.13.

$$\begin{aligned} M_n &= \frac{M_u}{\phi} = \rho b d^2 f_y \left(1 - \frac{\rho f_y}{1.7 f'_c}\right) \\ &\quad \left(\frac{42.4 \text{ ft-kips}}{0.9}\right) \left(12 \frac{\text{in}}{\text{ft}}\right) \\ &= \rho(12 \text{ in})(21.5 \text{ in})^2 \left(60 \frac{\text{kips}}{\text{in}^2}\right) \\ &\quad \times \left(1 - \frac{\rho \left(60 \frac{\text{kips}}{\text{in}^2}\right)}{(1.7) \left(3.5 \frac{\text{kips}}{\text{in}^2}\right)}\right) \\ &= 0.0017 \end{aligned}$$

Per ACI 318 Sec. 14.1.2 and Sec. 10.5.1, the minimum reinforcement ratio is the larger of

$$\rho_{\min} = \frac{200}{f_y} = \frac{200}{60,000 \frac{\text{lbf}}{\text{in}^2}} = 0.0033 \quad [\text{controls}]$$

$$\rho_{\min} = \frac{3\sqrt{f'_c}}{f_y} = \frac{3\sqrt{3500 \frac{\text{lbf}}{\text{in}^2}}}{60,000 \frac{\text{lbf}}{\text{in}^2}} = 0.0030$$

The required steel area per foot of wall width is

$$A_s = \rho bd = (0.0033)(12 \text{ in})(21.5 \text{ in}) = 0.85 \text{ in}^2$$

This can be provided with no. 9 bars at 12 in spacing.

The minimum area requirements could have been neglected if ACI 318 Sec. 10.5.3 were followed. The reinforcement ratio required by design moment calculations ( $\rho = 0.002$ ) may be increased by a factor of  $1/3$  as long as the resulting reinforcement ratio is still below the specified minimum ( $\rho = 0.0033$ ). The lower reinforcement ratio would then be

$$\rho = (0.002)\left(1 + \frac{1}{3}\right) = 0.0027 \quad [< 0.0033]$$

Therefore, the steel area is

$$A_s = \rho bd = (0.0027)(12 \text{ in})(21.5 \text{ in}^2) = 0.70 \text{ in}^2$$

## Nomenclature

$A$	area	in <sup>2</sup>
$A_f$	base area of footing per ACI 318 Sec. 15.2.2	in <sup>2</sup>
$A_{ff}$	largest footing area geometrically similar to the column	in <sup>2</sup>
$A_{sd}$	area of steel parallel to the short direction in a rectangular footing	in <sup>2</sup>
$b$	dimension	in
$b_o$	punching shear area perimeter	in
$B$	one of the plan dimensions of a rectangular footing	in
$d$	effective footing depth (to steel layer)	in
$d_b$	diameter of a bar	in
$e$	distance from the critical section to the edge	in
$f'_c$	compressive strength of concrete	lbf/in <sup>2</sup>
$f_y$	yield strength of steel	lbf/in <sup>2</sup>
$h$	overall height (thickness) of footing	in
$H$	distance from soil surface to footing base	in
$I$	moment of inertia	in <sup>4</sup>
$J$	polar moment of inertia of punching shear surface	in <sup>4</sup>
$K_{tr}$	transverse reinforcement index	—
$l$	length of critical section	in
$L$	one of the plan dimensions of a rectangular footing	in
$M_s$	service moment	ft-kips
$M_u$	factored moment in a column at the junction with the footing	ft-kips
$N$	number	—
$P$	axial load	kips
$P_u$	column load or wall load per unit length (factored)	kips
$q$	footing load per unit length	lbf/ft
$q$	pressure under footing	lbf/ft <sup>2</sup>
$R$	factored resultant of soil pressure distribution	lbf
$t$	wall thickness	in
$v_n$	nominal concrete shear stress	lbf/in <sup>2</sup>
$v_u$	shear stress due to factored loads	lbf/in <sup>2</sup>

## Symbols

$\alpha$	strength enhancement factor	—
$\beta$	ratio of long side to short side of a footing	—
$\beta_c$	ratio of long side to short side of a column	—
$\gamma$	specific weight	lbf/ft <sup>3</sup>
$\gamma_v$	fraction of moment that affects the punching shear stress	—
$\epsilon$	load eccentricity	ft
$\lambda$	distance from centroid of compression area to extreme compression fiber	in
$\lambda$	lightweight aggregate factor	—
$\phi$	capacity reduction factor	—
$\psi_e$	epoxy coating factor	—
$\psi_s$	reinforcement size factor	—
$\psi_t$	reinforcement location factor	—

## Subscripts

$a$	allowable
$b$	bar
$brg$	head net bearing
$c$	compressive, concrete, or centroidal
$d$	dead or development
$db$	dowel bar
$dc$	compressive development
$dh$	development hooked
$dt$	development headed deformed
$f$	footing
$ff$	footing frustum
$g$	gross
$h$	hook
$l$	live
$n$	net or nominal
$p$	bearing or punching shear
$s$	soil, steel, or service
$sd$	short dimension
$u$	factored or ultimate
$v$	shear
$y$	yield

## 1. INTRODUCTION

Footings are designed in two steps: (a) selecting the footing area, and (b) selecting the footing thickness and reinforcement. The footing area is chosen so that the soil contact pressure is within limits. The footing thickness and the reinforcement are chosen to keep the shear and bending stresses in the footing within permissible limits.

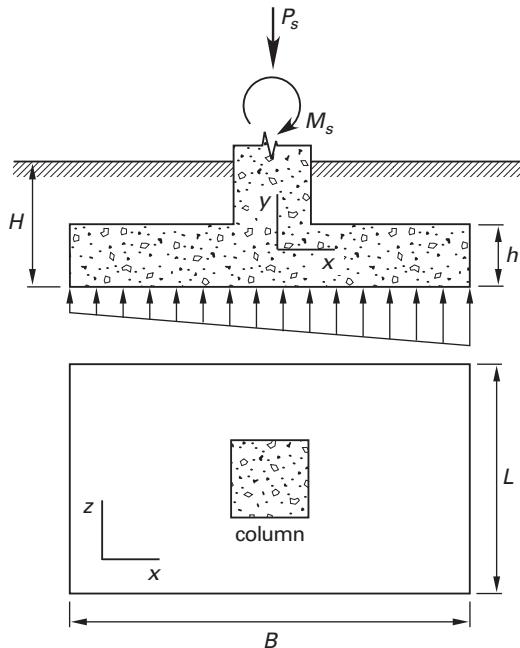

Although the footing area is obtained from the unfactored service loads, the footing thickness and reinforcement are calculated from factored loads. This is because the weight of the footing and the overburden contribute to the contact stress, but these forces do not induce shears or bending moments in the footing.

Figure 55.1 illustrates the general case of a footing with dimensions  $L$  and  $B$  carrying a vertical (downward) axial service load,  $P_s$ , and a service moment,  $M_s$ . For such cases, the maximum and minimum service soil pressures are given by Eq. 55.1.

$$q_s = \frac{P_s}{A_f} + \gamma_c h + \gamma_s (H - h) \pm \frac{M_s (\frac{B}{2})}{I_f} \leq q_a \quad 55.1$$

$$I_f = \frac{1}{12} LB^3 \quad 55.2$$

**Figure 55.1** General Footing Loading

## 2. WALL FOOTINGS

For a wall footing, the factored load per unit length at failure is

$$q_u = \frac{P_u}{B} \quad 55.3$$

The factored load is

$$P_u = 1.2P_d + 1.6P_l \quad 55.4$$

The critical plane for shear is assumed to be located a distance,  $d$  (the effective footing depth), from the wall face, where  $d$  is measured to the center of the flexural steel layer. (See Fig. 55.2.) The thickness of wall footings

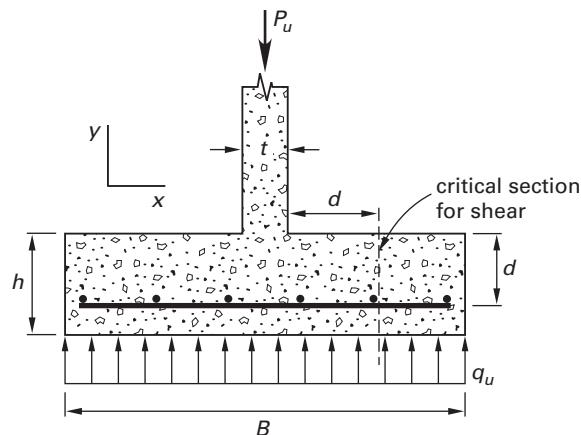

is selected to satisfy the shear stress requirement of Eq. 55.5.  $v_u$  is the shear stress at a distance,  $d$ , from the face of the wall;  $v_n$  is the shear stress of the concrete. For shear,  $\phi = 0.75$ . From ACI 318 Sec. 11.1.1 and Sec. 11.2.1,

$$\phi V_n \geq V_u \quad 55.5$$

$$V_n = V_c + V_s \quad 55.6$$

$$V_c = v_c L d = 2\lambda \sqrt{f'_c} L d \quad 55.7$$

**Figure 55.2** Critical Section for Shear in Wall Footing

The *lightweight aggregate factor*,  $\lambda$ , is 0.75 for all-lightweight concrete, 0.85 for sand-lightweight concrete, and 1.0 for normalweight concrete. (See Sec. 48.11.)

Referring to Fig. 55.2, the shear stress at the critical section is

$$v_u = \frac{q_u}{d} \left( \frac{B - t}{2} - d \right) \quad 55.8$$

Combining Eq. 55.5 and Eq. 55.8,

$$d = \frac{q_u(B - t)}{2(q_u + \phi v_n)} \quad 55.9$$

In a wall footing, the main steel ( $x$ -direction) resists flexure and is perpendicular to the wall face. Orthogonal steel ( $z$ -direction) runs parallel to the wall and is placed in contact with the main steel. The total thickness of the wall footing is

$$h = d + \frac{1}{2}(\text{diameter of } x \text{ bars}) + \text{diameter of } z \text{ bars} + \text{cover} \\ \left[ \begin{array}{l} \text{orthogonal reinforcement} \\ \text{under main steel} \end{array} \right] \quad 55.10(a)$$

$$h = d + \frac{1}{2}(\text{diameter of } x \text{ bars}) + \text{cover} \\ \left[ \begin{array}{l} \text{orthogonal reinforcement} \\ \text{over main steel} \end{array} \right] \quad 55.10(b)$$

The specified cover (below the bars) for cast-in-place concrete cast against and permanently exposed to earth is 3 in [ACI 318 Sec. 7.7.1]. The minimum depth above the bottom reinforcement is 6 in [ACI 318 Sec. 15.7]. Therefore, the minimum total thickness of a footing is

$$\begin{aligned} h &\geq 6 \text{ in} + \text{diameter of } x \text{ bars} \\ &+ \text{diameter of } z \text{ bars} + 3 \text{ in} \end{aligned} \quad 55.11$$

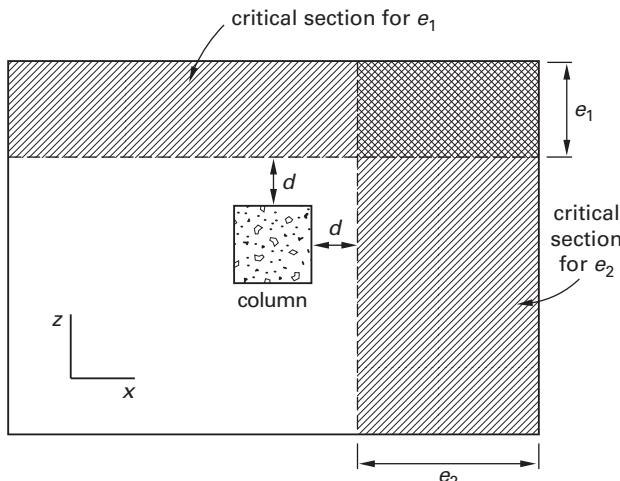

### 3. COLUMN FOOTINGS

The effective depth,  $d$  (and thickness,  $h$ ), of column footings is controlled by shear strength. Two shear failure mechanisms are considered: one-way shear and two-way shear. The footing depth is taken as the larger of the two values calculated. In the majority of cases, the required depth is controlled by two-way shear.

For *one-way shear* (also known as *single-action shear* and *wide-beam shear*), the critical sections are a distance,  $d$ , from the face of the column. (See Fig. 55.3.) Equation 55.12 applies for the case of uniform pressure distribution (i.e., where there is no moment). The section with the largest values of  $e$  controls.

$$v_u = \frac{q_u e}{d} \quad 55.12$$

**Figure 55.3 Critical Section for One-Way Shear**

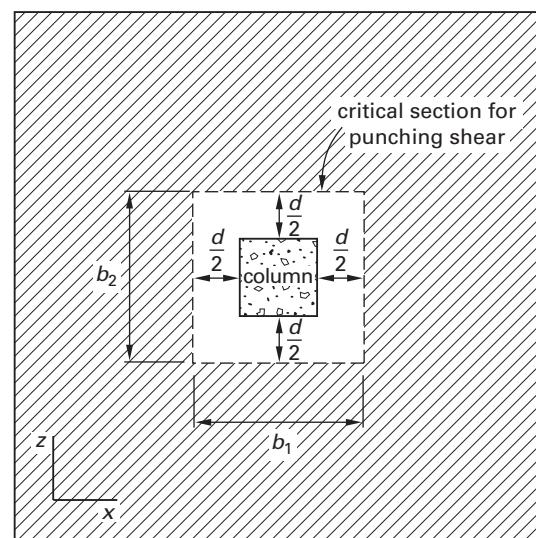

In addition to the footing failing in shear as a wide beam, failure can also occur in *two-way shear* (also known as *double-action shear* and *punching shear*). In this failure mode, the column and an attached concrete piece punch through the footing. Although the failure plane is actually inclined outward, the failure surface is assumed for simplicity to consist of vertical planes located a distance  $d/2$  from the column sides. (See Fig. 55.4.)

The area in punching is given by Eq. 55.13.  $b_1$  is the length of the critical area parallel to the axis of the

applied column moment. Similarly,  $b_2$  is the length of the critical area normal to the axis of the applied column moment.

$$A_p = 2(b_1 + b_2)d \quad 55.13$$

**Figure 55.4 Critical Section for Two-Way Shear**

Assume for generality that the column supports a moment. The maximum shear stress on the critical shear plane is computed as the sum of the shear stresses resulting from the axial load and the moment. The punching shear stress is given by Eq. 55.14 [ACI 318 Sec. R11.11.7.2].

$$\begin{aligned} v_u &= \frac{V_u}{A_c} + \frac{\gamma_v M_u c}{J_c} \\ &= \frac{P_u - R}{A_p} + \frac{\gamma_v M_u (0.5 b_1)}{J_c} \end{aligned} \quad 55.14$$

In Eq. 55.14,  $R$  is the resultant of the factored soil pressure acting over the area  $b_1 b_2$ . The stresses from the moment cancel over this area, so  $R$  is

$$R = \frac{P_u b_1 b_2}{A_f} \quad 55.15$$

$\gamma_v$  is the fraction of the moment  $M_u$  that is assumed to contribute to shear stress [ACI 318 Sec. 11.11.7.1 and Sec. 13.5.3.2]. The remaining fraction,  $1 - \gamma_v$ , of the moment  $M_u$  is resisted by bending action.

$$\gamma_v = 1 - \frac{1}{1 + \frac{2}{3} \sqrt{\frac{b_1}{b_2}}} \quad 55.16$$

When the column is located at the center of the footing, the constant  $J_c$  is given by Eq. 55.17 [ACI 318 Fig. R11.11.7.2].

$$J_c = \frac{db_1^3}{6} \left( 1 + \left( \frac{d}{b_1} \right)^2 + 3 \left( \frac{b_2}{b_1} \right) \right) \quad 55.17$$

The nominal concrete shear stress for punching shear is given by Eq. 55.18.

$$v_n = (2 + y) \lambda \sqrt{f'_c} \quad 55.18$$

$$y = \min \{2, 4/\beta_c, 40d/b_o\} \quad 55.19$$

$$\beta_c = \frac{\text{column long side}}{\text{column short side}} \quad 55.20$$

$$b_o = \frac{A_p}{d} = 2(b_1 + b_2) \quad 55.21$$

Determining the footing thickness is accomplished through trial and error. Obtain the required depth for punching shear using the following procedure.

*step 1:* Assume a value of  $d$ .

*step 2:* Compute  $b_1$  and  $b_2$ .

*step 3:* Evaluate  $A_p$ ,  $J_c$ , and  $\gamma_v$ .

*step 4:* Compute  $R$ .

*step 5:* Compute  $v_u$ .

*step 6:* Calculate  $v_n$ .

*step 7:* If  $v_u \geq \phi v_n$ , increase  $d$  and repeat from step 2.

If  $v_u < \phi v_n$ , the punching shear strength is adequate. If the excess in capacity is substantial, reduce  $d$  and repeat from step (2).

Check the adequacy of the footing depth for one-way shear.

The effective depth for shear is typically assumed to be the distance from the top of the footing to the average depth of the two perpendicular steel reinforcement layers. (The two steel layers may use different bar diameters, so the average depth may not correspond to the contact point.) The total thickness of a column footing is

$$h = d + \frac{1}{2}(\text{diameter of } x \text{ bars} + \text{diameter of } z \text{ bars}) + \text{cover} \quad 55.22$$

As with wall footings, the specified cover (below the bars) for cast-in-place concrete cast against and permanently exposed to earth is 3 in [ACI 318 Sec. 7.7.1]. The minimum depth above the bottom reinforcement is 6 in [ACI 318 Sec. 15.7]. Therefore, the minimum total thickness of a footing is

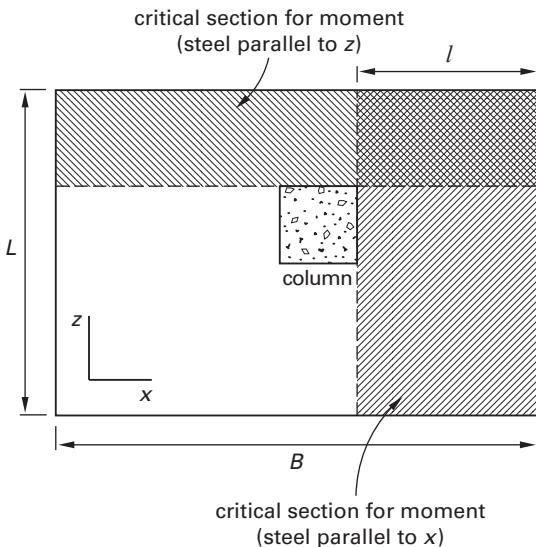

$$h \geq 6 \text{ in} + \text{diameter of } x \text{ bars} + \text{diameter of } z \text{ bars} + 3 \text{ in} \quad 55.23$$

#### 4. SELECTION OF FLEXURAL REINFORCEMENT

For the purpose of designing flexural reinforcement, spread footings are treated as cantilever beams carrying an upward-acting, nonuniform distributed load. The critical section for flexure is located at the face of the column or wall. (See Fig. 55.5.) (Masonry walls are exceptions. The critical section is halfway between the center and the edge of the wall [ACI 318 Sec. 15.4.2].) The moment acting at the critical section from a uniformly distributed soil pressure distribution (i.e., as when there is no column moment) is

$$M_u = \frac{q_u L t^2}{2} \quad [\text{no column moment}] \quad 55.24$$

**Figure 55.5** Critical Section for Moment

The required steel area is given by Eq. 55.25. As with beams, a good starting point is  $\lambda = 0.1d$ .

$$A_s = \frac{M_u}{\phi f_y(d - \lambda)} \quad 55.25$$

The effective depth of the flexural reinforcement will differ in each perpendicular direction. However, it is customary to design both layers using a single effective depth. While the conservative approach is to use the smaller effective depth for both layers, it is not unusual in practice to design the steel in the  $x$  and  $z$  directions based on the average effective depth.

The following provisions apply.

- According to ACI 318 Sec. 10.5.4, for footings of uniform thickness, the minimum area of tension reinforcement in the direction of the span is the same as that required by ACI 318 Sec. 7.12.2.1. The maximum spacing of this reinforcement is not to exceed three times the thickness nor 18 in. The minimum steel ratio (based on the gross cross-sectional area) in any direction is 0.002 for  $f_y = 40$  kips/in<sup>2</sup> and

50 kips/in<sup>2</sup> steel and is 0.0018 for  $f_y = 60$  kips/in<sup>2</sup> steel [ACI 318 Sec. 7.12.2.1].

- In one-way wall footings and square two-way footings, the steel is distributed uniformly [ACI 318 Sec. 15.4.3].
- In rectangular two-way footings, the steel parallel to the long dimension,  $A_s$ , is distributed uniformly. However, the total steel parallel to the short dimension,  $A_{sd}$ , is divided into two parts [ACI 318 Sec. 15.4.4.2].

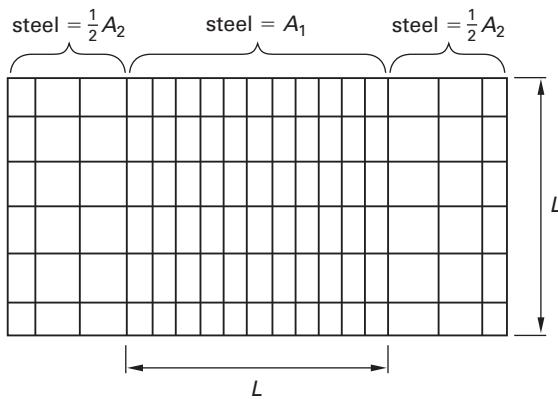

$$A_1 = A_{sd} \left( \frac{2}{\beta + 1} \right) \quad 55.26$$

$$A_2 = A_{sd} - A_1 \quad 55.27$$

$\beta$  is the ratio of the long footing side to the short footing side. The steel area  $A_1$  is distributed uniformly in a band centered on the column and having a width equal to the short dimension of the footing. The area  $A_2$  is distributed uniformly in the remaining part of the footing. (See Fig. 55.6.)

- The maximum spacing center-to-center of bars cannot exceed the lesser of  $3h$  (three times the overall footing thickness) or 18 in [ACI 318 Sec. 10.5.4]. (The 18 in maximum spacing usually controls in footings.)
- The steel bars must be properly anchored.

**Figure 55.6** Distribution of Steel (parallel to the short dimension)

## 5. DEVELOPMENT LENGTH OF FLEXURAL REINFORCEMENT

Either ACI 318 Sec. 12.2.2 or Sec. 12.2.3 can be used to calculate the development length in concrete of straight deformed bars of diameter  $d_b$  in tension. However, both sections offer a number of complex alternatives and require knowledge that may not be available. The simpler section [ACI 318 Sec. 12.2.2] contains four development length equations for straight bars in tension in concrete. The appropriate equation varies based on bar size, clear spacing, and clear cover. Equation 55.28 and Eq. 55.29 are used when: (a) the clear spacing and cover are greater than  $d_b$ , and stirrups and ties throughout the development length are not less

than the minimum required by ACI 318; or (b) clear spacing is greater than  $2d_b$ , and clear cover is greater than  $d_b$ . Equation 55.30 and Eq. 55.31 are used in all other cases. Regardless of the equation used, the development length must not be less than 12 in.

$$l_d = \frac{dbf_y\psi_t\psi_e}{25\lambda\sqrt{f'_c}} \geq 12 \text{ in} \quad [\text{no. 6 bars and smaller}] \quad 55.28$$

$$l_d = \frac{dbf_y\psi_t\psi_e}{20\lambda\sqrt{f'_c}} \geq 12 \text{ in} \quad [\text{no. 7 bars and larger}] \quad 55.29$$

$$l_d = \frac{3dbf_y\psi_t\psi_e}{50\lambda\sqrt{f'_c}} \geq 12 \text{ in} \quad \begin{cases} \text{no. 6 bars and smaller;} \\ \text{Eq. 55.27 requirements} \\ \text{not met} \end{cases} \quad 55.30$$

$$l_d = \frac{3dbf_y\psi_t\psi_e}{40\lambda\sqrt{f'_c}} \geq 12 \text{ in} \quad \begin{cases} \text{no. 7 bars and larger;} \\ \text{Eq. 55.28 requirements} \\ \text{not met} \end{cases} \quad 55.31$$

Using ACI 318 Sec. 12.2.3, the development length is calculated using Eq. 55.32 [ACI 318 Eq. 12-1].

$$l_d = \frac{3dbf_y\psi_t\psi_e\psi_s}{40\lambda\sqrt{f'_c}\left(\frac{c_b + K_{tr}}{d_b}\right)} \geq 12 \text{ in} \quad 55.32$$

$(c_b + K_{tr})/d_b$  is called the *confinement term* and must be less than or equal to 2.5.  $c_b$  is the smaller of the distance from the center of the bar to the nearest concrete surface, or one-half of the center-to-center spacing.

The *transverse reinforcement index*,  $K_{tr}$ , is found from Eq. 55.33.  $N$  is the number of bars or wires that are spliced or that develop along the splitting plane,  $s$  is the center-to-center spacing, and  $A_{tr}$  is the total transverse reinforcement area. To simplify design, a value of 0 may be used for  $K_{tr}$  even if transverse reinforcement is present [ACI 318 Sec. 12.2.3].

$$K_{tr} = \frac{40A_{tr}}{sN} \quad 55.33$$

The *epoxy coating factor*,  $\psi_e$ , the *reinforcement size factor*,  $\psi_s$ , the *reinforcement location factor*,  $\psi_t$ , and the *lightweight aggregate factor*,  $\lambda$ , are given in ACI 318 Sec. 12.2.4. The product of  $\psi_t\psi_e$  need not exceed 1.7.

$\psi_e = 1.5$	epoxy-coated, cover $\leq 3d_b$ , or clear spacing $\leq 6d_b$
$\psi_e = 1.2$	for all other epoxy-coated bars
$\psi_e = 1.0$	uncoated and zinc-coated (galvanized) bars
$\psi_s = 0.8$	for no. 6 or smaller bars
$\psi_s = 1.0$	for no. 7 or larger bars
$\psi_t = 1.3$	development length or splice $> 12$ in above fresh cast concrete (top bars)
$\psi_t = 1.0$	for all other situations (bottom bars)
$\lambda = 0.75$	lightweight concrete
$\lambda = 1.0$	normalweight concrete

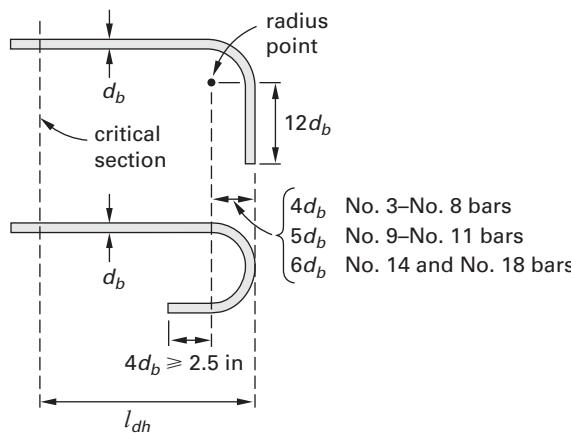

Equation 55.34 can be used for bars in tension with standard hooks [ACI 318 Sec. 12.5]. (See Fig. 55.7.)

$$l_{dh} = \frac{0.02\psi_e d_b f_y}{\lambda \sqrt{f'_c}} \geq 8d_b \geq 6 \text{ in} \quad [\text{hooked bars}] \quad 55.34$$

For Eq. 55.34 only, the epoxy coating factors are given in ACI 318 Sec. 12.5.2 as shown. The lightweight aggregate factors are unchanged.

- $\psi_e = 1.2$  for epoxy-coated
- $\psi_e = 1.0$  for all other cases

**Figure 55.7** Standard Hooks

Used with permission of the American Concrete Institute.

In lieu of using hooked bar anchorages in areas where steel reinforcement may become congested, ACI 318 Sec. 12.6 permits the use of *headed deformed bars*, which contain heads attached at one or both ends. For bars in tension, the heads allow the bars to achieve the required development length in a shorter length than that typically required for standard hooked bars.

Headed deformed bars may only be used if all conditions given in ACI 318 Sec. 12.6 are satisfied.

1. The specified yield strength of the reinforcement,  $f_y$ , does not exceed 60,000 lbf/in<sup>2</sup>.
2. The bar size is no. 11 or smaller.
3. Normalweight concrete is used.
4. The net bearing area of the heads,  $A_{brg}$ , is greater than or equal to  $4A_b$ .
5. The clear cover is greater than or equal to  $2d_b$ .
6. The clear spacing between bars is greater than or equal to  $4d_b$ .

From ACI 318 Sec. 12.6.2, the development length for headed deformed bars in tension is

$$l_{dt} = \frac{0.016d_b f_y \psi_e}{\sqrt{f'_c}} \geq 8d_b \text{ or } 6 \text{ in} \quad 55.35$$

The epoxy coating factors for Eq. 55.35 are the same as those used for Eq. 55.34. The concrete compressive strength must be less than or equal to 6000 lbf/in<sup>2</sup>.

## 6. TRANSFER OF FORCE AT COLUMN BASE

Column and wall forces are transferred to footings by direct bearing and by forces in steel bars. The steel bars used to transfer forces from one member to the other are known as *dowels* or *dowel bars*. Dowel bars are left to extend above the footing after the footing concrete has hardened, and they are spliced into the column or wall reinforcement prior to pouring the column or wall concrete.

It is common practice to use at least four dowel bars in a column. Where a significant moment must be transferred from a column to a footing, the dowel steel provided is typically chosen to match the column steel. Generally, the number of dowels and longitudinal bars are equal. The minimum dowel area is [ACI 318 Sec. 15.8.2.1]

$$A_{db,min} = 0.005A_g \quad 55.36$$

The dowels must extend into the footing no less than the *compressive development length*,  $l_{dc}$ , of the dowels [ACI 318 Sec. 12.3.2]. For straight bars in compression,

$$l_{dc} = \left( \frac{0.02d_b}{\lambda} \right) \left( \frac{f_y}{\sqrt{f'_c}} \right) \geq 0.0003d_b f_y \\ \geq 8 \text{ in} \quad 55.37$$

If the dowel bar is bent in an L-shape, the development length must be achieved over the vertical portion. (While hooks and bends can be used to decrease the required development length for dowels acting in tension, hooks and bends are ineffective for compressive forces.) Since lap splices are considered to be class-B splices [ACI 318 Sec. 12.15.2], the dowel bar must extend into the column or wall 1.3 times the development length of the dowel or 1.3 times the development length of the bar in the column or wall, whichever is larger [ACI 318 Sec. 12.15.1].

The footing thickness sets a limit on the length of dowel that is effective. If the footing depth is less than the development length, smaller bars must be used. The maximum effective dowel length is

$$l_d \leq h - \text{cover} - \text{diameter of } x \text{ steel} \\ - \text{diameter of } z \text{ steel} \quad 55.38$$

The maximum bearing strength of column concrete is  $f_{bearing} = 0.85f'_c$  [ACI 318 Sec. 10.14.1]. The load carried by bearing on the column is given by Eq. 55.39. Note that in ACI 318,  $A_c$  is  $A_1$ .

$$P_{bearing,column} = 0.85\phi f'_{c,column} A_c \quad 55.39$$

However, the effective bearing capacity of the footing is actually greater than  $f_{bearing}A_c$ , since a redistribution of

stressed area over the larger footing area will increase the effective allowable bearing load. The load carried by bearing on the footing concrete is given by Eq. 55.40 [ACI 318 Sec. 10.14.1]. For bearing on concrete, as in Eq. 55.39 and Eq. 55.40,  $\phi = 0.65$  [ACI 318 Sec. 9.3.2.4].

$$P_{\text{bearing,footing}} = 0.85\alpha\phi f'_{c,\text{footing}} A_c \quad 55.40$$

$\alpha$  accounts for the enhancement in the capacity of the concrete that results because the loaded area is only a fraction of the total area of the footing.

$$\alpha = \sqrt{\frac{A_{ff}}{A_c}} \leq 2 \quad 55.41$$

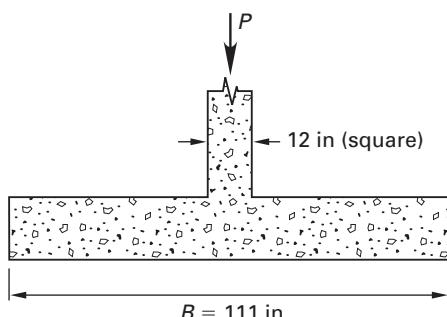

If the footing thickness and geometry are such that the frustum requirements of ACI 318 Sec. 10.14.1 are satisfied,  $A_{ff}$  ( $A_2$  in ACI 318) is the largest footing area that is geometrically similar to the column starting at the edges of the column, at a slope of 1:2 (vertical:horizontal) down to the footing base, and that does not extend beyond any of the edges of the footing [ACI 318 Sec. 10.14.1]. For a square column and square footing,  $A_{ff}$  is not permitted to exceed four times the bearing area ( $A_1$  in ACI 318). ACI 318 Fig. R10.14 depicts this limitation.

For the case of pure axial loading (no moment), the required area of the dowel bars is given by Eq. 55.42, in which  $\phi$  has a value of 0.65.

$$A_{db} = \frac{P_u - \text{smaller of } \left\{ \begin{array}{l} P_{\text{bearing,column}} \\ P_{\text{bearing,footing}} \end{array} \right\}}{\phi f_y} \geq A_{db,\min} \quad 55.42$$

### Example 55.1

A 111 in square footing supports a 12 in square column. The service loads are 82.56 kips dead load and 75.4 kips live load. Normalweight concrete is used. Material properties are  $f'_c = 4000$  lbf/in<sup>2</sup> and  $f_y = 60,000$  lbf/in<sup>2</sup>. Design the footing depth and reinforcement.

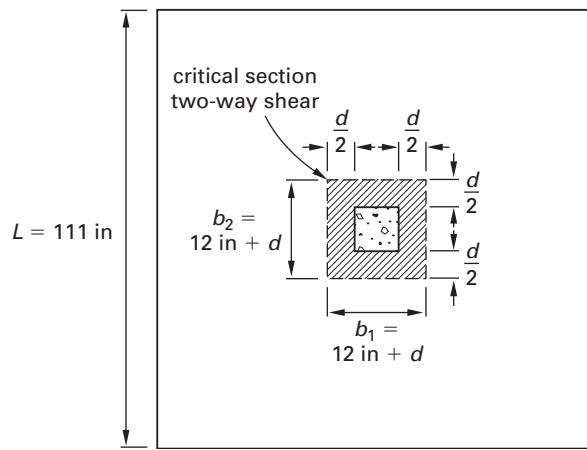

*Solution*

step 1: Assume punching shear controls the depth.

$$b_1 = b_2 = 12 \text{ in} + (2)\left(\frac{d}{2}\right) = 12 \text{ in} + d$$

The area resisting the punching shear is given by Eq. 55.13.

$$A_p = 2(b_1 + b_2)d = 2(12 \text{ in} + d + 12 \text{ in} + d)d = 48d + 4d^2$$

The factored load is

$$\begin{aligned} P_u &= 1.2P_d + 1.6P_l \\ &= (1.2)(82.56 \text{ kips}) + (1.6)(75.4 \text{ kips}) \\ &= 219.71 \text{ kips} \end{aligned}$$

The upward force from the soil pressure that acts to reduce the total punching shear force is given by Eq. 55.15.

$$\begin{aligned} R &= \frac{P_u b_1 b_2}{A_f} \\ &= \frac{(219.71 \text{ kips})(12 \text{ in} + d)(12 \text{ in} + d)}{(111 \text{ in})^2} \\ &= \left(0.0178 \frac{\text{kip}}{\text{in}^2}\right)(12 \text{ in} + d)^2 \end{aligned}$$

There is no moment. The punching shear stress is given by Eq. 55.14.

$$\begin{aligned} v_u &= \frac{P_u - R}{A_p} \\ &= \frac{219.71 \text{ kips} - \left(0.0178 \frac{\text{kips}}{\text{in}^2}\right)(12 \text{ in} + d)^2}{48d + 4d^2} \end{aligned}$$

Using  $y = 2$ , the allowable stress for punching shear is given by Eq. 55.18.

$$\begin{aligned} v_n &= (2 + y)\lambda\sqrt{f'_c} = (2 + 2)(1.0)\sqrt{4000 \frac{\text{lbf}}{\text{in}^2}} \\ &= 252.98 \text{ lbf/in}^2 \end{aligned}$$

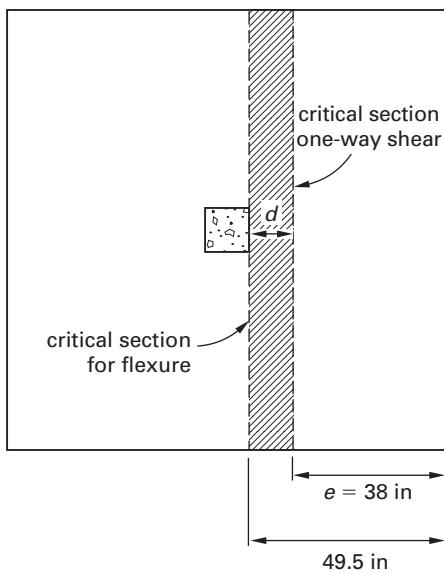

Equate the capacity to the shear stress. From Eq. 55.5,

$$\begin{aligned} \phi v_n &= v_u \\ \frac{(0.75)(252.98 \text{ lbf/in}^2)}{1000 \text{ lbf/kip}} &= \frac{219.71 \text{ kips} - \left(0.0178 \frac{\text{kips}}{\text{in}^2}\right)(12 \text{ in} + d)^2}{48d + 4d^2} \\ d &= 11.7 \text{ in} \\ b_o &= 2(b_1 + b_2) = (2)(2)(12 \text{ in} + d) \\ &= (2)(2)(12 \text{ in} + 11.7 \text{ in}) \\ &= 94.8 \text{ in} \\ \frac{40d}{b_o} &= \frac{(40)(11.5 \text{ in})}{94.8 \text{ in}} = 4.85 > 2 \end{aligned}$$

*step 2:* Check the capacity of the footing in one-way shear.

The critical section for one-way shear is at a distance,  $d$ , from the face of the column.

$$\begin{aligned} e &= (0.5)(111 \text{ in} - 12 \text{ in}) - d \\ &= (0.5)(111 \text{ in} - 12 \text{ in}) - 11.7 \text{ in} \\ &= 37.8 \text{ in} \end{aligned}$$

The soil contact pressure is

$$\begin{aligned} q_u &= \frac{P_u}{A_f} = \frac{219.71 \text{ kips}}{(111 \text{ in})^2} \\ &= 0.0178 \text{ kip/in}^2 \end{aligned}$$

The shear stress at the critical section is given by Eq. 55.12.

$$\begin{aligned} v_u &= \frac{q_u e}{d} \\ &= \frac{\left(0.0178 \frac{\text{kips}}{\text{in}^2}\right)(37.8 \text{ in})(1000 \frac{\text{lbf}}{\text{kip}})}{11.7 \text{ in}} \\ &= 57.51 \text{ lbf/in}^2 \end{aligned}$$

The nominal shear stress capacity for one-way shear is given by Eq. 55.7.

$$\begin{aligned} v_n &= 2\lambda\sqrt{f'_c} = (2)(1.0)\sqrt{4000 \frac{\text{lbf}}{\text{in}^2}} \\ &= 126.49 \text{ lbf/in}^2 \end{aligned}$$

Compare  $v_u$  and  $\phi v_n$  to determine if the value of  $d$  is adequate.

$$\begin{aligned} 57.51 \frac{\text{lbf}}{\text{in}^2} &< (0.75)\left(126.49 \frac{\text{lbf}}{\text{in}^2}\right) \\ &= 94.87 \text{ lbf/in}^2 \end{aligned}$$

*step 3:* Design the flexural reinforcement.

Assuming no. 6 bars and taking the average for both layers, the overall depth of the footing is

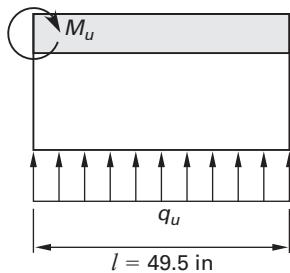

$$h = 11.7 \text{ in} + 0.75 \text{ in} + 3.0 \text{ in} = 15.45 \text{ in}$$

It is customary to use a footing depth that is rounded to the nearest inch. Use  $h = 16$  in. Using no. 6 bars, the actual (average) effective depth is

$$d = 16 \text{ in} - 3 \text{ in} - 0.75 \text{ in} = 12.25 \text{ in}$$

The critical section for moment is at the face of the column. From the free-body diagram,

$$\begin{aligned} M_u &= \frac{q_u L l^2}{2} \\ &= \frac{\left(0.0178 \frac{\text{kips}}{\text{in}^2}\right)(111 \text{ in}) \times (49.5 \text{ in})^2}{2} \\ &= 2420.6 \text{ in-kips} \end{aligned}$$

The minimum steel is

$$\begin{aligned} A_{s,\min} &= (0.0018)(111 \text{ in})(16 \text{ in}) \\ &= 3.20 \text{ in}^2 \quad [\text{does not control}] \end{aligned}$$

*step 4:* Check the development length of the flexural reinforcement. For uncoated no. 6 bars, using Eq. 55.30, where  $\psi_t = 1.0$ ,  $\psi_e = 1.0$ , and  $\lambda = 1.0$  per ACI 318 Sec. 12.2.4,

$$\begin{aligned} l_d &= \frac{3d_b f_y \psi_t \psi_e}{50\lambda \sqrt{f'_c}} \\ &= \frac{(3)(0.75 \text{ in}) \left( 60,000 \frac{\text{lbf}}{\text{in}^2} \right) (1.0)}{(50)(1.0) \sqrt{4000 \frac{\text{lbf}}{\text{in}^2}}} \\ &= 42.7 \text{ in} \end{aligned}$$

The available distance for development (with a 2 in cover at the tip of the bar) is  $49.5 \text{ in} - 2 \text{ in} = 47.5 \text{ in}$ . Since the available distance exceeds  $l_d$ , the anchorage is adequate. From Table 50.3, use 10 no. 6 bars spaced evenly in each direction (providing  $4.40 \text{ in}^2$ ). Using 2 in end cover on each bar end, the spacing is

$$\begin{aligned} &\frac{111 \text{ in} - (2)(2 \text{ in}) - (10 \text{ bars})(0.75 \text{ in})}{9 \text{ gaps}} \\ &= 11 \text{ in} > 2d_b \end{aligned}$$

The spacing does not exceed the maximum permissible value of 18 in.

As with beams, start by assuming  $\lambda$ .

$$\lambda = 0.1d = (0.1)(12.25 \text{ in}) = 1.22 \text{ in}$$

The steel area is given by Eq. 55.25.

$$\begin{aligned} A_s &= \frac{M_u}{\phi f_y(d - \lambda)} \\ &= \frac{2420.6 \text{ in-kips}}{(0.9) \left( 60 \frac{\text{kips}}{\text{in}^2} \right) (12.25 \text{ in} - 1.22 \text{ in})} \\ &= 4.06 \text{ in}^2 \end{aligned}$$

Check the assumed value of  $\lambda$ . Use Eq. 50.26.

$$\begin{aligned} A_c &= \frac{f_y A_s}{0.85 f'_c} = \frac{\left( 60 \frac{\text{kips}}{\text{in}^2} \right) (4.06 \text{ in}^2)}{(0.85) \left( 4 \frac{\text{kips}}{\text{in}^2} \right)} \\ &= 71.65 \text{ in}^2 \end{aligned}$$

Since the compressed zone is rectangular with a width of 111 in, the value of  $\lambda$  is given by Eq. 50.29.

$$\lambda = \frac{A_c}{2b} = \frac{71.65 \text{ in}^2}{(2)(111 \text{ in})} = 0.32 \text{ in}$$

Using  $\lambda = 0.32 \text{ in}$ , the revised steel area is given by Eq. 55.25.

$$\begin{aligned} A_s &= \frac{M_u}{\phi f_y(d - \lambda)} \\ &= \frac{2420.6 \text{ in-kips}}{(0.9) \left( 60 \frac{\text{kips}}{\text{in}^2} \right) (12.25 \text{ in} - 0.32 \text{ in})} \\ &= 3.76 \text{ in}^2 \end{aligned}$$

# 56 Prestressed Concrete

## Nomenclature

$A$	area	in <sup>2</sup>	mm <sup>2</sup>
$A_g$	area of gross cross section	in <sup>2</sup>	mm <sup>2</sup>
$A_{ps}$	area of prestressed reinforcement in tension zone	in <sup>2</sup>	mm <sup>2</sup>
$A_s$	area of nonprestressed tension reinforcement	in <sup>2</sup>	mm <sup>2</sup>
$b$	width of compression face of member	in	mm
$c$	distance from extreme compression fiber to neutral axis	in	mm
$d$	distance from extreme compression fiber to centroid of nonprestressed tension reinforcement ( $\geq 0.8h$ (ACI 318 Sec. 11.3.1))	in	mm
$d'$	distance from extreme compression fiber to centroid of compression reinforcement	in	mm
$d_p$	distance from extreme compression fiber to centroid of prestressed reinforcement	in	mm
$e$	eccentricity	in	mm
$E$	modulus of elasticity	lbf/in <sup>2</sup>	Pa
$f'_c$	specified compressive strength of concrete	lbf/in <sup>2</sup>	Pa
$f'_{ci}$	compressive strength of concrete at time of initial prestress	lbf/in <sup>2</sup>	Pa
$f_{pbt}$	compressive stress immediately prior to transfer	lbf/in <sup>2</sup>	Pa
$f_{pe}$	compressive stress at service limit state after loss	lbf/in <sup>2</sup>	Pa
$f_{pi}$	steel prestress immediately prior to transfer	lbf/in <sup>2</sup>	Pa
$f_{pLT}$	long term prestress	lbf/in <sup>2</sup>	Pa

$f_{pR}$	steel relaxation loss	lbf/in <sup>2</sup>	Pa
$f_{ps}$	stress in prestressing tendons	lbf/in <sup>2</sup>	Pa
$f_{pu}$	specified ultimate tensile strength of prestressing tendons	lbf/in <sup>2</sup>	Pa
$f_{py}$	specified yield strength of prestressing tendons	lbf/in <sup>2</sup>	Pa
$f_s$	tensile steel stress	lbf/in <sup>2</sup>	Pa
$f_t$	extreme fiber stress	lbf/in <sup>2</sup>	Pa
$f_y$	specified yield strength of nonprestressed reinforcement	lbf/in <sup>2</sup>	Pa
$h$	overall beam/girder depth	in	mm
$H$	average annual relative humidity	%	%
$I$	moment of inertia	in <sup>4</sup>	mm <sup>4</sup>
$L$	length	in	mm
$M$	moment	in-lbf	N·m
$n$	modular ratio	—	—
$n$	number (quantity)	—	—
$P$	axial load	lbf	N
PPR	partial prestress ratio	—	—
$S$	section modulus	in <sup>3</sup>	mm <sup>3</sup>
$T$	tensile force	lbf	N
$V$	shear strength	lbf	N
$w$	unit weight of concrete	lbf/ft <sup>3</sup>	n.a.
$w$	weight per unit length	lbf/ft	N/m
$x$	tensile zone depth	in	mm
$y$	distance	in	mm

## Symbols

$\beta_1$	equivalent stress block ratio	—	—
$\gamma_h$	average annual relative humidity factor	—	—
$\gamma_p$	tendon prestressing factor	—	—
$\gamma_{st}$	concrete prestress transfer factor	—	—
$\Delta$	deflection	in	mm
$\lambda$	long-term deflection factor	—	—
$\xi$	time-dependent factor	—	—
$\rho$	nonprestressed reinforcement ratio	—	—
$\rho_p$	prestressed reinforcement ratio	—	—
$\phi$	strength reduction factor (load factor)	—	—
$\phi_w$	concrete creep reduction factor	—	—

t	top or total
u	ultimate (factored) tensile
y	yield

## 1. INTRODUCTION

Concrete is strong under compressive stresses but weak under tensile stresses. The tensile strength of concrete varies from 8% to 14% of its compressive strength. Because of the low tensile strength of concrete, flexural cracks develop at early stages of loading.

In traditional reinforced concrete structures, steel provides the tensile strength that the concrete is incapable of developing. However, it is also possible to impose an initial state of stress such that, when the stresses from the applied loads are added, no tensile stresses occur. The initial state of stress is provided by high-strength tendons compressing the concrete. The prestressing force keeps all or most of the member's cross section in compression. (See Fig. 56.1.)

## 2. PRETENSIONING AND POST-TENSIONING

Prestressing can be achieved by two different procedures: pretensioning and post-tensioning. In *pretensioned construction*, the tendons are pulled to the specified tensile force before placing the concrete. Then, concrete is poured around the tendons. After the concrete reaches the specified strength,  $f'_{ci}$ , the tendons are cut at the anchorages. The compressive stress caused by the shortening of the wires transfers to the concrete through a steel-concrete bond.

In *post-tensioned construction*, the tendons are free to slide within the member inside tubes, sheaths, or conduits. (Early tendons were paper-wrapped bundles of greased wires.) After the concrete hardens, the tendons are tensioned by anchoring them to one end and pulling ("jacking") from the other. Tubes may or may not be subsequently grouted ("bonded") to prevent corrosion. The tubes can also be filled with corrosion-resistant grease.

## 3. BONDED AND UNBONDED TENDONS

Unbonded tendons can be used in relatively shallow construction. Unbonded construction has made the post-tensioning of longer-span flat plates, shallow beams, and slabs practical and economical.

Grouting bonds tendons directly to the concrete. If a bonded tendon breaks at any point, it is still capable of providing local prestress for part of the structure. A

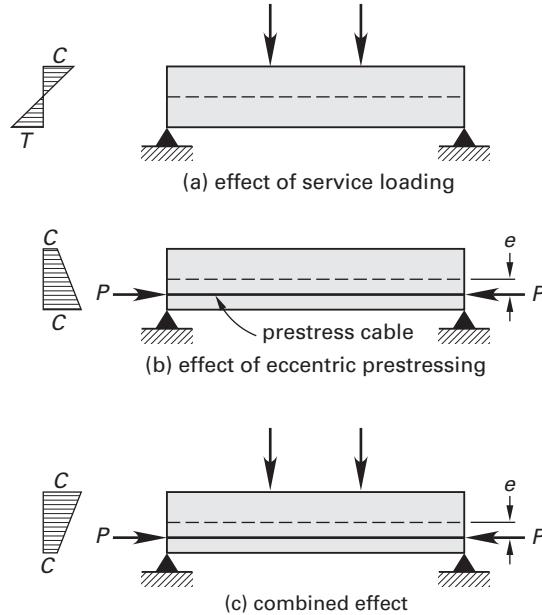

failed unbonded tendon, on the other hand, stops contributing when it fails. Unbonded failure is sudden; bonded failure is gradual. Because of this, bonded tendons may be required in areas subject to seismic loading. (However, unbonded tendons were originally used in nuclear power plants where they could be replaced as needed.)

The ultimate strength of a simple beam with unbonded tendons is about 30% less than the same beam with bonded tendons. The ultimate strength of a continuous unbonded beam or slab versus a bonded beam or slab is about 20% less. Unbonded tendons do not help in controlling crack size and growth.

## 4. BENEFITS AND DISADVANTAGES

Prestressed members are shallower in depth than conventional reinforced concrete members for the same spans and loading conditions. In general, the depth of a prestressed concrete member is usually about 65% to 80% of the depth of the equivalent conventionally reinforced concrete member. This can lead to savings due to reductions in concrete and steel. However, the materials needed for prestressed construction are of higher quality and are, therefore, more expensive, so the cost savings may be minimal.

Figure 56.1 Prestressing Effect on a Simple Beam

Prestressing significantly reduces the amount of cracking in a beam at service load levels. Since uncracked sections have a larger moment of inertia than cracked sections, the deflection of a prestressed beam for a given applied load is less than that of a conventionally reinforced beam. The increased stiffness of prestressed construction permits smaller, lighter sections to be used, thereby reducing dead weight and some components of

the total cost. Other benefits are increased protection of the steel from the environment and the fact that the prestressing can be used to induce camber.

The dead weight of nonprestressed concrete members in excess of 70–90 ft (21–27 m) long can become excessive, resulting in greater long-term deflection and cracking. Therefore, the best construction technique for long-span concrete members is prestressed concrete. In fact, very long concrete spans, such as those found in cable-stayed bridges, can only be constructed with prestressing.

Prestressed concrete members have high toughness (i.e., the ability to absorb energy under impact loads). The fatigue resistance of prestressed concrete members is also high due to the low steel stress variation.

The disadvantages of prestressed construction are the costs associated with the prestressing itself and the increased costs that derive from higher quality materials, inspection, testing, and quality control.

## 5. PRESTRESSING LIMITATIONS

When a live load acting on a beam is a large fraction of the total load but acts intermittently, it may not be possible to design the beam so that it has no tensile stresses under full live load and still behaves appropriately when the live load is not present. High prestressing required for a full live load may be such that, when the live load is not present, the beam deforms upward excessively. This upward camber can be exacerbated by long-term effects from creep and shrinkage. Very large prestressing forces may also produce enough axial shortening in the beam to damage other framing members.

In such cases, it is better to allow some tensile stresses to develop when the beam is fully loaded. Members in which tensile stresses are allowed under service loads are termed *partially prestressed members*. When no tensile stresses are permitted, the term *fully prestressed members* is utilized.

## 6. CONSTRUCTION METHODS AND MATERIALS

The performance of prestressed concrete structures is related directly to the quality of the materials used. Strict production methods and quality assurance are needed at the various stages of production, construction, and maintenance.

High-quality concrete and steel tendons are used. Minimum center-to-center spacing of strands is covered in ACI 318 Sec. 7.6.7.1. The two major qualities of concrete are strength and long-term endurance. Concrete strengths of 4000 psi, 5000 psi, and 6000 psi (27.6 MPa, 34.5 MPa, and 41.3 MPa) are common. The specified concrete strength,  $f'_c$ , must be developed by the time of prestressing.

Accelerating agents containing chlorides are avoided because they contribute to strand corrosion.

## 7. CREEP AND SHRINKAGE

Long-term deflections (deformations) related to creep and shrinkage can reduce the prestressing forces and can lead to unexpected failure. Both creep and shrinkage are time-dependent phenomena. *Creep* is the deformation that occurs under a constant load over a period of time. Creep depends primarily on loading and time, but is also influenced by the composition of concrete, the environmental conditions, and the size of the member.

*Shrinkage* is a volume change that is unrelated to load application. Shrinkage is closely related to creep. As a general rule, concrete that has a low volume change also has a low creep tendency.

Creep and shrinkage contribute to a loss of prestressing force as well as increased deflection. For prestressed members without compression reinforcement, the long-term deflection can be estimated from the immediate deflection by use of a *long-term deflection factor*,  $\lambda$ . For members without compression reinforcement,  $\xi$  has values of 1.0 for three months, 1.2 for six months, 1.4 for twelve months, and 2.0 for five years or more [ACI 318 Sec. 9.5.2.5].  $\rho'$  is the reinforcement ratio at midspan for simple and continuous spans, and at the supports for cantilevers.

$$\Delta_{\text{long term}} = \lambda \Delta_{\text{immediate}} \quad 56.1$$

$$\lambda = \frac{\xi}{1 + 50\rho'} \quad 56.2$$

## 8. PRESTRESS LOSSES

Several effects tend to reduce the prestress, including tendon seating, creep and shrinkage in the concrete, elastic shortening of the member from the applied compressive stress, movements at the anchorage sitting, relaxation of the steel tendons, and friction between the tendons and the tubes (in the case of ungrouted post-tensioned construction). The strains associated with these losses are close to the strain associated with yielding of conventional 40,000 psi (270 MPa) reinforcement, so regular-grade steel cannot be used for prestressing. The tendons used for prestressing are manufactured from steel with an ultimate tensile strength,  $f_{pu}$ , of 250 ksi or 270 ksi (1.70 GPa or 1.90 GPa), and the typical losses average 25–35 ksi (170–240 MPa).

High early strength concrete, such as that made with type III cement, with a compressive strength,  $f'_c$ , of 4000–10,000 psi (27.6–69.0 MPa) is commonly used. This concrete sets up quickly and suffers smaller elastic compression losses. Due to the higher quality of

concrete, the *modular ratio*,  $n$ , is typically lower than in conventional construction.

$$n = \frac{E_s}{E_c} \quad 56.3$$

Losses of prestressing force occur in the prestressing steel due to relaxation of steel and creep and shrinkage of the concrete. This type of loss is known as *time-dependent loss*. On the other hand, there are immediate elastic losses due to fabrication or construction techniques. Those include elastic shortening of concrete, anchorage losses, and frictional losses. The exact amounts of these losses are difficult to estimate analytically, though methods exist.

Since accurate determination of prestress losses is dependent on configuration knowledge that may not exist prior to the final design, initial estimates of losses are based on empirical methods (i.e., rules of thumb).

Table 56.1 shows the magnitudes of *lump-sum losses* (exclusive of friction) that can be expected for typical designs (i.e., designs that are not exceptionally long or that do not have atypical cross sections, anchorage methods, materials, or exposure).<sup>1</sup> Friction losses are highly variable and should be determined separately from manufacturing and installation details.

**Table 56.1** Typical Lump-Sum Prestress Losses in psi (MPa) (exclusive of frictional losses; not for design use)<sup>a,b</sup>

type of prestressing steel	total loss	
	4000 psi concrete (27.6 MPa concrete)	5000 psi concrete (34.5 MPa concrete)
pretensioning strand	—	45,000 (310)
post-tensioning wire or strand	32,000 (221)	33,000 (228)
bars	22,000 (152)	23,000 (159)

(Multiply psi by 0.00689 to obtain MPa.)

<sup>a</sup>For normalweight concrete, normal prestress levels, and average exposure conditions. Use exact methods for exceptionally long spans and unusual designs.

<sup>b</sup>Losses due to friction are excluded. Such losses should be calculated according to AASHTO specifications.

Adapted from *Standard Specifications for Highway Bridges*, 17th ed., 2002, AASHTO, Div. 1, Table 9.16.2.2, p. 236.

<sup>1</sup>This table actually appeared in AASHTO's *Standard Specifications for Highway Bridges*, 17th edition, 2002, now superseded. For designs made with those specifications, the prestress losses given could be used in lieu of the analytical methods for normalweight concrete, normal prestress levels, and average exposure.

## 9. ANALYTICAL ESTIMATION OF PRESTRESS LOSSES

Extremely accurate expectations of prestress loss are found from "refined methods." AASHTO's *LRFD Bridge Design Specifications* (AASHTO *LRFD*) specifies simpler methods of obtaining an "approximate estimate of time-dependent losses" under certain conditions. Specifically, those conditions include having a typical design,<sup>2</sup> experiencing typical prestress levels, using typical construction staging, using typical materials (i.e., normal-weight concrete that is either steam- or moist-cured and prestressing bars and strands that have low-normal elastic properties), and experiencing average site conditions of exposure and temperature. In such cases, the long-term prestress loss,  $\Delta f_{pLT}$ , in kips/in<sup>2</sup> (ksi) due to concrete creep and shrinkage and steel relaxation can be calculated from Eq. 56.4 [AASHTO *LRFD* Eq. 5.9.5.3-1]. The three terms in Eq. 56.4 account for creep losses, shrinkage losses, and relaxation losses, respectively.

$$\Delta f_{pLT,ksi} = 10 \left( \frac{f_{pi,ksi} A_{ps}}{A_g} \right) \gamma_h \gamma_{st} + 12 \gamma_h \gamma_{st} + \Delta f_{pR} \quad [time\text{-dependent losses}] \quad 56.4$$

In Eq. 56.4,  $f_{pi}$  is the steel prestress immediately prior to transfer.  $A_{ps}$  and  $A_g$  are the areas of the prestressing tendons and the gross cross section, respectively.  $\gamma_h$  and  $\gamma_{st}$  in Eq. 56.4 are not specific weights.  $\gamma_h$  is a correction factor that accounts for the average annual relative humidity,  $H$  (expressed in percent), of the ambient air. Although high-desert environments might have low relative humidities, typical values are 40–100%.  $\gamma_{st}$  accounts for the concrete strength at the time of pre-stress transfer.

$$\gamma_h = 1.7 - 0.01H \quad 56.5$$

$$\gamma_{st} = \frac{5}{1 + f'_{ci}} \quad 56.6$$

In the absence of manufacturer's recommendations, the relaxation loss,  $\Delta f_{pR}$ , is assumed to be 2.4 ksi for low-relaxation strands and 10 ksi for relieved strands.

## 10. DEFLECTIONS

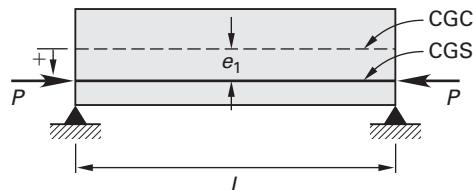

Prestressed concrete members are generally thinner than conventional reinforced concrete members. This makes them subject to increased deflection. Deflection consists of the short-term (instantaneous) and long-term effects.

Several assumptions are made when calculating deflection. (a) The modulus of elasticity of concrete is given

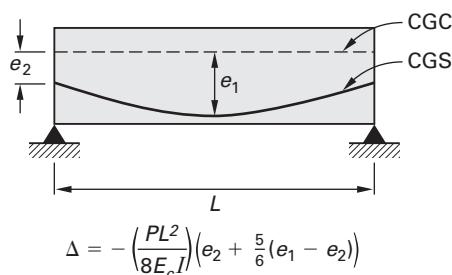

<sup>2</sup>Typical designs include a wide range of precast prestressed concrete I-beams, box beams, inverted tee beams, and voided slabs. Atypical designs would have volume/surface area ratios much different from 3.5 in.

by the empirical equation  $E_c = 33w^{1.5}\sqrt{f'_c}$  [ACI 318 Eq. 8.5.1]. (b) The moment of inertia is calculated for the concrete cross-sectional area. (c) Superposition can be used to calculate the combined deflection due to applied loads and the opposing *camber*. (d) All of the strands act as a single tendon with a combined steel area. (e) Deflection computations can be based on the center of gravity of the prestressing strands (CGS). (f) Deflections resulting from shear deformations can be ignored. (See Fig. 56.2.)

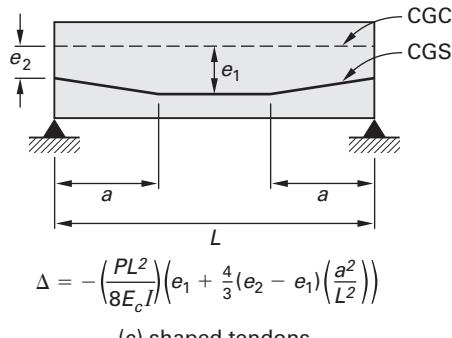

**Figure 56.2** Midspan Deflections from Prestressing\*

(b) parabolically draped tendons

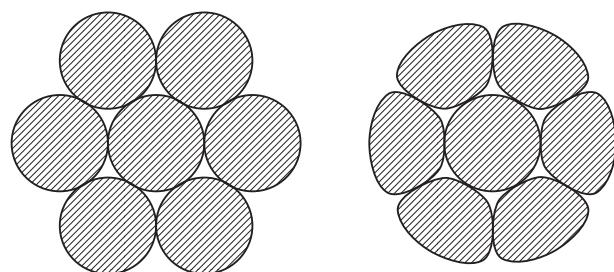

(c) shaped tendons

\*CGC—centroid of concrete; CGS—centroid of prestressing tendons

## 11. STRANDS

Prestressing tendons can be single wires, strands composed of several wires twisted together, or high-strength bars. Seven-wire strands, manufactured by twisting six wires around a larger, straight central wire, are the most widely used. (See Fig. 56.3.) Strands come in two grades, 250 ksi and 270 ksi (1.70 GPa and 1.90 GPa), representing the ultimate tensile strength. Different diameters are available. (See Table 56.2.)

**Figure 56.3** Typical Cross Sections for Seven-Wire Prestressing Tendons

**Table 56.2** ASTM Standard Prestressing Tendons

type <sup>a</sup>	nominal diameter (in)	nominal area (in <sup>2</sup> )	nominal weight (lbf/ft)
grade 250 <sup>b</sup> seven-wire strand (ASTM A416)	$\frac{1}{4}$ $\frac{5}{16}$ $\frac{3}{8}$ $\frac{7}{16}$ $\frac{1}{2}$ —	(0.250) (0.313) (0.375) (0.438) (0.500) (0.600)	0.036 0.058 0.080 0.108 0.144 0.216
grade 270 <sup>b</sup> seven-wire strand	$\frac{3}{8}$ $\frac{7}{16}$ $\frac{1}{2}$ —	(0.375) (0.438) (0.500) (0.600)	0.085 0.115 0.153 0.217

(Multiply in by 25.4 to obtain mm.)

(Multiply in<sup>2</sup> by 645 to obtain mm<sup>2</sup>.)

(Multiply lbf/ft by 1.51 to obtain kg/m.)

(Multiply ksi by 6.89 to obtain MPa.)

<sup>a</sup>All sizes in all types may not be readily available.

<sup>b</sup>Strand grade is  $f_{pu}$  in kips/in<sup>2</sup>.

<sup>c</sup>Per ASTM A421, tensile strengths vary from 235 ksi to 250 ksi.

The high-strength steel strands are stress-relieved to reduce residual stresses caused by cold-working during winding. Stress-relieving consists of heating the steel to about 930°F (500°C). The stress-relieving process improves the ductility of steel and reduces the stress relaxation. *Stress relaxation* is the loss of prestress when wires or strands are subject to constant strain. It is similar to creep in concrete, except that creep is a change in strain whereas relaxation in steel is a loss in steel stress.

Carbon, glass, and aramid tendons are potential alternatives to steel tendons. *Aramid tendons* are manufactured from aramid fibers. Aramid tendons are the focus of ongoing research and experimental use. Tensile rigidities are approximately one-fifth of those from prestressing steel, so uses are limited to special applications.

## 12. CORROSION PROTECTION

Any reduction in the cross-sectional area of prestressing tendons reduces the nominal moment strength of the prestressed section. Therefore, prestressing tendons should be protected against corrosion. In pretensioned members, protection against corrosion is provided by the concrete surrounding the tendon, while in post-tensioned members, grouting is commonly used to prevent moisture from entering the ducts. However, concrete with grouted tendons is susceptible to freeze-induced cracking if grouting occurs during the winter. Therefore,

other options, including heat-sealed and extruded coatings, can be specified.

## 13. MAXIMUM STRESSES

The maximum stresses in concrete and reinforcement permitted by ACI 318 are presented in Table 56.3. Prestressed flexural members are classified in ACI 318 Sec. 18.3.3 as Class U, Class T, or Class C based on the computed extreme fiber stress,  $f_t$ , at service loads in the precompressed tensile zone, as follows.

- Class U:  $f_t \leq 7.5\sqrt{f'_c}$
- Class T:  $7.5\sqrt{f'_c} < f_t \leq 12\sqrt{f'_c}$
- Class C:  $f_t > 12\sqrt{f'_c}$

Prestressed two-way slab systems must be designed as Class U, with  $f_t \leq 6\sqrt{f'_c}$ .

For Class U and Class T flexural members, stresses at service loads are permitted to be calculated using the uncracked section. For Class C flexural members, stresses at service loads must be calculated using the cracked transformed section. Class C flexural members are subject to the deflection and crack control requirements of ACI 318 [ACI 318 Sec. 18.3.4].

AASHTO's *LRFD Bridge Design Specifications* gives different maximum stresses for prestressed tendons and concrete in various configurations. AASHTO does not

**Table 56.3** ACI 318 Maximum Stresses in Prestressed Concrete

### Concrete Stresses in Flexure

*Stresses in concrete immediately after prestress transfer (before time-dependent prestress losses) may not exceed the following:*

(1) extreme fiber stress in compression except as permitted in (2)	$0.60f'_{ci}$
(2) extreme fiber stress in compression at ends of simply supported members	$0.70f'_{ci}$
(3) extreme fiber stress in tension except as permitted in (4)	$[U.S.] \quad 3\sqrt{f'_{ci}}$ $[SI] \quad \frac{1}{4}\sqrt{f'_{ci}}$
(4) extreme fiber stress in tension at ends of simply supported members	$[U.S.] \quad 6\sqrt{f'_{ci}}$ $[SI] \quad \frac{1}{2}\sqrt{f'_{ci}}$

*For Class U and Class T prestressed flexural members, stresses in concrete at service loads (based on uncracked section properties and measured after all prestress losses) may not exceed the following:*

(1) extreme fiber stress in compression due to prestress plus sustained load	$0.45f'_c$
(2) extreme fiber stress in compression due to prestress plus total load	$0.60f'_c$

### Prestressing Steel Stresses

(1) due to tendon jacking force (but not greater than the lesser of $0.80f_{pu}$ or the maximum value recommended by the manufacturer of prestressing tendons or anchorage devices)	$0.94f_{py}$
(2) immediately after prestress transfer (but not more than $0.74f_{pu}$ )	$0.82f_{py}$
(3) post-tensioning tendons at anchorage devices and couplers, immediately after force transfer	$0.70f_{pu}$

Source: ACI 318 Sec. 18.4 and Sec. 18.5

differentiate maximum stresses by the ACI classification of prestressed flexural members, but rather differentiates between segmentally constructed bridges and other monolithic construction methods.<sup>3</sup> Various instances of stress are recognized, such as the prestress prior to losses and the service stress (“service limit state”). The “service limit state” includes cases of “extreme loading” that occur during installation and service.

AASHTO specifies its own load factors and resistance factors (i.e., strength reduction factors,  $\phi$ ), and selecting the correct value requires much more than merely knowing the nature of the stress. Load factors depend on the type (e.g., wind, snow, or earthquake) and duration of loading. In addition to depending on the nature of stress (e.g., flexure or shear), resistance factors can depend on the type of construction (e.g., conventional or segmental), type of component (e.g., girder or column), type of concrete (e.g., normalweight or lightweight), type of loading (e.g., earthquake or otherwise), the geographic seismic zone, the partial pressure ratio, the location of the stress (e.g., anchorage zones or other), the controlling stress (e.g., tension or compression), the degree of bonding of the post-tensioning system, and other factors.<sup>4</sup> As an example, for flexure in conventional (i.e., not segmental) construction, in tension-controlled, prestressed normalweight concrete,  $\phi = 1.0$  and, for shear in normalweight concrete,  $\phi = 0.90$  [AASHTO *LRFD* Sec. 5.5.4.2].

Values of the resistance factors for segmental construction under the most common assumptions are listed in Table 56.4 [AASHTO *LRFD* Table 5.5.4.2.2-1].

**Table 56.4** Resistance (Strength Reduction) Factors,  $\phi$ , for Joints in Prestressed Segmental Construction

	flexure	shear
normalweight concrete, fully bonded tendons	0.95	0.90
normalweight concrete, unbonded or partially bonded tendons	0.90	0.85
sand-lightweight concrete, fully bonded tendons	0.90	0.70
sand-lightweight concrete, unbonded or partially bonded tendons	0.85	0.65

From *A Policy on Geometric Design of Highways and Streets*, 2011, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

<sup>3</sup>Segmental construction is typified by precast segments of the bridge deck being lifted into place. However, cast-in-place decks may also be constructed in segments.

<sup>4</sup>In order to be considered fully bonded at a section, a tendon must be embedded to the full development length specified in AASHTO *LRFD* Sec. 5.11.4.

The strength,  $f_{pu}$ , of a prestressing tendon is specified by the tendon manufacturer. Maximum stresses are specified in fractions of  $f_{pu}$ . As long as maximum stress limits are not exceeded elsewhere, AASHTO permits tendons to be stressed in tension to  $0.90f_{pu}$  for short periods of time prior to seating in order to offset seating and friction losses. Table 56.5 lists AASHTO tensile stress limits that must be observed in addition to the manufacturer’s recommendations [AASHTO *LRFD* Table 5.9.3-1].

**Table 56.5** AASHTO Tensile Stress Limits in Prestressed Concrete

	tendon type		
condition	stress-relieved strand and plain high-strength bars	low relaxation strand	deformed high-strength bars
<i>pretensioning</i>			
immediately prior to transfer, $f_{pbt}$	$0.70f_{pu}$	$0.75f_{pu}$	—
at service limit state after all losses, $f_{pe}$	$0.80f_{py}$	$0.80f_{py}$	$0.80f_{py}$
<i>post-tensioning</i>			
prior to seating —short-term $f_{pbt}$ may be allowed	$0.90f_{py}$	$0.90f_{py}$	$0.90f_{py}$
at anchorages and couplers immediately after anchor set	$0.70f_{pu}$	$0.70f_{pu}$	$0.70f_{pu}$
elsewhere along length of member away from anchorages and couplers immediately after anchor set	$0.70f_{pu}$	$0.74f_{pu}$	$0.70f_{pu}$
at service limit state after losses, $f_{pe}$	$0.80f_{py}$	$0.80f_{py}$	$0.80f_{py}$

From *A Policy on Geometric Design of Highways and Streets*, 2011, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

AASHTO specifies the upper limit for the concrete compressive stress as  $0.60f'_{ci}$ . This limit applies to all concrete components, including segmentally constructed bridges, and to both pretensioned and post-tensioned components. In most cases, however, the maximum permitted compressive stress at service limit states will be lower, as per Table 56.6 [AASHTO *LRFD* Table 5.9.4.2.1-1].

**Table 56.6** AASHTO Concrete Compressive Stress Limits with Prestressing Tendons

location	stress limit (ksi)
in other than segmentally constructed bridges due to the sum of effective prestress and permanent loads	$0.45f'_c$
in segmentally constructed bridges due to the sum of effective prestress and permanent loads	$0.45f'_c$
due to the sum of effective prestress, permanent loads, and transient loads, and during shipping and handling	$0.60\phi_w f'_c$

From *A Policy on Geometric Design of Highways and Streets*, 2011, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

The reduction factor  $\phi_w$  in Table 56.6 accounts for the concrete in bridge girders not being confined internally by steel (as are concrete columns), and accordingly, the concrete creeps to failure at compressive loads much less than the concrete compressive strength. The factor is taken as 1.0 when the web and flange slenderness ratios are not greater than 15. Provisions for calculating the factor for other configurations are given in AASHTO LRFD Sec. 5.7.4.7.2 and Sec. 5.9.4.2.1.

Tensile stresses in concrete are not generally permitted by AASHTO unless tensile reinforcing is provided. The required reinforcement area,  $A_s$ , is found by dividing the tensile force in the tensile zone by the permitted steel tensile stress. The tensile zone is identified from the elastic stress distribution. Permitted steel tensile stress is limited to the lower of  $0.5f_y$  or 30 ksi. Referring to Fig. 56.4, the tensile force,  $T$ , to be carried by the reinforcement is

$$T = \frac{1}{2}f_{ci,top} b_{top} x = f_s A_s \quad 56.7$$

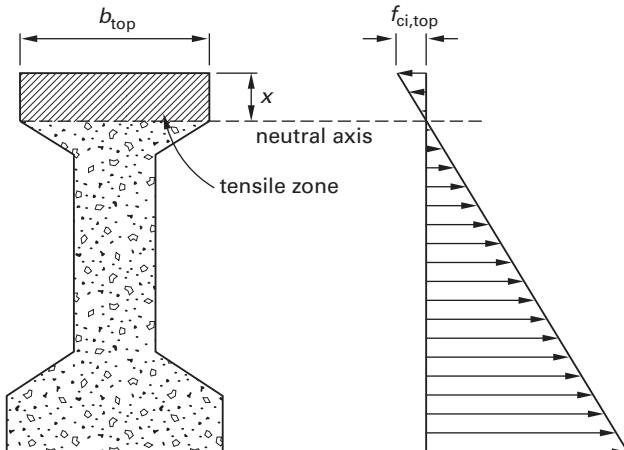

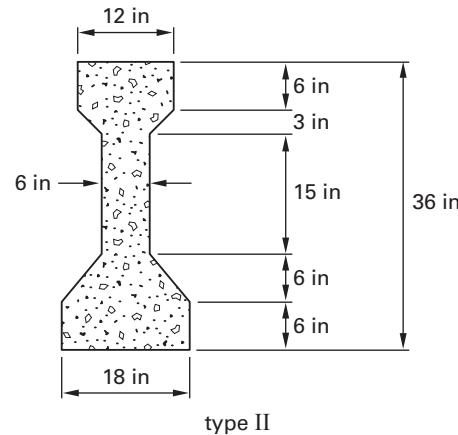

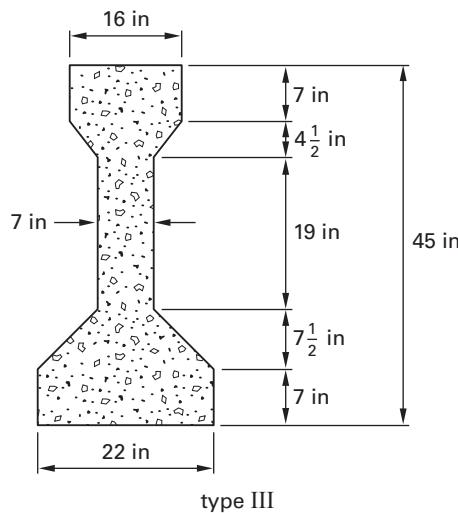

**Figure 56.4** Bridge Beam Tensile Zone

(The typical 5% increase for steel weight is not included.)

AASHTO specifies maximum concrete tensile stresses for various durations (i.e., temporarily before losses and permanently at service limit states after losses), configurations (i.e., segmentally constructed bridges and other, conventional types), locations (e.g., in joints and other areas), and reinforcement configurations (e.g., with and without bonded reinforcements). For example, in the absence of any other limitations, the principal concrete tensile stress in ksi at the neutral axis of the web in a segmentally constructed bridge girder with fully prestressed components is limited at the service limit state after losses to  $0.11\sqrt{f'_{ci}}$  [AASHTO LRFD Table 5.9.4.1.2-1].

### Example 56.1

An 88 ft long AASHTO-PCI type III standard girder must develop a limiting prestress force of 980 kips at transfer, when the concrete has reached a strength of  $f'_{ci} = 4500$  lbf/in<sup>2</sup>. The prestressing strands will be arranged in five rows on a 2 in grid pattern. Strands are limited to an individual force of 29 kips each. (a) Determine the location of the centroid of the prestressing steel. (b) Determine the eccentricity of the prestressing force. (c) What is the maximum stress at the lower surface of the beam? (d) Use ACI criteria to determine if the maximum stress at the lower surface of the beam is acceptable.

#### Solution

(a) The total number of strands is

$$n_t = \frac{980 \text{ kips}}{29 \text{ kips}} = 33.8$$

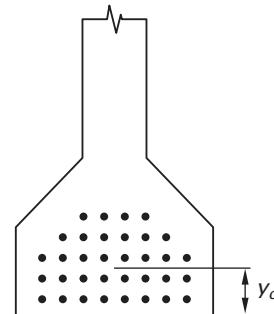

Try 34 strands. The first layer will be located 2 in from the bottom of the girder. Allowing 2 in cover on the sides, 8 strands can be placed in each layer. Use three

layers of 8 strands, one layer of 6 strands, and one layer of 4 strands. The strand (layer) separation is 2 in.

$$y_c = \frac{\sum ny}{\sum n}$$

$$= \frac{(8)(2 \text{ in}) + (8)(4 \text{ in}) + (8)(6 \text{ in}) + (6)(8 \text{ in}) + (4)(10 \text{ in})}{8 + 8 + 8 + 6 + 4}$$

$$= 5.41 \text{ in}$$

(b) From Table 56.7, the centroid of a type III girder is located 20.27 in from the lower surface. The eccentricity of the prestressing force is

$$e = 20.27 \text{ in} - 5.41 \text{ in} = 14.86 \text{ in}$$

(c) From Table 56.7, the concrete weight is 583 lbf/ft. If the type of prestressing tendons is known, the actual steel weight can be determined from the weights per unit length in Table 56.2. For convenience, the steel weight is assumed to add 5%. The dead load is

$$w_D = (1 + 0.05) \left( 583 \frac{\text{lbf}}{\text{ft}} \right)$$

$$= 612.2 \text{ lbf/ft}$$

The moment due to the dead load is

$$M_D = \frac{w_DL^2}{8} = \frac{\left(612.2 \frac{\text{lbf}}{\text{ft}}\right)(88 \text{ ft})^2 \left(12 \frac{\text{in}}{\text{ft}}\right)}{(8)\left(1000 \frac{\text{lbf}}{\text{kip}}\right)}$$

$$= 7111 \text{ in-kips}$$

The stress at the lower surface is compressive due to the prestressing tension.

$$f_{\text{bottom}} = \pm \frac{P}{A} \pm \frac{Pe}{S_{\text{bottom}}} \pm \frac{M_D}{S_{\text{bottom}}}$$

$$= -\frac{980 \text{ kips}}{560 \text{ in}^2} - \frac{(980 \text{ kips})(14.86 \text{ in})}{6186 \text{ in}^3}$$

$$+ \frac{7111 \text{ in-kips}}{6186 \text{ in}^3}$$

$$= -2.95 \text{ kips/in}^2$$

(d) From Table 56.3, the maximum compressive stress immediately after transfer is

$$f_{c,\text{max}} = 0.60f'_{ci} = (0.60)\left(4500 \frac{\text{lbf}}{\text{in}^2}\right)$$

$$= 2700 \text{ lbf/in}^2 \quad (2.7 \text{ ksi})$$

2.7 ksi is less than the actual compressive stress of 2.95 ksi, so the beam should be redesigned.

#### 14. ACI PROVISIONS FOR STRENGTH

ACI 318 contains the following strength-related provisions.

- (1) The moment due to factored loads,  $M_u$ , cannot exceed the design moment strength,  $\phi M_n$ .
- (2) The design moment strength,  $\phi M_n$ , must be at least 1.2 times the cracking moment,  $M_{cr}$ , calculated from the modulus of rupture [ACI 318 Sec. 18.8.2]. However, this may be waived for flexural members with shear and flexural strength at least two times the value determined by analysis.
- (3) The area of prestressed and nonprestressed reinforcement used to compute the design moment strength,  $\phi M_n$ , of prestressed flexural members is limited in ACI 318 App. B to ensure that failure is initiated by yielding of the steel and not by crushing of the concrete in compression. (Exact values are specified in ACI 318 Sec. B.18.8.1.) In ACI 318 Chap. 18, prestressed concrete sections, like reinforced concrete sections, are classified as either tension controlled, transition, or compression controlled, in accordance with ACI 318 Sec. 10.3.3 and Sec. 10.3.4. The appropriate  $\phi$  factor from ACI 318 Sec. 9.3.2 applies.

The design moment strength,  $\phi M_n$ , is calculated in the same manner as for a conventional reinforced section. The only aspect specific to prestressed construction is

the fact that the tension in the steel at failure is computed from formulas that apply for specific circumstances. For example, in ACI 318 Sec. 18.7.2, the common case of members with bonded tendons, the ultimate stress in the tendons,  $f_{ps}$ , is

$$f_{ps} = f_{pu} \left( 1 - \left( \frac{\gamma_p}{\beta_1} \right) \left( \rho_p \left( \frac{f_{pu}}{f'_c} \right) + \left( \frac{d}{d_p} \right) (\omega - \omega') \right) \right)$$

[bonded tendons]

56.8

$\gamma_p$  is the tendon prestressing factor, equal to 0.55 when  $0.80 \leq f_{py}/f_{pu} < 0.85$ ; 0.40 when  $0.85 \leq f_{py}/f_{pu} < 0.90$ ; and 0.28 when  $f_{py}/f_{pu} \geq 0.90$ .

$\rho_p$  is the *prestressing steel ratio*.

$$\rho_p = \frac{A_{ps}}{bd_p}$$

56.9

If any compression reinforcement is taken into account, the negative part of Eq. 56.8 cannot be less than 0.17, and the distance from the extreme compression fiber to the centroid of the compression reinforcement,  $d'$ , cannot be greater than  $0.15d_p$ , where  $d_p$  is the distance from the extreme compression fiber to the centroid of the prestressed reinforcement.

$$\rho_p \left( \frac{f_{pu}}{f'_c} \right) + \left( \frac{d}{d_p} \right) (\omega - \omega') \geq 0.17$$

56.10

For Eq. 56.10 to apply, the stress in the tendons after all losses have been subtracted may not be less than  $0.5f_{pu}$  [ACI 318 Sec. 18.7.2]. Other formulas for  $f_{ps}$  can be found in ACI 318 Sec. 18.7.2.

The *cracking moment*,  $M_{cr}$ , is computed as the moment required to induce a tensile stress equal to the modulus or to the rupture. In this calculation, the force in the tendons after all losses must be used. Long-term losses are frequently assumed to be 35,000 psi (240 MPa) for pretensioned construction and 25,000 psi (170 MPa) for post-tensioned construction.

#### 15. ANALYSIS OF PRESTRESSED BEAMS

If a beam's tendon layout is known, the flexural strength to support a particular load distribution can be determined.

##### Service Load Review

*step 1:* Compute the moment of inertia for the cross section. If the beam is post-tensioned and the tendons are not grouted, the area of steel of the tendons should not be considered.

*step 2:* Calculate the eccentricity,  $e$ , of the tendons as the distance from the centroid of the tendons to the centroid of the gross concrete section.

*step 3:* Compute the stress distribution in the concrete at transfer from Eq. 56.11.  $P$  is the net prestress force acting on the beam before losses,  $M_s$  is the moment due to the loads on the beam at transfer (typically the self-weight only), and  $y$  is the distance from the centroidal axis to the fiber in question.  $y$  is positive upward. Negative stresses indicate compression.

$$\begin{aligned} f_c &= \frac{-P}{A} - \frac{Pey}{I} + \frac{M_s y}{I} \\ &= \frac{-P}{A} - \frac{Pe}{S} + \frac{M_s}{S} \quad [\text{maximum}] \end{aligned} \quad 56.11$$

*step 4:* Compute the stresses in the concrete when the full service load is acting. These stresses are also computed with Eq. 56.11 with the following changes:  $P$  is the force in the tendons after all losses, and  $M_s$  is the moment due to the full service load.

### Strength Review

*step 5:* Compute the ultimate stress in the tendons from Eq. 56.8. (Use the appropriate ACI 318 equation if the tendon is not bonded.)

*step 6:* Use the stress from step 5 to calculate the design moment strength,  $\phi M_n$ . Compare this to the maximum moment due to factored loads,  $M_u$ . If  $\phi$  is based on a tension-controlled section, it must be verified that the section is in fact tension controlled.

*step 7:* Use Eq. 56.11 to compute the cracking moment. The cracking moment is the value of  $M_s$  required to induce a tension stress equal to the modulus of rupture. Check to see if the requirement  $\phi M_n \geq 1.2 M_{cr}$  is satisfied [ACI 318 Sec. 18.8.2].

## 16. SHEAR IN PRESTRESSED SECTIONS

The shear design requirement for prestressed concrete members is the same as for conventionally reinforced concrete members.

$$V_u < \phi V_n \quad 56.12$$

For prestressed and reinforced concrete members, the nominal shear strength,  $V_n$ , is the sum of the shear strengths provided by the concrete and the steel.

$$V_n = V_c + V_s \quad 56.13$$

For prestressed concrete members, ACI 318 Sec. 11.1.3.2 states that the critical section for computing the maximum factored shear,  $V_w$ , is located at a distance of  $h/2$  from the face of the support. This is different from the provisions for conventional reinforced concrete members where the critical section is located at a distance,  $d$ , from the face of the support.

$s$	steel
$t$	top

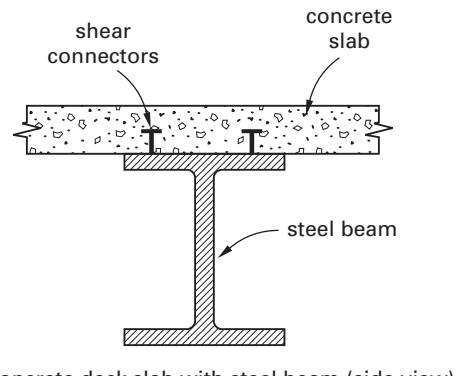

## 1. INTRODUCTION

Any conventionally reinforced concrete structure could be considered a composite structure since it contains two dissimilar materials. However, the term “composite member” normally refers to the combination of concrete with structural steel in a member, as shown in Fig. 57.1.

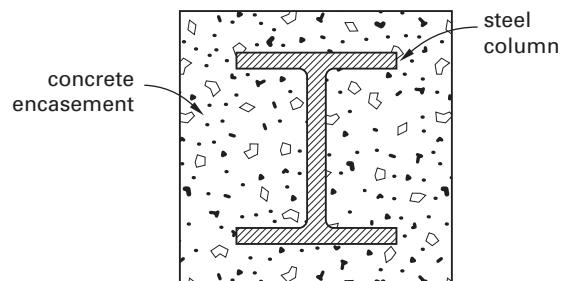

The composite construction shown in Fig. 57.1(a) is widely used for highway bridges. A cast-in-place reinforced concrete slab is bonded to a steel beam, producing a stronger and stiffer structure. Figure 57.2 shows a typical highway bridge utilizing composite construction.

There are two authoritative documents governing composite design: (a) AASHTO's *LRFD Bridge Design Specifications* (AASHTO LRFD), and (b) the *AISC Manual* (AISC). The requirements imposed by these two documents are similar, though not always exactly the same. In addition, ACI 318 applies to the concrete parts of composite construction.

Figure 57.1 Composite Members

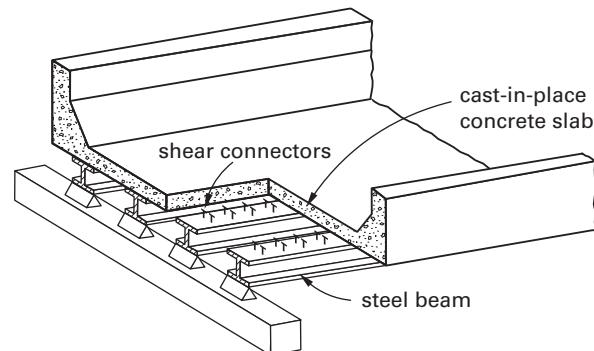

(a) concrete deck slab with steel beam (side view)

(b) concrete-encased steel column (end view)

Figure 57.2 Highway Bridge Deck

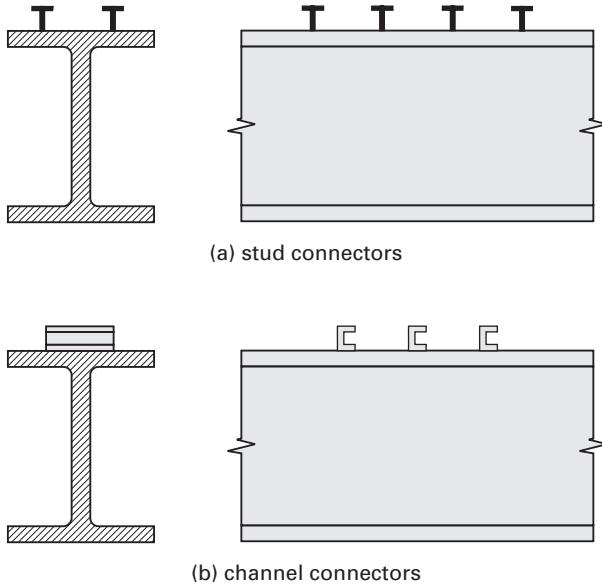

## 2. COMPOSITE ACTION

Composite construction depends on *composite action* between the two materials. Composite action means that the steel and the concrete components act together to resist loading. There is a tendency for slip to occur at

the interface between the concrete slab and the steel beam. Slippage nullifies composite action. The tendency to slip is maximum near the supports, where the vertical (and horizontal) shear forces are the greatest. Tendency to slip is zero at the point of maximum bending moment.

To prevent slippage from occurring, *shear connectors* (straight studs, L-connectors, or steel channels) are welded to the top flange of the steel beam as shown in Fig. 57.3. When the concrete is poured, the encased studs bond the beam to the slab.

**Figure 57.3** Types of Shear Connectors

According to the AASHTO *LRFD* specifications, the following criteria for shear connectors should be met. (a) The clear depth of concrete cover over the tops of all shear connectors must be no less than 2 in. (b) The connectors must penetrate at least 2 in into the bottom of the deck slab. (c) The clear distance between the edge of the beam flange and the edge of the connector must be no less than 1 in. (d) The welds for channel shear connectors must be at least  $\frac{3}{16}$  in fillets. Adjacent stud shear connectors must not be closer than 4 diameters center-to-center transverse to the longitudinal axis of the beam [AASHTO *LRFD* Sec. 6.10.10]. The center-to-center pitch along the line of force must be less than or equal to 24 in and less than 6 times the stud diameter [AASHTO *LRFD* Sec. 6.10.10]. The height-to-diameter ratio of the shear stud must be no less than 4.0.

AASHTO specifications also require the shear connectors be designed for fatigue and checked for strength [AASHTO *LRFD* Sec. 6.10.10].

### 3. ADVANTAGES

The primary advantages of composite construction are as follows. (a) The load-carrying capacity of a composite system is greater than that of the same system in the absence of composite action. (b) A composite system is

stronger and more rigid than a noncomposite system. (c) Smaller and shallower steel beams can be used. This will provide economic savings in the steel to be used for a given project. The savings in weight can reach about 20–30%. (d) Spans can be longer without exceeding the allowable deflection.

### 4. DISADVANTAGES

The disadvantages of composite construction are as follows. (a) There are additional materials and labor costs related to the shear connectors. However, the savings from using smaller sections generally offset the additional costs of the connectors. (b) The construction of composite members requires additional supervision and quality control.

Despite these disadvantages of composite construction, a large number of medium-span highway bridges in the United States are constructed using the slab-beam composite system.

### 5. EFFECTIVE SLAB WIDTH

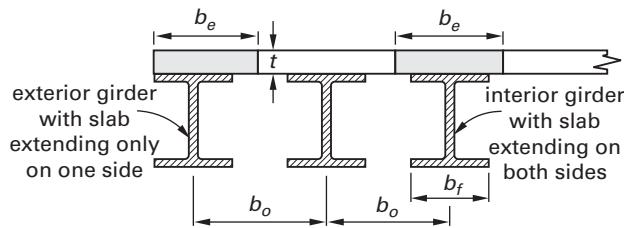

In the slab-beam composite system used for bridge decking, the steel beams (girders) are placed parallel to each other in the direction parallel to the traffic. The steel beams can be standard W shapes with cover plates to increase the resistance of the beam in the regions of high moment, or they can be built-up plate girders.

The concrete slab is designed for bending in the transverse direction (i.e., is designed as a one-way slab). However, all of the slab may not be considered effective in resisting compressive stresses. The portion of the slab that resists the compressive stresses is the *effective width*,  $b_e$ . (See Fig. 57.4.) The *AISC Manual* Sec. I3 states that the effective width of the slab is the sum of each of the other two sides' effective widths measured from the beam's centerline. For interior beams, the effective width,  $b_e$ , is usually twice the side effective width,  $b_{e,side}$ . Each side's effective width must not exceed

- one-eighth of the beam span, center-to-center of supports
- one-half the distance to the centerline of the adjacent beam
- the distance to the edge of the slab

AASHTO specifies the effective flange width differently than AISC (and differently than previous AASHTO specifications). AASHTO's effective flange width applies to both composite construction (concrete deck with steel girders) and monolithic construction (concrete deck with integral concrete girders).<sup>1</sup> The effective flange width for the purposes of determining stiffness and flexural resistance is equal to the "tributary width

<sup>1</sup>Orthotropic steel decks are treated differently. Also, AASHTO correlates the effective flange width for segmental and single-cell, cast-in-place concrete box beams to girder length and superstructure depth. Graphical solutions are provided for such cases.

**Figure 57.4** Effective Width

perpendicular to the axis of the member.” For simple designs of slabs of uniform thickness supported on uniformly spaced rectangular girders, the effective flange width is equal to the main girder spacing. *Shear lag* is not a factor, and the entire flange is considered to be effective, regardless of slab thickness, length/span ratios, and whether the girder is interior or exterior [AASHTO LRFD Sec. 4.6.2.6].<sup>2</sup> AASHTO requires a refined analysis in some cases, such as with a skew angle greater than 75°, when the slab is designed for two-way action, when the slab spans longitudinally between transverse floorbeams, when the slab supports significant combined axial and bending forces, and for configurations such as tied arches. A more detailed analysis is also suggested for beams other than the main girders (i.e., for the stringers).

## 6. SECTION PROPERTIES

In order to compute the stresses for a nonhomogeneous cross section, the section properties (e.g., centroidal axis location, moment of inertia, and section modulus) are computed using transformed cross sections.

The concrete modulus of elasticity may be calculated from the ACI formula [ACI 318 Sec. 8.5.1]. The *modular ratio*, *n*, is found from Eq. 57.1. (See Table 57.1.)

$$n = \frac{E_s}{E_c} \quad 57.1$$

The transformed slab width is calculated by dividing *b<sub>e</sub>* by *n*. This “transforms” the concrete slab to steel. The neutral axis and moment of inertia are calculated for the transformed section.

## 7. STRENGTH OF COMPOSITE SECTIONS

The ultimate strength of the composite section depends on the (a) section properties of the steel beam (girder), (b) yield strength of the steel beam, (c) compressive strength of concrete used for the slab, and (d) capacity of the shear connectors.

In analyzing a composite section, it is assumed that the shear connectors transfer the total shear at the steel-concrete interface. It is also assumed that concrete

<sup>2</sup>The AASHTO specifications for effective flange width have been validated by extensive experimentation and studies of existing bridges with length/span ratios as low as 3:1. Full-width effectiveness was found to exist in all but a few cases, and in those cases, considerable excess capacity existed.

**Table 57.1** Modular Ratio<sup>a</sup>

compressive strength <sup>c</sup> , <i>f<sub>c'</sub></i> (psi)	modular ratio, <i>n</i> (MPa)
3000	21
3500	24
4000	28
4500	31
5000	35
6000	42

(Multiply psi by 0.00689 to obtain MPa.)

<sup>a</sup>The ratio is based on a concrete unit (specific) weight of 145 lbf/ft<sup>3</sup> and a steel modulus of elasticity of 29,000,000 psi.

<sup>b</sup>In recognition of the approximate nature of the modulus of elasticity, the modular ratio is often rounded to the nearest integer or nearest multiple of 0.5. In the past, when the modular ratio was an integral part of ACI 318, rounding to the nearest whole number (as long as it was not less than 6) was permitted. Rounding of the modular ratio is now left to agency conventions.

<sup>c</sup>AASHTO allows the use of design concrete strengths up to 10,000 psi. Above 10,000 psi, physical tests are necessary to establish the relationship between concrete strength and other properties.

carries only compressive stress, and the small tensile stress capacity of concrete is ignored.

When analyzing or designing a composite section, the effects of noncomposite and composite loads should be considered. Also, the method of construction of composite members (with or without shoring) will have an effect on the actual stresses resulting from loads.

*Noncomposite loads* are those loads acting on the steel beam before the concrete slab hardens and can contribute to the strength. These loads include the weight of the steel beam, the weight of the fresh concrete slab, and the weight of formwork and bracing members. In unshored construction, the flexural stresses caused by these loads are resisted by the steel beam alone. *Composite loads* are those loads that act on the section after concrete has hardened. Composite loads include live loads from traffic, snow, and ice, and any additional dead load such as that of future roadway surfacing, sidewalks, railing, and permanent utilities fixtures.

Erection of composite members can be done either without shoring (unshored) or with shoring (shored). *Unshored construction* is the simplest construction method. The steel beams are placed first and used to support the formwork, fresh concrete, and live loads of construction crew and equipment. The steel beam acts noncompositely. It supports all noncomposite loads by itself.

With *shored construction*, the steel beams are supported by temporary falsework until the concrete cures. All noncomposite loads, including the steel beam itself, are supported by the falsework. After the concrete cures, the falsework is removed and the section acts compositely to resist all noncomposite and composite loads. Shored construction results in a reduction in the service load stresses.

The ultimate moment capacity of the composite section depends on the location of the neutral axis of the composite section. There are two possible locations of the neutral axis. (a) If the neutral axis is within the concrete slab, the slab is capable of resisting the total compressive force. In this case, the slab is "adequate." (b) If the neutral axis is within the steel beam below the concrete slab, the slab resists only a portion of the compressive force. The remainder is carried by the steel beam. The slab is said to be "inadequate." The calculation of the ultimate moment capacities in both cases is similar to calculations for T-beam sections.

## 8. METAL DECK SYSTEMS IN COMPOSITE CONSTRUCTION

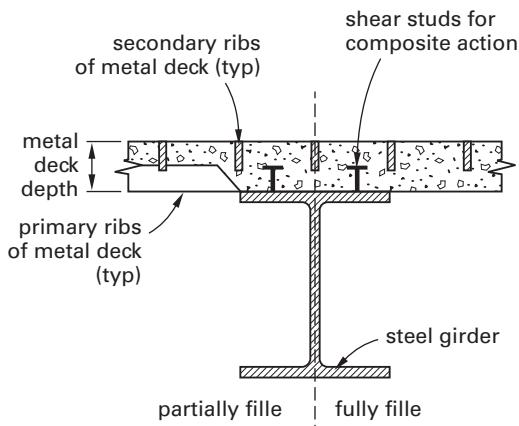

*Metal deck systems* used in bridges include open grid floors, filled grid decks, partially filled decks, unfilled grid decks composite with reinforced concrete slabs, and orthotropic steel decks. These systems differ in methods of construction, structural behavior, and cost. Metal deck systems often have two sets of ribs—the larger and lower primary ribs that run perpendicular to the longitudinal girders, and the smaller and higher secondary ribs that run parallel to the longitudinal girders.

*Open grid floors* are metal decks with metal grid gratings that act as both the deck and the riding (wearing) surface. The grating consists of primary and secondary metal ribs (bars) in a grid pattern. Open grid floors must be connected to the supporting superstructure components with either welds or mechanical fasteners. There is an insignificant degree of *composite action* between the open grid floor and superstructure. Open grid floors have a relatively low self-weight and are frequently used in *vertical lift bridges*, where a section of the deck has to be lifted vertically for navigational clearance, and in *bascule (draw) bridges*, where a cantilevered section of the deck swings upward, pivoted at one end.

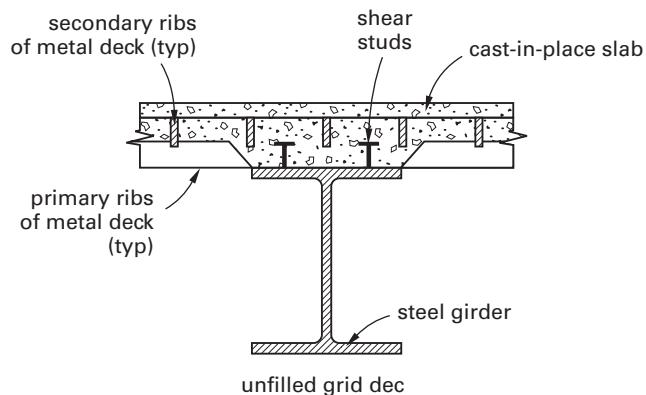

*Filled and partially filled metal decks* are attached to girders by shear studs for composite action. The shear studs (connectors) contribute to composite action between the superstructure and the deck. In partially filled decks, concrete covers only the secondary ribs, or the full depth of the primary ribs is covered. (Both options are illustrated in Fig. 57.5.) These types of metal deck systems are lightweight and can also be used in vertical lift and bascule bridges.

An *unfilled grid deck composite with a reinforced concrete slab* combines the attributes of a concrete deck and

**Figure 57.5 Filled and Partially Filled Metal Decks**

**Figure 57.6 Unfilled Grid Deck Composite with Concrete Slab**

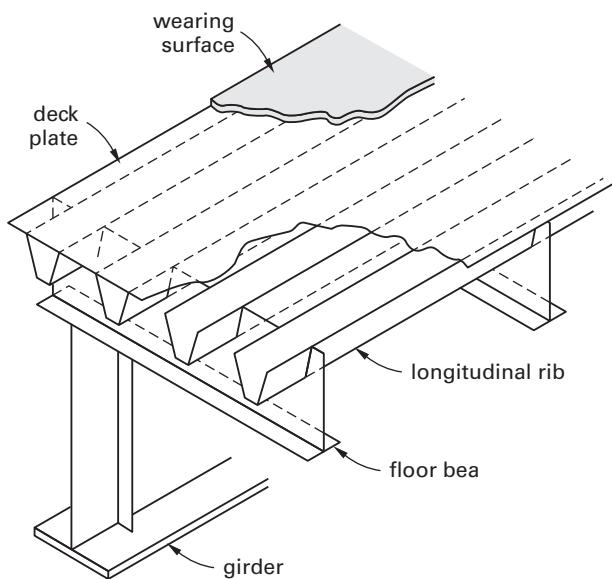

a steel grid. It consists of a concrete slab cast-in-place on top of the unfilled steel grid. A typical cross section is shown in Fig. 57.6. Shear studs ensure composite action between the concrete slab and the grid; bolting or welding ensures composite action between the grid deck and the superstructure.

An *orthotropic steel deck* is a deck made up of a steel plate stiffened and supported by longitudinal ribs and transverse floor beams as shown in Fig. 57.7.<sup>3</sup> The deck plate connection to the stringers and floor beams is designed for composite action. The wearing surface can be a cast-in-place topping or the deck plate itself. If a cast-in-place topping is the wearing surface, it must be properly bonded to the top of the deck plate to prevent movement of the wearing surface relative to the deck plate.

<sup>3</sup>The term *orthotropic* means that the material has different properties in orthogonal directions. The vertical stiffness of an orthotropic deck contributes vehicle load support, while the (different) lateral and torsional stiffnesses contribute to superstructure strength.

<i>f</i>	computed stress	ksi
<i>F</i>	strength or allowable stress	ksi
<i>G</i>	shear modulus	ksi
<i>h</i>	clear distance between flanges	in
<i>I</i>	area moment of inertia	in <sup>4</sup>
<i>M</i>	moment	in-kips
<i>t</i>	thickness	in
<i>V</i>	shear	kips
<i>w</i>	width	in
<i>y</i>	distance	in

### Symbols

$\alpha$	coefficient of thermal expansion	1/°F
$\nu$	Poisson's ratio	—
$\rho$	density	lbm/ft <sup>3</sup>
$\phi$	resistance factor	—

### Subscripts

<i>c</i>	centroidal
<i>f</i>	flange
<i>n</i>	nominal
<i>t</i>	tensile
<i>u</i>	ultimate (maximum) tensile
<i>y</i>	yield

### 1. STEEL NOMENCLATURE AND UNITS

In contrast to concrete nomenclature, it is traditional in steel design to use the uppercase letter *F* to indicate strength or allowable stress. Furthermore, such strengths or maximum stresses are specified in ksi (MPa in metricated countries). For example,  $F_y = 36$  ksi indicates that

a steel has a yield stress of 36 ksi. Similarly,  $V_n$  is the nominal shear strength, and  $\phi M_n$  is the flexural design strength, both in ksi. Actual or computed stresses are given the symbol of lowercase *f*. Computed stresses are also specified in ksi. For example,  $f_t$  is a computed tensile stress in ksi.

In the United States, steel design is carried out exclusively in customary U.S. (inch-pound) units.

### 2. TYPES OF STRUCTURAL STEEL AND CONNECTING ELEMENTS

The term *structural steel* refers to a number of steels that, because of their economy and desirable mechanical properties, are suitable for load-carrying members in structures. In the United States, the customary way to specify a structural steel is to use an ASTM International (previously known as the American Society for Testing and Materials) designation. For ferrous metals, the designation has the prefix letter "A" followed by two or three numerical digits (e.g., ASTM A36, ASTM A992). The general requirements for such steels are covered under ASTM A6 specifications. Basically, three groups of hot-rolled structural steels are available for use in buildings: carbon steels, high-strength low-alloy steels, and quenched and tempered alloy steels.

*Carbon steels* use carbon as the chief strengthening element. These are divided into four categories based on the percentages of carbon: *low-carbon* (less than 0.15%), *mild-carbon* (0.15–0.29%), *medium-carbon* (0.30–0.59%), and *high-carbon* (0.60–1.70%). ASTM A36 belongs to the mild-carbon category, and it has a maximum carbon content varying from 0.25–0.29%, depending on thickness. Carbon steels used in structures have minimum yield stresses ranging from 36 ksi to 55 ksi. An increase in carbon content raises the yield stress but reduces ductility, making welding more difficult. The maximum percentages of other elements of carbon steels are: 1.65% manganese, 0.60% silicon, and 0.60% copper.

*High-strength low-alloy* (HSLA) steels having yield stresses from 40 ksi to 70 ksi are available under several ASTM designations. In addition to carbon and manganese, these steels contain one or more alloying elements (e.g., columbium, vanadium, chromium, silicon, copper, and nickel) that improve strength and other mechanical properties. The term "low-alloy" is arbitrarily used to indicate that the total of all alloying elements is limited to 5%. No heat treatment is used in the manufacture of HSLA steels. These steels generally have greater

atmospheric corrosion resistance than the carbon steels. ASTM designations A242, A441, A572, A588, and A992, among others, belong to this group.

*Quenched and tempered alloy steels* have yield stresses between 70 ksi and 100 ksi. These steels of higher strengths are obtained by heat-treating low-alloy steels. The heat treatment consists of quenching (rapid cooling) and tempering (reheating). ASTM designations A514, A852, and A709 belong to this category.

### 3. STEEL PROPERTIES

Each structural steel is produced to specified minimum mechanical properties as required by the specific ASTM designation by which it is identified. Some properties of steel (such as the modulus of elasticity and density) are essentially independent of the type of steel. Other properties (such as the tensile strength and the yield stress) depend not only on the type of steel, but also on the size or thickness of the piece. The mechanical properties of structural steel are generally determined from tension tests on small specimens in accordance with standard ASTM procedures. The results of a tension test are displayed on a stress-strain diagram. Table 58.1 gives typical properties of structural steels, and Fig. 58.1 shows typical diagrams of three different types of steels.

**Table 58.1** Typical Properties of Structural Steels

	A992 <sup>a</sup> /A572, grade 50	A36
modulus of elasticity, $E$	29,000 ksi <sup>b</sup>	
tensile yield strength, $F_y$	50 ksi	36 ksi (up to 8 in thickness)
tensile strength, $F_u$	65 ksi (min)	58 ksi (min)
endurance strength		30 ksi (approx)
density, $\rho$		490 lbf/ft <sup>3</sup>
Poisson's ratio, $\nu$		0.30 (ave)
shear modulus, $G$		11,200 ksi <sup>b</sup>
coefficient of thermal expansion, $\alpha$		$6.5 \times 10^{-6}$ 1/F (ave)
specific heat (32–212°F)		0.107 Btu/lbm·°F

(Multiply ksi by 6.9 to obtain MPa.)

(Multiply by 25.4 to obtain mm.)

(Multiply lbm/ft<sup>3</sup> by 16 to obtain kg/m<sup>3</sup>.)

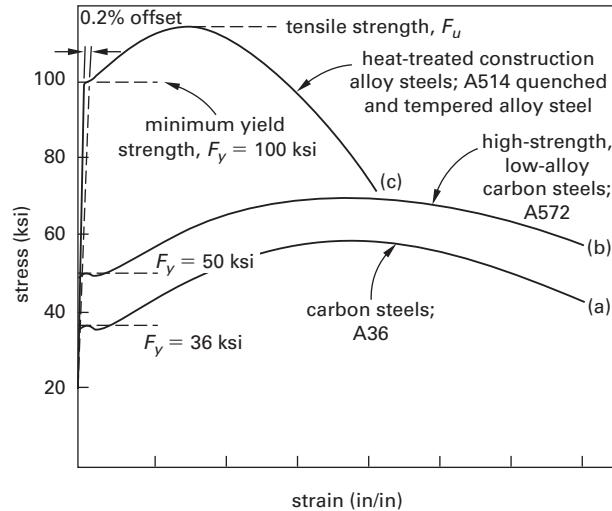

(Multiply °F<sup>-1</sup> by 9/5 to obtain °C<sup>-1</sup>.)

<sup>a</sup>A992 steel is the *de facto* material for rolled W-shapes, having replaced A36 and A572 in most designs for new structures.

<sup>b</sup>as designated by AISC

*Yield stress*,  $F_y$ , is that unit tensile stress at which the stress-strain curve exhibits a well-defined increase in strain without an increase in stress. For carbon and HSLA steels that show sharply defined yield points,  $F_y$  represents the stress at the obvious yield point. For the heat-treated steels that do not show a definite *yield point*,  $F_y$  represents the yield strength. The *yield strength* is defined as the stress corresponding to a

**Figure 58.1** Typical Stress-Strain Curves for Structural Steels

specified deviation (usually 0.2%) from perfectly elastic behavior. The elastic behavior is characterized by the initial, nearly vertical straight-line portion of the stress-strain diagram. The yield stress property is extremely important in structural design because it serves as a limiting value of a member's usefulness.

*Tensile strength*,  $F_u$ , is the largest unit stress that the material achieves in a tension test. The *modulus of elasticity*,  $E$ , is the slope of the initial straight-line portion of the stress-strain diagram. For all structural steels, it is usually taken as 29,000 ksi for design calculations. *Ductility* is the ability of the material to undergo large inelastic deformations without fracture. In a tension test, it is generally measured by percent elongation for a specified gage length (usually 2 in or 8 in). This property allows redistribution of stresses in continuous members and at points of high local stresses, such as those at holes or other discontinuities.

*Toughness* is the ability of a specimen to absorb energy and is characterized by the area under a stress-strain curve. *Weldability* is the ability of steel to be welded without changing its basic mechanical properties. Generally, weldability decreases with increases in carbon and manganese. *Poisson's ratio* is the ratio of transverse strain to longitudinal strain. Poisson's ratio is essentially the same for all structural steels and has a value of 0.3 in the elastic range. *Shear modulus* is the ratio of shearing stress to shearing strain during the initial elastic behavior.

Appendix 58.A lists common structural steels along with their minimum yield stresses, tensile strengths, and uses. Under normal conditions, characterized by a fairly narrow temperature range (usually taken as between -30°F and 120°F), the yield stress, tensile strength, and modulus of elasticity of a structural steel remain virtually constant. But when steel members are subjected to the elevated temperatures of a fire, significant reductions in strength and rigidity occur over time. (See App. 58.B.) For that reason, structural steels are given a spray-applied fire-resistant coating.

#### 4. STRUCTURAL SHAPES

Many different structural shapes are available. The dimension and weight is added to the designation to uniquely identify the shape. For example, W30 × 132 refers to a W shape with an overall depth of approximately 30 in that weighs 132 lbf/ft. The term *hollow structural sections* (HSS) is used to describe round and rectangular tubular members, which are often used as struts in trusses and space frames. Table 58.2 lists structural *shape designations*, and Fig. 58.2 shows common structural shapes.

**Table 58.2** Structural Shape Designations

shape	designation
wide flange beam	W
American standard beam	S
bearing piles	HP
miscellaneous (those that cannot be classified as W, S, or HP)	M
American standard channel	C
miscellaneous channel	MC
angle	L
structural tee (cut from W, S, or M)	WT or ST
structural tubing	TS
round and rectangular tubing	HSS
pipe	pipe or P
plate	PL
bar	bar

**Figure 58.2** Structural Shapes

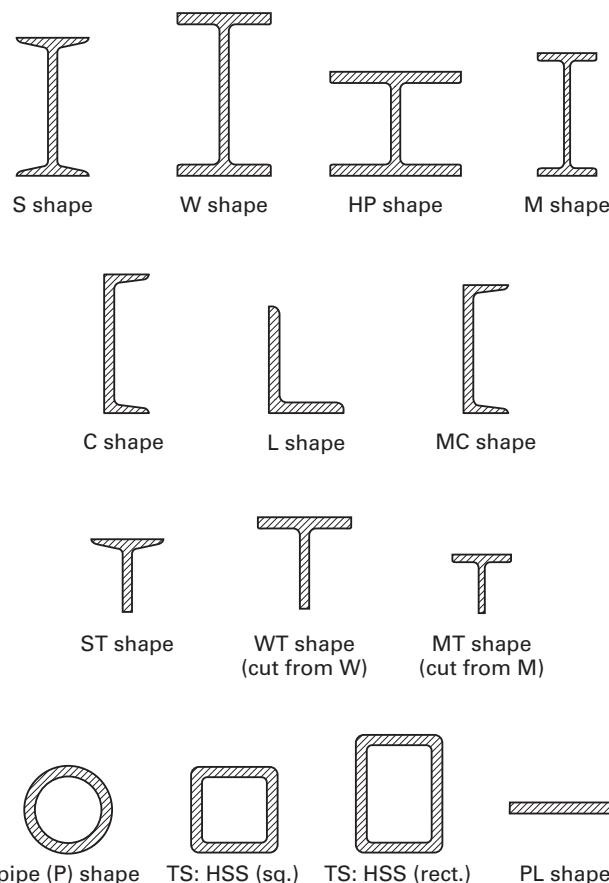

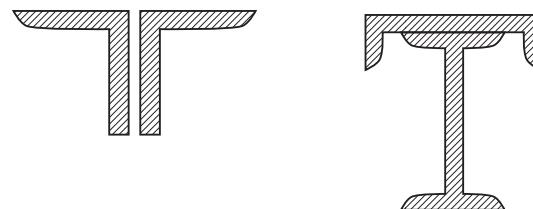

Figure 58.3 illustrates two combinations of shapes that are typically used in construction. The double-angle combination is particularly useful for carrying axial loads. Combinations of W shapes and channels, channels with channels, or channels with angles are used for a variety of special applications, including struts and light crane rails. Properties for certain combinations are tabulated in the *AISC Manual*.

Occasionally, it will be desirable to provide additional bending or compressive strength to a shape by adding plates. It is generally easy to calculate the properties of the built-up section from the properties of the shape and plate. The following characteristics can be used when it is necessary to specify plate reinforcement.

- Plate widths should not be the same as the flange width,  $b_f$ , due to difficulty in welding. Widths should be somewhat larger or smaller. It is better to keep the plate width as close to  $b_f$  as possible, as width-thickness ratios specified in the *AISC Manual* may govern.
- Width and length tolerances smaller than  $\frac{1}{8}$  in are not practical. Table 58.3 should be considered when specifying the nominal plate width.

**Figure 58.3** Typical Combined Sections

**Table 58.3** Width Tolerance for Universal Mill Plates

thickness (in)	width (in)		
	8 to 20 exclusive	20 to 36 exclusive	36 and above
0 to $\frac{3}{8}$ , exclusive	$\frac{1}{8}$	$\frac{3}{16}$	$\frac{5}{16}$
$\frac{3}{8}$ to $\frac{5}{8}$ , exclusive	$\frac{1}{8}$	$\frac{1}{4}$	$\frac{3}{8}$
$\frac{5}{8}$ to 1, exclusive	$\frac{3}{16}$	$\frac{5}{16}$	$\frac{7}{16}$
1 to 2, inclusive	$\frac{1}{4}$	$\frac{3}{8}$	$\frac{1}{2}$
over 2 to 10, inclusive	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{9}{16}$
over 10 to 15, inclusive	$\frac{1}{2}$	$\frac{9}{16}$	$\frac{5}{8}$

(Multiply in by 25.4 to obtain mm.)

Source: *AISC Manual*, Part 1, Standard Mill Practices

- Not every plate exists in the larger thicknesses. Unless special plates are called for, the following thickness guidelines should be used.

$\frac{1}{32}$  in increments up to  $\frac{1}{2}$  in

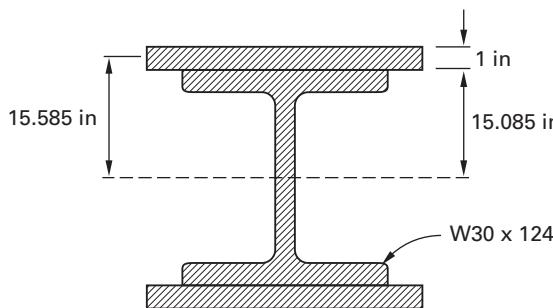

$\frac{1}{16}$  in increments from  $\frac{9}{16}$  in to 1 in

$\frac{1}{8}$  in increments from  $1\frac{1}{8}$  in to 3 in

$\frac{1}{4}$  in increments for  $3\frac{1}{4}$  in and above

### Example 58.1

A W30 × 124 shape must be reinforced to achieve the strong-axis bending strength of a W30 × 173 shape by welding plates to both flanges. The plates are welded continuously to the flanges. What size plate is required if all plate sizes are available?

### Solution

The moments of inertia for the W30 × 124 and W30 × 173 beams are  $5360 \text{ in}^4$  and  $8230 \text{ in}^4$ , respectively. The difference in moments of inertia to be provided by the supplemental plates is

$$I_{\text{plates}} = 8230 \text{ in}^4 - 5360 \text{ in}^4 = 2870 \text{ in}^4$$

For ease of welding, assume the plate thickness,  $t$ , will be approximately the same as the flange thickness. For the W30 × 124 beam, the flange thickness is 0.930 in, so choose a plate thickness of 1.0 in. If  $w$  is the required plate width in inches, the centroidal moment of inertia of the two plates acting together is

$$I_{c,\text{plates}} = \frac{(\text{number of plates})wh^3}{12} = \frac{2w(1 \text{ in})^3}{12} = w/6$$

The depth of the W30 × 124 beam is 30.2 in. Therefore, the distance from the neutral axis to the plate centroid is

$$y_c = \frac{d}{2} + \frac{t}{2} = \frac{30.2 \text{ in}}{2} + \frac{1 \text{ in}}{2} = 15.6 \text{ in}$$

From the parallel axis theorem, the moment of inertia of the two plates about the neutral axis is

$$I_{\text{plates}} = \frac{w}{6} + 2w(1 \text{ in})(15.6 \text{ in})^2 = 486.9w$$

The required moment of inertia is  $2870 \text{ in}^4$ .

$$w = \frac{2870 \text{ in}^4}{486.9 \text{ in}^3} = 5.89 \text{ in} \quad [\text{use } 6 \text{ in}]$$

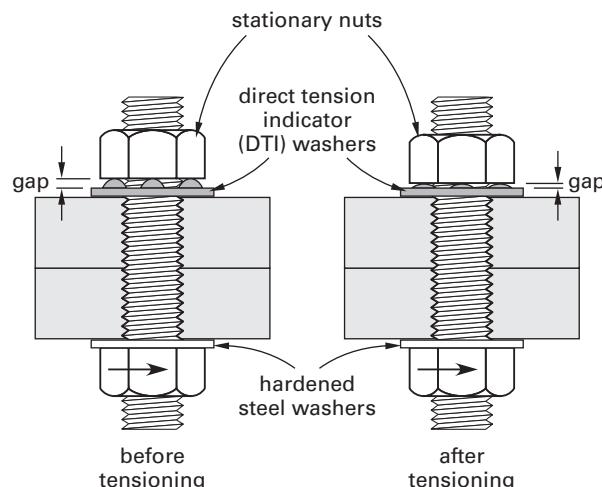

## 5. STEEL CONNECTORS AND CONNECTING ELEMENTS

Specific types of steel are used for the bolts, nuts, and washers that make up the structural connections of steel girder systems, including bridges. *High-strength bolts* are commonly ASTM A325 and ASTM A490, which for bridges are equivalent to AASHTO M164 and AASHTO M253, respectively. ASTM A325 bolts have minimum tensile strengths of 120 ksi for diameters 0.5 in through 1.0 in, and 105 ksi for diameters 1.125 in through 1.5 in. ASTM 490 bolts have a minimum tensile strength of 150 ksi. Both bolt types are heat treated and have varieties for use with weathering and galvanized steels. Nuts are specific to the type of bolt used. For example, nuts conforming to ASTM 563 (AASHTO M291) grades DH, DH3, C, C3, and D may be used with ASTM A325 bolts. Washers must conform to ASTM F436 (AASHTO M293) grade. If the bolts are galvanized, the nuts and washers should be galvanized and lubricated when installed.

*Direct tension indicator (DTI)* washers are increasingly used for reliable installation of pretensioned bolts. (See Fig. 58.4.) The DTI can be used to indicate visually and to verify with a feeler gauge that the correct pretension in the bolt has been reached during bolt installation.

Shear stud connectors must conform to ASTM A108 (AASHTO M169) and have a minimum yield of 50 ksi and a tensile strength of 60 ksi. All welding filler metal for welded bridge construction should meet the requirements of the American Welding Society's *Bridge Welding Code* (AWS D1.5) and AASHTO's *LRFD Bridge Design Specifications*.

**Figure 58.4** Direct Tension Indicator (DTI) Washer

## 6. SPECIFICATIONS AND BUILDING CODES

Although the terms “specification” and “building code” are often used interchangeably in the context of steel design, there is a difference between the two. A *specification* is a set of guidelines or recommendations put forth by a group of experts in the field of steel research and design with the intent of ensuring safety. A specification is not legally enforceable unless it is a part of a building code.

The design of steel buildings in the United States is principally based on the specifications of the American Institute of Steel Construction (AISC), a nonprofit trade association representing and serving the fabricated structural steel industry in the United States. AISC's *Steel Construction Manual* (referred to as the *AISC Manual* in this book) describes and defines the details of the two permitted methods of design: load and resistance factor design (LRFD) and allowable strength design (ASD).<sup>1</sup> The *AISC Manual* includes the AISC *Specification for Structural Steel Buildings* (referred to as *AISC Specification* in this book). In addition to the ASD and LRFD specifications, the *AISC Manual* contains a wealth of information on products available, design aids, examples, erection guidelines, and other applicable specifications.

A *building code* is a broad-based document covering all facets of safety, such as design loadings, occupancy limits, plumbing, electrical requirements, and fire protection. Building codes are adopted by states, cities, or other government bodies as a legally enforceable means of protecting public safety and welfare. Although other codes have seen widespread use, since 2000 the predominant building code in the United States has been the *International Building Code* (IBC), maintained and published by the International Code Council (ICC).<sup>2</sup> The ICC adopts AISC methodologies, both by reference and by duplication, with and without modifications.

<sup>1</sup>For over 100 years, steel structures in the United States were designed to keep induced stresses less than allowable stresses. This method was universally referred to as the *allowable stress design* (ASD) method. Since the introduction of design methods (e.g., LRFD) based on ultimate strength, allowable stress design has become disfavored, even though it is explicitly permitted in the *AISC Manual*. Accordingly, in a move to make all design methods “strength” related processes, starting with the 13th edition of the *AISC Manual*, ASD was renamed as the *allowable strength design* method, even though ASD does not utilize ultimate strength concepts at all. The name *allowable stress design* is still used by other authorities, including ASCE/SEI7.

<sup>2</sup>Prior to the widespread adoption of the IBC, three model building codes were in use in the United States: the *Uniform Building Code* (UBC) from the International Conference of Building Officials (ICBO), the *National Building Code* (NBC) from the Building Officials and Codes Administrators International, Inc. (BOCA), and the *Standard Building Code* (SBC) from the Southern Building Code Congress International (SBCCI).

## 7. METHODS OF DESIGN

There are two methods of design in current use in the United States: *allowable strength design* (ASD) and *load and resistance factor design* (LRFD).

The ASD method is based on the premise that structural members remain elastic when subject to applied loads. According to this method, a structural member is designed so that its computed strength under service or working loads does not exceed available strength. The available strengths are prescribed by the building codes or specifications to provide a factor of safety against attaining some limiting strength such as that defined by yielding or buckling.

The LRFD method, also referred to as *limit states design*, is the predominant design method for concrete structures. The method was first introduced for steel structures in 1986 with the publication of the first edition of AISC's *Manual of Steel Construction: Load and Resistance Factor Design*. “Limit state” is a general term meaning a condition at which a structure or some part of it ceases to fulfill its intended function. There are two categories of limit states: strength and serviceability. The *strength limit states* that are of primary concern to designers include plastic strength, fracture, buckling, fatigue, and so on. These affect the safety or load-carrying capacity of a structure. The *serviceability limit states* refer to the performance under normal service loads and pertain to uses and/or occupancy of structures, including excessive deflection, drift, vibration, and cracking. Subsequent chapters in this book use the LRFD method in examples unless otherwise noted.

## 8. LOADS

Structures are designed to resist many types of loads including dead loads, live loads, snow loads, wind loads, and earthquake loads. The complete design must take into account all effects of these loads, including all applicable load combinations. Building codes (state, municipal, or other) usually provide minimum loads for a designer's use in a particular area. In the absence of such provisions, refer to *Minimum Design Loads for Buildings and Other Structures* (ASCE/SEI7). For LRFD, the load combinations in ASCE/SEI7 Sec. 2.3 apply, and for ASD, the load combinations in ASCE/SEI7 Sec. 2.4 apply.

## 9. FATIGUE LOADING

The effects of fatigue loading are generally not considered, except in the cases of bridge and connection design. If a load is to be applied and removed less than 20,000 times (roughly equivalent to twice daily for 25 years), as would be the case in a conventional building, no provision for repeated loading is necessary.

However, some designs, such as for crane runway girders and supports, must consider the effects of fatigue. Design for fatigue loading is covered in App. 3 of the *AISC Specification*.

## 10. MOST ECONOMICAL SHAPE

Since a major part of the cost of using a rolled shape in construction is the cost of raw materials, the lightest shape possible that will satisfy the structural requirements should usually be used. Generally speaking, the *most economical shape* is the structural shape that has the lightest weight per foot and that has the required strength. The beam selection table and chart are designed to make choosing economical shapes possible.

Prior to 1995, there was a significant cost differential between ASTM A36 steel and the stronger ASTM grade 50 steel. However, that cost differential vanished when steel producers began to make a *dual-certified* steel that met the more restrictive criteria from the specifications for both ASTM A36 and A572 grade 50. Consequently, A992 steel with a minimum specified yield strength of 50 ksi is now standard for new construction in the United States.

## 11. DESIGNING WITH WEATHERING STEEL

*Weathering steel* is a term used to describe A588 steel when it is used unpainted, particularly as part of bridge substructures. The natural layer of oxidation (rust) that forms provides all the protection needed for most applications. The higher cost of the material is offset by eliminating the need to paint and repaint the structure. (A588 steel usually costs somewhat less than painted A572 and A992 grade 50 steels, which also have a 50 ksi yield strength.)

If used without a careful evaluation of environmental location and detailing, however, weathering steel can experience significant corrosion and cracking. Successful use depends on considering several factors in the design. (a) The use of A588 steel in locations that interfere with the development of the protective oxide coating should be avoided. For example, contact between the steel and vegetation, masonry, wood, or other materials should be avoided so that weathering can be maintained on a natural basis. (b) Retention of water and debris on steel surfaces should be avoided. In bridge decks, rely on camber rather than on deck drains that can be easily clogged by roadside debris. (c) “Jointless,” continuous construction should be used, or the steel beneath joints should be protected and sealed by galvanizing. (d) Surface runoff from the deck to the steel below should be prevented. Similarly, the “tunnel effect,” whereby road salts are sucked onto the substructure due to limited space between it and surrounding terrain or features, should be eliminated. (e) Areas where debris has collected should be flushed and cleaned regularly to prevent the buildup of corrosive salts.

To prevent unsightly staining of concrete abutments and piers in urban areas, the first 5 ft to 6 ft (1.5 m to 1.8 m) of the steel structure can be painted.

## 12. HIGH-PERFORMANCE STEEL

The term *high-performance steel* (HPS), as used in bridge design, refers to *weathering steel*<sup>3</sup> that meets ASTM A709 specifications. It is tougher and lighter in weight, and has greater resistance to atmospheric corrosion than traditional grades. It also has a greater fatigue resistance and a lower low-temperature fracture transition. Available primarily in plate form, it is increasingly used in bridge steel plate girders where savings can range from 10% to 20% in cost and up to 30% in weight due to reductions in material. HPS was developed through a joint program between the U.S. Federal Highway Administration (FHWA) and the American Iron and Steel Institute (AISI).

HPS is manufactured in various grades: HPS 100W, HPS 70W, and HPS 50W, where the grade number refers to the minimum yield strength. (See Table 58.4.) HPS 70W was the original grade developed. The other grades were developed based on the success of HPS 70W. Most HPS 70W plate is quenched and tempered (Q&T), a manufacturing operation that involves additional heating and cooling steps, and that limits plate lengths to approximately 50 ft (15 m) and thicknesses to approximately 4 in (100 mm). Advanced compositions and processes are allowing HPS plate to be manufactured longer and thicker without quenching and tempering. Thermo-mechanical controlled processing (TMCP) is used to produce HPS 70W up to 2 in (50 mm) thick and 125 ft (38 m) long, depending on weight. True structural sections may eventually be possible.

**Table 58.4** Mechanical Properties of High-Performance Steel Plate

	HPS 50W up to 4 in, as rolled	HPS 70W up 4 in (Q&T) or 2 in (TMCP)
minimum yield strength, $F_y$ (ksi (MPa))	50 (345)	70 (485)
ultimate tensile strength, $F_u$ (ksi (MPa))	70 (485)	85–110 (585–760)
minimum Charpy V-notch (CVN) toughness, longitudinal orientation* (ft-lbf (J))	25 (41) at 10°F (−12°C)	30 (48) at −10°F (−23°C)

\*HPS far exceeds the toughness specifications.

<sup>3</sup>A *weathering steel* is able to perform its function without being painted when exposed to the atmosphere.

As with all high-strength steel, welding protocol must be strictly controlled to avoid hydrogen embrittlement (hydrogen cracking). Specific techniques and different consumables (e.g., rod, flux, and shield gas) are required for each combination of steels to be joined.

### 13. HIGH-STRENGTH STEEL

100 ksi (690 MPa) high-strength structural steel is readily available, and rods and prestressing steel can have strengths near or over 200 ksi (1380 MPa). These steels are frequently used in structural steel connectors (A514 quenched and tempered steel with a 100 ksi (690 MPa) yield, for example). However, high-strength steels have particular characteristics that must be considered.

Higher strengths are obtained at the expense of decreased ductility and increased brittleness. Very high-strength steels have very little or almost no margin of strength above the yield strength. The design stress that controls is often half of the tensile strength, and it may be lower than the fraction of yield used in lower-strength steels. In the same vein, the transition temperature, below which the steel loses its ductility, must be considered.

High-strength steels used in structural shapes are sensitive to welding-induced hydrogen cracking. Welding may change the grain structure significantly, introducing discontinuities (flaws) in the steel structure that can serve as sites for fractures. Also, welding may introduce residual stresses, particularly with thick plates and complex joints, unless preheating and postheating are used. Some complex joints may need to be fabricated offsite, heated in an annealing furnace, and allowed to cool slowly in order to reduce the high levels of residual stresses introduced by welding.

High-strength steels are sensitive to fatigue (dynamic loading) and the rate of stress application. Bridges, for example, are subjected to thousands or millions of vehicle loads over their lifetimes. The design stress in such cases is limited to the endurance strength, which might be only a fraction of the design stress in the absence of fatigue.

High-strength steels are also more sensitive to corrosion, leading to *stress-corrosion cracking*. Even environments where the strongest corrosive is rainwater may cause high-strength bolts to fail.

For applications where the use of high-strength steel is problematic, several options exist. (a) Use a lower-strength steel or a steel with a higher fracture toughness. Some state highway departments limit the strength of connectors that are used in thick members for this reason. (b) Closely monitor pretensioning of bolts. (c) Use accepted procedures for welding and weld inspection. (d) Design for redundancy. For example, in bridge design, a larger number of smaller stringers is preferred over ever-larger rolled sections or large sections built up by welding. (e) Predict fatigue-crack rates in order to determine realistic service lives of structures subjected to repeated loadings, such as bridges and offshore structures. (f) Design for inspection. (g) Use proper inspection techniques. For example, bolt tension cannot be adequately field-checked by using a torque wrench.

<i>u</i>	ultimate
<i>v</i>	shear
<i>w</i>	web or warping
<i>x</i>	strong axis
<i>y</i>	yield or weak axis

### 1. TYPES OF BEAMS

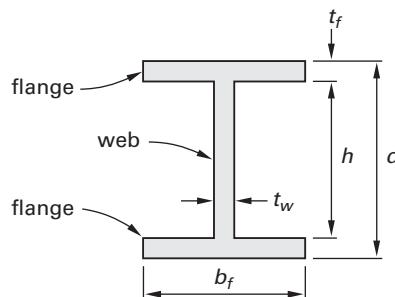

Beams primarily support transverse loads (i.e., loads that are applied at right angles to the longitudinal axis of the member). They are subjected primarily to flexure

(bending). Although some axial loading is unavoidable in any structural member, the effect of axial loads is generally negligible, and the member can be treated strictly as a beam. If an axial compressive load of substantial magnitude is also present with transverse loads, the member is called a *beam-column*.

Beams are often designated by names that are representative of some specialized functions: A *girder* is a major beam that often provides supports for other beams. A *stringer* is a main longitudinal beam, usually supporting bridge decks. A *floor beam* is a transverse beam in bridge decks. A *joist* is a light beam that supports a floor. A *lintel* is a beam spanning an opening (a door or window), usually in masonry construction. A *spandrel* is a beam on the outside perimeter of a building that supports, among other loads, the exterior wall. A *purlin* is a beam that supports a roof and frames between or over supports, such as roof trusses or rigid frames. A *girt* is a light beam that supports only the lightweight exterior sides of a building, as is typical in pre-engineered metal buildings.

Commonly used beam cross sections are standard hot-rolled shapes including the W-, S-, M-, C-, T-, and L-shapes. Doubly symmetrical shapes, such as W, S, and M sections, are the most efficient. They have excellent flexural strength and relatively good lateral strength for their weight. Channels have reasonably good flexural strength but poor lateral strength, and they require horizontal bracing or some other lateral support. Tees and angles are suitable only for light loads. Nomenclature and terminology for W-shapes are shown in Fig. 59.1.

**Figure 59.1** Nomenclature and Terminology for Steel W-Shape Beams

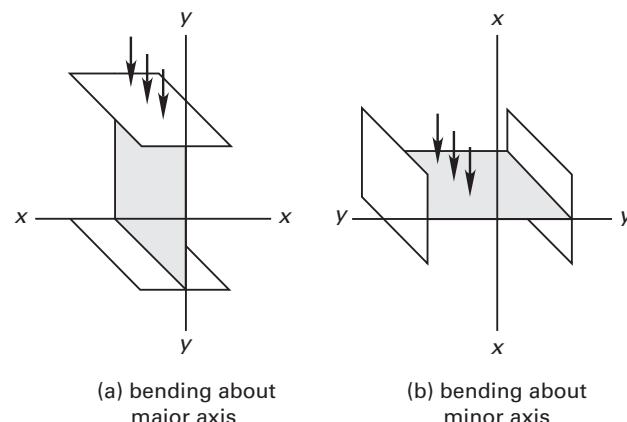

The flexural strength of a rolled section can be improved by adding flange plates. But if the loadings are too great or the spans are too long for a standard rolled section, a plate girder may be necessary. *Plate girders* are built up from plates in I (most common), H, or box shapes of any depth. A *box shape* is used if depth is restricted or if intrinsic lateral stability is needed.

## 2. BEAM BENDING PLANES

The property tables for W-shapes contain two moments of inertia,  $I_x$  and  $I_y$ , for each beam. There are several

ways of referring to the *plane of bending*. Figure 59.2(a) shows a W-shape beam as it is used typically. The value of  $I_x$  should be used to calculate bending stress. This bending mode is referred to as “bending about the major (or strong) axis.” However, it is also referred to as “loading in the plane of the web.” Fig. 59.2(b) shows a W-shape “bending about the minor (or weak) axis.” This mode is also referred to as “loading perpendicular to the plane of the web.”

**Figure 59.2** Beam Bending Planes

## 3. FLEXURAL STRENGTH IN STEEL BEAMS

Design and analysis of simple beams are based on comparing the moment due to the loads to a nominal flexural strength modified by a safety factor. For compact sections with adequate lateral support, the nominal flexural strength is given by

$$M_n = F_y Z_x \quad [\text{AISC Eq. F2-1}] \quad 59.1$$

For ASD, the nominal flexural strength is modified by the safety factor,  $\Omega_b$ , for bending. The design equation is

$$M = M_D + M_L \leq \frac{M_n}{\Omega_b} \quad [\text{ASD}] \quad 59.2$$

$M$  is the moment due to the loads, and  $\Omega_b = 1.67$  per *AISC Specification F1*.

For LRFD, the nominal strength is modified by the resistance factor,  $\phi_b$ , for bending. The design equation is

$$M_u = 1.6M_L + 1.2M_D \leq \phi_b M_n \quad [\text{LRFD}] \quad 59.3$$

$M_u$  is the factored ultimate moment due to the loads, and  $\phi_b = 0.90$  (*AISC Specification Sec. F1*).

## 4. COMPACT SECTIONS

All of the compression elements of *compact sections* satisfy the limits of *AISC Specification* Table B4.1. Beams whose compression elements are compact are known as compact beams. Compact beams achieve

higher strengths and may be more highly loaded than noncompact beams. Compactness requires more than compression element geometry. For a beam to be compact, its flanges must be attached to the web continuously along the beam length. Therefore, a built-up section or plate girder constructed with intermittent welds does not qualify. In addition, Eq. 59.4 and Eq. 59.5 must be satisfied by standard rolled shapes without flange stiffeners. Equation 59.4 applies only to flanges in flexural compression. Equation 59.5 applies only to webs in flexural compression [AISC Specification Table B4.1, with  $b = b_f / 2$ ].

$$\frac{b_f}{2t_f} \leq 0.38 \sqrt{\frac{E}{F_y}} \quad \begin{array}{l} \text{flanges in flexural} \\ \text{compression only} \end{array} \quad 59.4$$

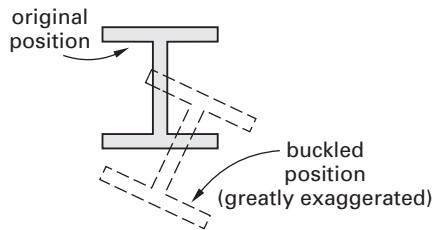

$$\frac{h}{t_w} \leq 3.76 \sqrt{\frac{E}{F_y}} \quad \begin{array}{l} \text{webs in flexural} \\ \text{compression only} \end{array} \quad 59.5$$

Compactness, as Eq. 59.4 and Eq. 59.5 show, depends on the steel strength. Most rolled W-shapes are compact at lower values of  $F_y$ . However, a 36 ksi beam may be compact, while the same beam in 50 ksi steel may not be.

## 5. LATERAL BRACING

To prevent *lateral torsional buckling* (illustrated in Fig. 59.3), a beam's compression flange must be supported at frequent intervals. Complete support is achieved when a beam is fully encased in concrete or has its flange welded or bolted along its full length. (See Fig. 59.4.) In many designs, however, lateral support is provided only at regularly spaced intervals. The actual spacing between points of lateral bracing is designated as  $L_b$ .

**Figure 59.3** Lateral Buckling in a Beam

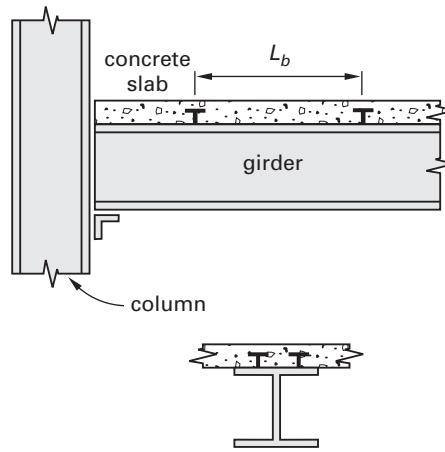

For the purpose of determining flexural design strength ( $M_n/\Omega$  or  $\phi_b M_n$ ), two spacing categories are distinguished:  $L_p < L_b \leq L_r$  and  $L_b > L_r$ . (See Fig. 59.5.)

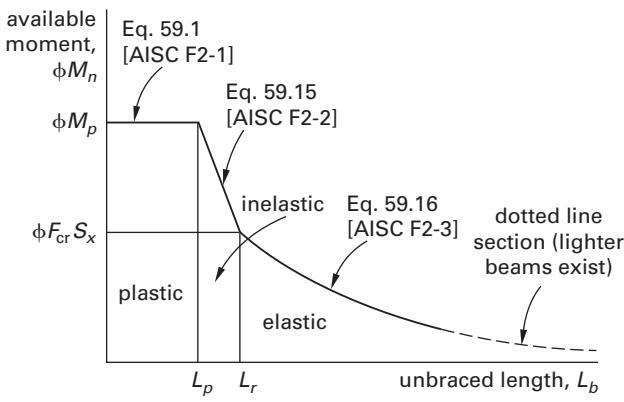

For most shapes,  $L_p$  is calculated from Eq. 59.6, and  $L_r$  is calculated from Eq. 59.7.

$$L_p = 1.76 r_y \sqrt{\frac{E}{F_y}} \quad [\text{AISC Eq. F2-5}] \quad 59.6$$

**Figure 59.4** Compression Flange Bracing Using Headed Studs

**Figure 59.5** Available Moment Versus Unbraced Length

$$L_r = 1.95 r_{ts} \left( \frac{E}{0.7 F_y} \right) \sqrt{\frac{J_c}{S_x h_o}} \times \sqrt{1 + \sqrt{1 + 6.76 \left( \frac{0.7 F_y S_x h_o}{E J_c} \right)^2}} \quad 59.7$$

[AISC Eq. F2-6]

$r_{ts}$  is the *effective radius of gyration* used to determine  $L_r$  for the lateral torsional buckling state. For doubly symmetrical, compact shapes bending about the major axis, it is accurately (and conservatively) estimated as the radius of gyration of the compression flange plus one-sixth of the radius of gyration of the web. It is tabulated in the shape tables in *AISC Manual Part 1*.

$$r_{ts} = \frac{b_f}{\sqrt{12 \left( 1 + \frac{h t_w}{6 b_f t_f} \right)}} \quad 59.8$$

$r_{ts}$  can also be calculated from Eq. 59.9 [AISC Eq. F2-7] in which both the elastic section modulus,  $S_x$ , and the

warping constant,  $C_w$ , are tabulated in the AISC shape tables.

$$r_{ts}^2 = \frac{\sqrt{I_y C_w}}{S_x} \quad 59.9$$

The warping constant,  $C_w$ , is a measure of a shape's resistance to failure by lateral buckling. For an assembly of standard shapes, each shape's warping constant can be summed to give the assembly's warping coefficient. An approximation of the warping constant for I-shapes is given by Eq. 59.10.<sup>1</sup> Obtaining exact values for more complex built-up sections requires substantial effort.

$$C_w = \frac{h^2 I_y}{4} \approx \frac{(d - t_f)^2 t_f b_f^3}{24} \quad 59.10$$

The symbol  $J$  denotes the *torsional constant*.<sup>2</sup> The torsional constant is a measure of the shape's resistance to failure by twisting. Values of  $J$  are tabulated in the shape tables in *AISC Manual* Part 1 for rolled shapes and angles.<sup>3</sup> For any other I-beam with element thickness,  $t$ , the torsional constant is

$$J = \frac{1}{3} \int_0^{b_f} t^3 \, db \approx \frac{1}{3} \sum bt^3 \quad [b > t; b/t > 10] \quad 59.11$$

The second form of Eq. 59.11 shows that  $J$  can be closely approximated for I-shapes and angles by dividing the cross-sectional shape into mutually exclusive rectangular pieces (as though the shape was being constructed of plate girders) and the quantities  $bt^3/3$  calculated for each, and then summed. The small contributions of the fillet radii are disregarded with this method. (This approximation cannot be used for closed shapes.)

For doubly symmetrical I-shapes,  $c = 1$  [*AISC Specification* Eq. F2-8a]. For a channel,  $c$  is calculated from *AISC Specification* Eq. F2-8b.

$$c = \frac{h_o}{2} \sqrt{\frac{I_y}{C_w}} \quad 59.12$$

<sup>1</sup>Equation 59.10 assumes the entire beam is solid, without bolt holes. However, hole geometry greatly affects the value. As such, it is not a conservative estimate.

<sup>2</sup>This  $J$  is the *St. Venant torsional constant*, not the polar moment of inertia (i.e., the sum of the moments of inertia about the  $x$ - and  $y$ -axes), even though (1) the same variable is used, (2) the units are the same, and (3) the values are identical for circular members. For I-beams and other shapes, the values are significantly different. For example, for a W8 × 24 shape, the polar moment of inertia is approximately 101 in<sup>4</sup>, whereas the torsional constant is only 0.35 in<sup>4</sup>. Using the polar moment of inertia for the torsional constant will result in grossly under-calculating stress.

<sup>3</sup>For double angles and other assemblies of shapes, the combined torsional constant is simply the sum of the torsional constants of each angle.

## 6. PROCESSES OF FLEXURAL FAILURE

Strength failure (as opposed to serviceability failure due to excessive deflection) of steel beams in flexure can occur through three different processes (known as *failure modes* corresponding to their respective limit states), depending on the unbraced length,  $L_b$ : (1) failure by yielding (material failure), when  $L_b < L_p$ ; (2) failure by inelastic buckling, when  $L_p < L_b < L_r$ ; and (3) failure by elastic buckling, when  $L_b > L_r$ . These three regions are shown in Fig. 59.5. Three different AISC equations are used to calculate values of  $M_n$  corresponding to the actual unbraced length. However, in most cases, values of  $M_n$  are read directly from tables in the *AISC Manual*.

## 7. LATERAL TORSIONAL BUCKLING

The laterally unsupported length of a beam can fail in lateral torsional buckling due to the applied moment. Lateral torsional buckling is fundamentally similar to the flexural buckling of a beam and flexural torsional buckling of a column subjected to axial loading. If the laterally unbraced length,  $L_b$ , is less than or equal to a plastic length,  $L_p$ , as in Eq. 59.6, then lateral torsional buckling will not be a problem, and the beam will develop its full plastic strength,  $M_p$ . However, if  $L_b$  is greater than  $L_p$ , then lateral torsional buckling will occur and the moment capacity of the beam will be reduced below the plastic strength,  $M_p$ .

Usually, the bending moment varies along the unbraced length of a beam. The worst case scenario is for beams subjected to uniform bending moments along their unbraced lengths. For this situation, the *AISC Manual* specifies a value  $C_b = 1$  for the *lateral torsional buckling modification factor*, also known as the *beam bending coefficient*, *moment modification factor*, and in the past, as the *moment gradient multiplier*. For nonuniform moment loadings,  $C_b$  is greater than 1.0, effectively increasing the strength of the beam.  $C_b$  is equal to 1.0 for uniform bending moments, and is always greater than 1.0 for nonuniform bending moments. Of course, the increased moment capacity for the nonuniform moment case cannot be more than  $M_p$ . If the calculated strength value,  $M_n$ , is greater than  $M_p$ , it must be reduced to  $M_p$ .

$$M_{n,\text{nonuniform moment}} = C_b M_{n,\text{uniform moment}} \quad 59.13$$

$C_b$  can always be conservatively assumed as 1.0. In fact, for cantilever beams where the free ends are unbraced,  $C_b = 1.0$ . However, with  $C_b$  values as high as 3, substantial material savings are possible by not being conservative.

Various theoretical and experimental methods exist for calculating  $C_b$ . The most convenient method is to read  $C_b$  directly from App. 59.A. *AISC Specification* Eq. F1-1 provides a method for calculating  $C_b$  when both ends of the unsupported segment are braced and the beam is bent in single or double curvature. In Eq. 59.14,  $M_{\max}$  is the

magnitude of maximum bending moment in  $L_b$ .  $M_A$ ,  $M_B$ , and  $M_C$  are the magnitudes of the bending moments at the quarter point, midpoint, and three-quarter point, respectively, along the unbraced segment of length  $L_b$ . Refer to *AISC Specification* Sec. F1 for other cases.

$$C_b = \frac{12.5M_{\max}}{2.5M_{\max} + 3M_A + 4M_B + 3M_C} \quad 59.14$$

## 8. FLEXURAL DESIGN STRENGTH: I-SHAPES BENDING ABOUT MAJOR AXIS

For I-shapes loaded in the plane of their webs and bending about the major axis, the nominal flexural strength will be  $M_p = F_y Z_x$  or less. If  $L_b \leq L_p$ , or if the bracing is continuous and the beam is compact, the nominal flexural strength,  $M_n$ , is  $M_p$ . If  $L_r \geq L_b > L_p$ , then

$$M_n = C_b \left( M_p - (M_p - 0.7F_y S_x) \left( \frac{L_b - L_p}{L_r - L_p} \right) \right) \leq M_p \quad [\text{AISC Eq. F2-2}] \quad 59.15$$

If  $L_b > L_r$ , or if there is no bracing at all between support points, then

$$M_n = F_{cr} S_x \leq M_p \quad [\text{AISC Eq. F2-3}] \quad 59.16$$

$$F_{cr} = \frac{C_b \pi^2 E}{\left( \frac{L_b}{r_{ts}} \right)^2} \sqrt{1 + 0.078 \frac{J_c}{S_x h_o} \left( \frac{L_b}{r_{ts}} \right)^2} \quad [\text{AISC Eq. F2-4}] \quad 59.17$$

## 9. FLEXURAL DESIGN STRENGTH: I-SHAPES BENDING ABOUT MINOR AXIS

If an I-shape is placed such that bending will occur about its weak axis, the nominal flexural strength will be  $M_p = F_y Z_y \leq 1.6F_y S_y$ . The shape must be compact, and other conditions may also apply. However, this is not an efficient use of the beam, so this configuration is seldom used. Nevertheless, weak-axis bending may occur, particularly in beam-columns.

## 10. SHEAR STRENGTH IN STEEL BEAMS

Although there are different requirements for plate girders, bolts, and rivets, the *nominal shear strength* of unstiffened or stiffened webs of singly and doubly symmetrical beams is given by Eq. 59.18 [*AISC Specification* Eq. G2-1]. It is assumed that only the web thickness carries shear in W-shapes. (See Fig. 59.1.)

$$V_n = 0.6F_y A_w C_v = 0.6F_y d t_w C_v \quad 59.18$$

The design criteria are

$$V_u = 1.6V_L + 1.2V_D \leq \phi_v V_n \quad [\text{LRFD}] \quad 59.19$$

$$V = V_L + V_D \leq \frac{V_n}{\Omega} \quad [\text{ASD}] \quad 59.20$$

The basic ASD safety factor for shear,  $\Omega_v$ , is 1.67, and the basic LRFD resistance factor for shear,  $\phi_v$ , is 0.90. However, for webs of virtually all W, S, and HP rolled 50 ksi shapes with  $h/t_w \leq 2.24\sqrt{E/F_y}$ ,  $\Omega_v$  is 1.5, and  $\phi_v$  is 1.00.<sup>4</sup> The *web shear coefficient*,  $C_v$ , is 1.0.

## 11. SERVICEABILITY AND BEAM DEFLECTIONS

In addition to being safe, a structure with all its components must be serviceable. While stresses in a beam due to moment and shear must be within allowable limits to ensure safety, the beam cannot be too flexible. Deflection of the beam usually limits the flexibility. Among the many reasons for avoiding excessive deflections are the effects on nonstructural elements (e.g., doors, windows, and partitions), undesirable vibrations, and the proper functioning of the roof drainage systems.

Steel beam deflections are calculated using traditional beam equations based on the principles of strength of materials. For common beams and loadings, the *AISC Manual Beam* section and the Beam Diagrams and Formulas, Table 3-23, contains deflection formulas. Deflection limitations are typically unique to each design situation and are generally expressed in terms of some fraction of the span length. The elastic deflection limit is  $L/360$  for beams and girders supporting plastered ceilings [*AISC Specification* Chap. L]. The *AISC Specification* suggests, but does not require, general guidelines to maintain appearance and occupant confidence in a structure. (See Chap. L of the *AISC Specification*. Special provisions in *AISC Specification* App. 2 are used to check for ponding.)

## 12. ANALYSIS OF STEEL BEAMS

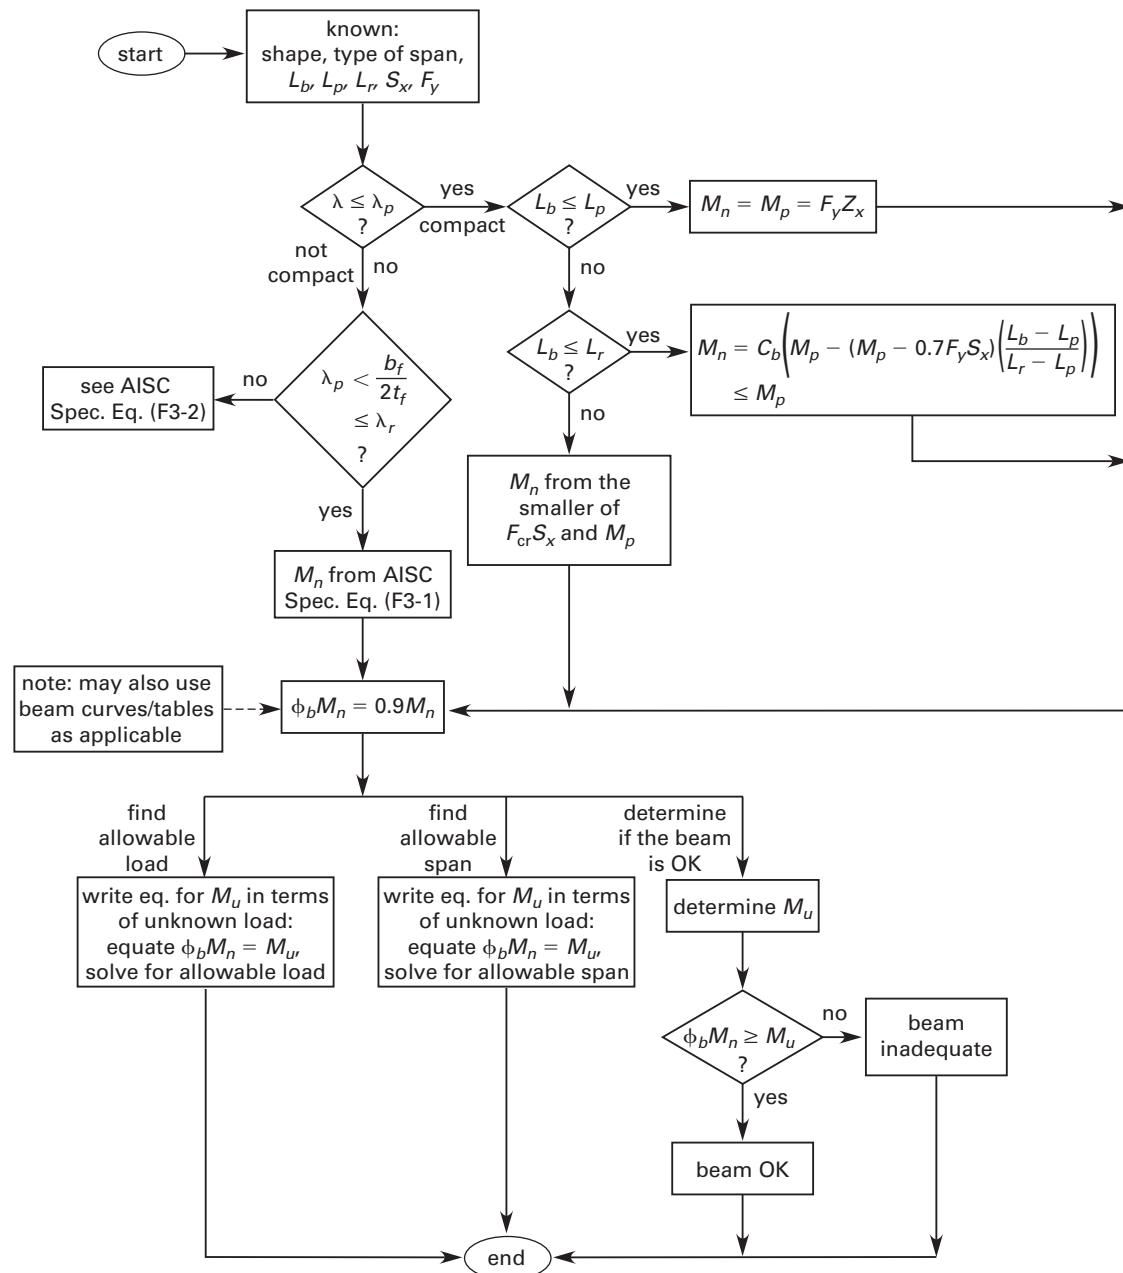

Although bending strength is the primary criterion for beams, a complete analysis of a steel beam of known cross section also includes checking for shear strength and deflection. A flowchart for beam analysis (moment capacity criterion only) is shown in Fig. 59.6.

### Example 59.1

Based on moments and flexural strength only, determine the maximum allowable superimposed uniformly distributed load that a W21 × 55 beam of A992 steel can carry on a simple span of 36 ft. Consider the compression flange to be braced at (a) 6 ft intervals, (b) 12 ft intervals, and (c) 18 ft intervals.

<sup>4</sup>50 ksi beams that are exceptions are W44 × 230, W40 × 149, W36 × 135, W33 × 118, W30 × 90, W24 × 55, W16 × 26, and W12 × 14 [*AISC Specification* Sec. G2.1(a)].

**Figure 59.6** Flowchart for LRFD Analysis of Beams (W-shape, strong-axis bending, moment criteria only)  
(Spec. = Specifications; Part 16 of the AISC Manual)

**Solution**

For A992 steel,  $F_y = 50$  ksi. Obtain the properties of a W21 × 55 beam from *AISC Manual* Table 1-1.

$$S_x = 110 \text{ in}^3$$

$$r_{ts} = 2.11 \text{ in}$$

Check for compactness. From Eq. 59.4,

$$\frac{b_f}{2t_f} = 7.87 < 0.38 \sqrt{\frac{E}{F_y}} = 0.38 \sqrt{\frac{29,000 \frac{\text{kips}}{\text{in}^2}}{50 \frac{\text{kips}}{\text{in}^2}}} = 9.15$$

From Eq. 59.5,

$$\frac{h}{t_w} = 50.0 < 3.76 \sqrt{\frac{E}{F_y}} = 3.76 \sqrt{\frac{29,000 \frac{\text{kips}}{\text{in}^2}}{50 \frac{\text{kips}}{\text{in}^2}}} = 90.55$$

The shape is compact.

From *AISC Manual* Table 3-2, for a W21 × 55,  $L_p = 6.11$  ft, and  $L_r = 17.4$  ft.

(a) The unbraced length is  $L_b = 6$  ft.

Since  $L_b < L_p$ , use Eq. 59.1 to find the design flexural strength.

$$\phi_b M_n = \phi_b M_p = \phi_b F_y Z_x \\ = \frac{(0.9) \left( 50 \frac{\text{kips}}{\text{in}^2} \right) (126 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}} = 473 \text{ ft-kips}$$

The actual bending moment is

$$M_u = \frac{w_u L^2}{8} = \frac{w_u (36 \text{ ft})^2}{8} = (162 \text{ ft}^2) w_u$$

Equate the flexural design strength to the actual bending moment.

$$473 \text{ ft-kips} = (162 \text{ ft}^2) w_u$$

$$w_u = 2.92 \text{ kips/ft}$$

Let  $w$  equal the superimposed load and  $w_D$  equal the weight of the beam. As given by ASCE/SEI7 Sec. 2.3, the factored load,  $w_u$ , is

$$w_u = 1.2w_D + 1.6w \\ 2.92 \frac{\text{kips}}{\text{ft}} = (1.2) \left( 0.055 \frac{\text{kips}}{\text{ft}} \right) + 1.6w \\ w = 1.784 \text{ kips/ft}$$

(b) The unbraced length is  $L_b = 12$  ft.

Since  $L_p < L_b < L_r$ , the nominal bending moment is given by Eq. 59.15. From App. 59.A,  $C_b = 1.45$  and  $C_b = 1.01$ . Use the more conservative 1.01 value.

$$M_n = C_b \left( M_p - (M_p - 0.7F_y S_x) \left( \frac{L_b - L_p}{L_r - L_p} \right) \right) \leq M_p \\ = (1.01) \left( \begin{array}{l} 525 \text{ ft-kips} \\ - \left( \begin{array}{l} 525 \text{ ft-kips} \\ - \frac{(0.7)(50 \frac{\text{kips}}{\text{in}^2})(110 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}} \end{array} \right) \\ \times \left( \frac{12 \text{ ft} - 6.11 \text{ ft}}{17.4 \text{ ft} - 6.11 \text{ ft}} \right) \end{array} \right) \\ = 423 \text{ ft-kips} \quad (< 525 \text{ ft-kips})$$

$$\phi M_n = (0.9)(423 \text{ ft-kips})$$

$$= 381 \text{ ft-kips}$$

$$381 \text{ ft-kips} = (162 \text{ ft}^2) w_u$$

$$w_u = 2.35 \text{ kips/ft}$$

$$w_u = 1.2w_D + 1.6w$$

$$2.35 \frac{\text{kips}}{\text{ft}} = (1.2) \left( 0.055 \frac{\text{kips}}{\text{ft}} \right) + 1.6w \\ w = 1.43 \text{ kips/ft}$$

(c) The unbraced length is  $L_b = 18$  ft.

$L_b > L_r$  so, from Eq. 59.16, the nominal bending moment is  $M_n = F_{cr} S_x \leq M_p$ . Use Eq. 59.17 to compute  $F_{cr}$ . From App. 59.A,  $C_b = 1.3$ .

$$\frac{L_b}{r_{ts}} = \frac{(18 \text{ ft})(12 \frac{\text{in}}{\text{ft}})}{2.11 \text{ in}} = 102.4$$

From Eq. 59.17,

$$\begin{aligned} F_{cr} &= \frac{C_b \pi^2 E}{\left(\frac{L_b}{r_{ts}}\right)^2} \sqrt{1 + 0.078 \frac{J_c}{S_x h_o} \left(\frac{L_b}{r_{ts}}\right)^2} \\ &= \frac{1.3 \pi^2 \left(29,000 \frac{\text{kips}}{\text{in}^2}\right)}{(102.4)^2} \\ &\quad \times \sqrt{1 + 0.078} \\ &\quad \times \left( \frac{(1.24 \text{ in}^4)(1)}{(110 \text{ in}^3)(20.3 \text{ in})} \right) \\ &\quad \times (102.4)^2 \\ &= 42.8 \frac{\text{kips}}{\text{in}^2} \end{aligned}$$

From Eq. 59.16,

$$\begin{aligned} M_n &= F_{cr} S_x \leq M_p \\ &= \frac{\left(42.8 \frac{\text{kips}}{\text{in}^2}\right)(110 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}} \\ &= 392.3 \text{ ft-kips} \leq 525 \text{ ft-kips} \\ \phi_b M_n &= (0.9)(392.3 \text{ ft-kips}) = 353.1 \text{ ft-kips} \\ w_u &= \frac{8\phi_b M_n}{L^2} = \frac{(8)(353.1 \text{ ft-kips})}{(36 \text{ ft})^2} \\ &= 2.180 \frac{\text{kips}}{\text{ft}} \end{aligned}$$

The superimposed load is

$$\begin{aligned} 2.180 \frac{\text{kips}}{\text{ft}} &= (1.2) \left(0.055 \frac{\text{kips}}{\text{ft}}\right) + 1.6w \\ w &= 1.32 \frac{\text{kips}}{\text{ft}} \end{aligned}$$

### 13. DESIGN OF STEEL BEAMS

Steel beams can be designed and analyzed with either the *allowable strength design* (ASD) method (also known as *allowable stress design* and, occasionally, *elastic design*) or *load and resistance factor design* (LRFD) (also known as *strength design*, *ultimate strength design*, *plastic design*, *inelastic design*, *load factor design*, *limit state design*, and *mechanism method*). LRFD may also be specified as being “in accordance with Appendix 1 of the AISC Specification.” Simple, single-span beams are usually designed by ASD since there is little advantage to using LRFD, which is well-suited for continuous spans and frames. LRFD should not be used with non-compact shapes, crane runway rails, members constructed from A514 steel, or steels with yield strengths

in excess of 65 ksi (450 MPa) [AISC Specification App. 1.2].

A detailed flowchart for design of steel beams is given in Fig. 59.7. The AISC Manual also provides three design aids for choosing beams: the W-shape Selection Tables (AISC Table 3-2 through Table 3-5), the Maximum Total Uniform Load Tables (AISC Table 3-6 through Table 3-9), and the Plots of Available Flexural Strength versus Unbraced Length Tables (AISC Table 3-10 through Table 3-11).

#### Design Selection Tables

The W-shape Selection Tables (AISC Table 3-2 through Table 3-5) are easy to use, and they provide a method for quickly selecting economical beams. Their use assumes that either the required plastic section modulus,  $Z$ , or the required design plastic moment,  $M_u = \phi M_p$ , is known, and one of these two criteria is used to select the beam. The tabulated values of  $\phi_v V_n$  (or  $V_n/\Omega_v$ ) and  $I_x$  may be used to determine shear design strength or deflection, and the designer must ensure that  $L_b \leq L_p$ , as well as check shear stress and deflection. Most tables for W-shapes assume that  $F_y = 50$  ksi.

Beams are grouped in the beam selection tables. Within a group, the most economical shape is listed at the top in bold print. This is the beam that should generally be used, even if the moment-resisting capacity and section modulus are greater than necessary. The weight of the most economical beam will be less than the beam in the group that most closely meets the structural requirements.

#### Beam Selection Tables

Table 3-2 of the AISC Manual contains other useful columns. The BF columns contain values representing a simplification of AISC Specification Eq. F2-2 and the slope of the straight line between  $L_p$  and  $L_r$ . (See Fig. 59.5.) BF values correspond to  $(M_p - M_r)/(L_r - L_p)$  and are useful in interpolating available moments.

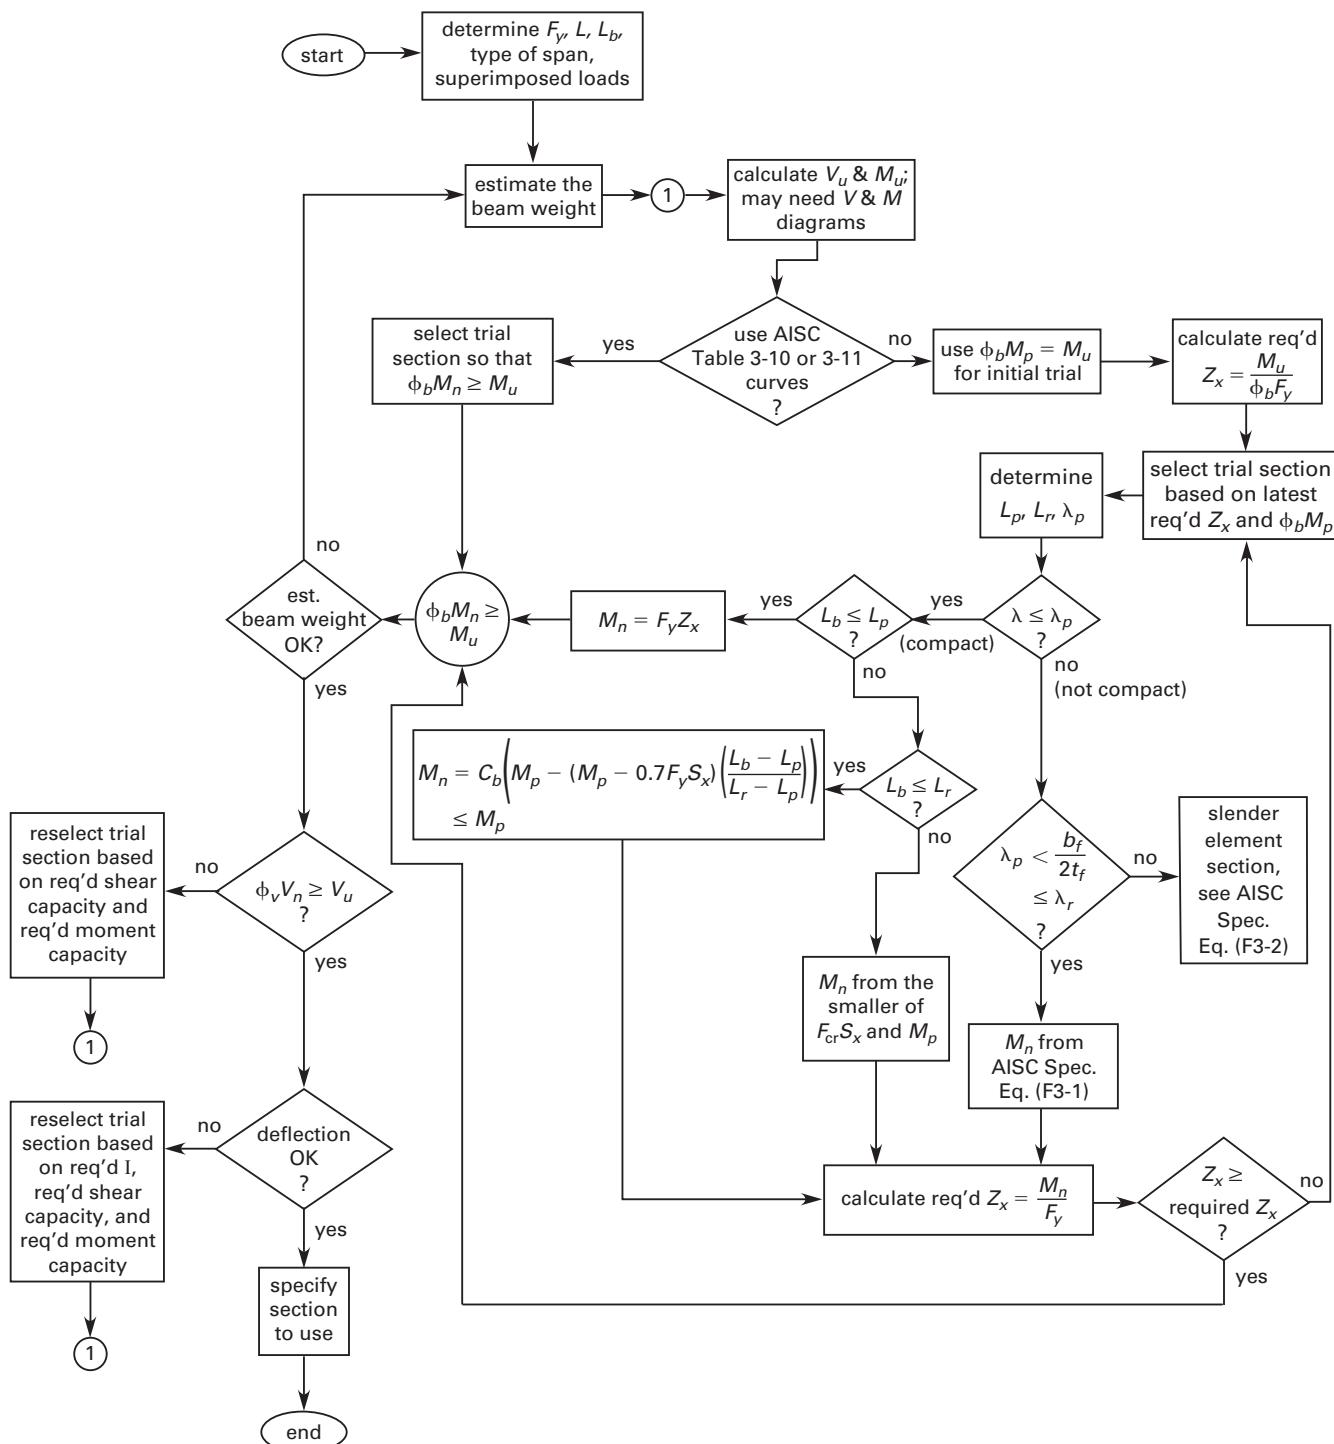

The  $M_{rx}$  columns pertain to functionality near the limit of the elastic region.  $M_r$  is the nominal moment capacity of the beam just as it enters the lateral torsional buckling region. Essentially, it is the nominal moment capacity of the beam when the unbraced length is  $L_r$  (see Fig. 59.5), as calculated using AISC Specification Eq. F2-6. AISC Specification Eq. F2-3 and Eq. F2-4 were used to calculate the value of  $M_n$ . The onset of buckling is known as the *critical point*, thus AISC Specification Eq. F2-3 uses the *critical stress*,  $F_{cr}$ , to calculate the value of  $M_r$  ( $M_n$ ).

$$M_n = F_{cr} S_x \quad 59.21$$

$M_p$  and  $M_n$  values differ by a value of approximately 1.6, corresponding to the ratio  $Z/S$ .

$$M_p = F_y Z \approx 1.6 F_y S \quad 59.22$$

**Figure 59.7** Flowchart for LRFD Beam Design (W- and M-shapes—moment, shear, and deflection criteria) (Spec. = Specifications; Part 16 of the AISC Manual)

## Maximum Total Uniform Load Table

In the Maximum Total Uniform Load Tables (AISC Table 3-6 through Table 3-9), loads are tabulated for  $F_y = 50$  ksi steels for W-shapes, and for 36 ksi for S-, C-, and MC-shapes. Loads can be read directly from the tables when  $L_b \leq L_p$  for compact and noncompact W-, S-, C-, and MC-shapes. When  $L_r \geq L_b > L_p$  or  $L_b < L_r$ , the tables are not applicable.

The tables are convenient for selecting laterally supported simple beams with equal concentrated loads spaced as shown in the *AISC Manual* table of Concentrated Load Equivalents [AISC Table 3-22a]. Except for short spans where shear controls the design, the beam load table may be entered with an equivalent uniform load.

## Available Moment vs. Unbraced Length Tables

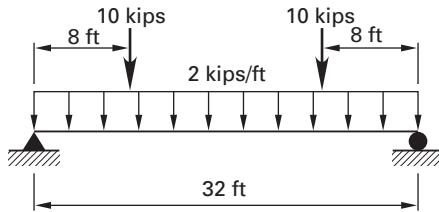

When the unbraced length  $L_b$  is greater than  $L_p$ , the Available Moment Versus Unbraced Length tables (AISC Table 3-10 for W-shapes and Table 3-11 for channels) should be used. *AISC Manual* Table 3-10 can be used for 50 ksi steel with unbraced lengths up to 100 ft, while Table 3-11 covers channels with 36 ksi steel. Each beam plotted on AISC Table 3-10 and Table 3-11 has a profile similar to that in Fig. 59.5.

AISC Table 3-10 and Table 3-11 are entered knowing  $L_b$  and  $M_u = \phi M_n$  (or  $M_n/\Omega$ ). (The plots allow for beam self-weight, which should be deducted when calculating the maximum uniform load. When the unbraced length varies along the beam span, use the longest unbraced length.) The nearest solid line above the intersection of the  $L_b$  and  $M_u$  values is the most economical beam. Dotted line sections mean that a lighter beam exists that has the same capacity. As with the W-shape Selection Table, shear stress and deflection must still be checked.

The Available Moment Versus Unbraced Length tables implicitly assume the beam bending moment coefficient,  $C_b$ , is 1, and this remains a conservative assumption. However, when a nonuniform moment gradient is desired,  $C_b$  can be calculated using *AISC Specification* Eq. F1-1.

### Example 59.2

Using the LRFD method, select the lightest W-shape of A992 steel for the beam and service loading shown. The load does not include the weight of the beam. Assume the compression flange is braced at the ends and at intervals of 8 ft. Consider moment, shear, and deflection. The maximum allowable deflection for the live load is  $L/360$ .

*Solution*

Design for moment.

$$\begin{aligned} M_u &= 1.6 \left( \frac{wL^2}{8} + Px \right) \\ &= (1.6) \left( \frac{\left( 2 \frac{\text{kips}}{\text{ft}} \right) (32 \text{ ft})^2}{8} + (10 \text{ kips})(8 \text{ ft}) \right) \\ &= 537.6 \text{ ft-kips} \end{aligned}$$

The required plastic section modulus is

$$Z_x = \frac{M_u}{\phi F_y} = \frac{(537.6 \text{ ft-kips}) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{(0.9)(50 \text{ ksi})} = 143.4 \text{ in}^3$$

From *AISC Manual* Table 3-2, try a W21 × 68 (in boldface type), which has the following properties.

$$Z_x = 160 \text{ in}^3$$

$$\phi M_p = 600 \text{ ft-kips}$$

$$L_p = 6.36 \text{ ft}$$

$$L_r = 18.7 \text{ ft}$$

Since  $L_p < L_b = 8 \text{ ft} \leq L_r$ , use Eq. 59.15.

$$\begin{aligned} \phi M_n &= \phi C_b \left( M_p - (M_p - 0.7F_y S_x) \left( \frac{L_b - L_p}{L_r - L_p} \right) \right) \leq \phi M_p \\ &= (0.9)(1.0) \end{aligned}$$

$$\begin{aligned} &\times \left( \begin{array}{c} 667 \text{ ft-kips} \\ - \left( \begin{array}{c} 667 \text{ ft-kips} \\ - (0.7) \left( 50 \frac{\text{kips}}{\text{in}^2} \right) \\ \times \frac{140 \text{ in}^3}{12 \frac{\text{in}}{\text{ft}}} \\ \times \left( \frac{8 \text{ ft} - 6.36 \text{ ft}}{18.7 \text{ ft} - 6.36 \text{ ft}} \right) \end{array} \right) \end{array} \right) \\ &= 569 \text{ ft-kips} \leq 600 \text{ ft-kips} \quad [\text{OK}] \end{aligned}$$

The total moment, including the moment due to self-weight, is

$$M_u = 537.6 \text{ ft-kips} + (1.2) \left( \frac{\left( 0.068 \frac{\text{kips}}{\text{ft}} \right) (32 \text{ ft})^2}{8} \right)$$

$$= 548 \text{ ft-kips}$$

$$\phi M_n = 569 \text{ ft-kips} \geq 548 \text{ ft-kips} \quad [\text{OK}]$$

Check the shear.

For this beam, the maximum shear occurs at the support and is equal to the reaction.

$$V_u = 1.6 \left( \frac{wL + 2P}{2} \right) + 1.2 \left( \frac{w_DL}{2} \right)$$

$$= (1.6) \left( \frac{\left( 2.0 \frac{\text{kips}}{\text{ft}} \right) (32 \text{ ft}) + (2)(10 \text{ kips})}{2} \right)$$

$$+ (1.2) \left( \frac{\left( 0.068 \frac{\text{kips}}{\text{ft}} \right) (32 \text{ ft})}{2} \right)$$

$$= 68.5 \text{ kips}$$

From AISC Table 3-2, the maximum permissible web shear for the W21 × 68 is 273 kips.

$$68.5 \text{ kips} < 273 \text{ kips} \quad [\text{OK}]$$

Check the live load deflection.

From AISC Table 3-2,  $I_x$  for the W21 × 68 is 1480 in<sup>4</sup>. The maximum allowable deflection is

$$\Delta = \frac{L}{360} = \frac{(32 \text{ ft}) (12 \frac{\text{in}}{\text{ft}})}{360} = 1.07 \text{ in}$$

From the Beam Diagrams and Formulas in *AISC Manual Part 3*, or from App. 44.A, the actual deflection is

$$\Delta = \frac{5wL^4}{384EI} + \frac{Pa(3L^2 - 4a^2)}{24EI}$$

$$= \frac{(5) \left( 2 \frac{\text{kips}}{\text{ft}} \right) (32 \text{ ft})^4 \left( 12 \frac{\text{in}}{\text{ft}} \right)^3}{(384) \left( 29,000 \frac{\text{kips}}{\text{in}^2} \right) (1480 \text{ in}^4)}$$

$$+ \frac{(10 \text{ kips})(8 \text{ ft}) \left( 12 \frac{\text{in}}{\text{ft}} \right)^3 \left( (3)(32 \text{ ft})^2 - (4)(8 \text{ ft})^2 \right)}{(24) \left( 29,000 \frac{\text{kips}}{\text{in}^2} \right) (1480 \text{ in}^4)}$$

$$= 1.48 \text{ in} \quad [\text{too large}]$$

Calculate the required moment of inertia. Since deflection is inversely proportional to moment of inertia,

$$I_{x,\text{req}} = \left( \frac{1.48 \text{ in}}{1.07 \text{ in}} \right) (1480 \text{ in}^4)$$

$$= 2047 \text{ in}^4$$

Therefore, from AISC Table 3-3, select a W24 × 76.

#### 14. LRFD DESIGN OF CONTINUOUS BEAMS

The W-shape Selection Tables in *AISC Manual Part 3* may be used to design economical continuous beams using the following procedure. Since the Plastic Design Tables are used, compactness is implicit. The procedure omits deflection checks and thickness checks that are required if the beam carries axial and transverse loads in combination.

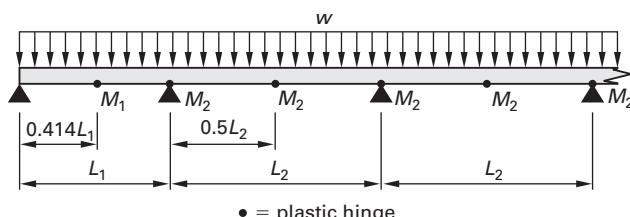

*step 1:* Obtain the factored loading. (Additional terms are needed when wind and earthquake loads are present.)

$$\text{factored load} = 1.2 \times \text{dead load}$$

$$+ 1.6 \times \text{live load} \quad 59.23$$

*step 2:* Based on the factored loading, calculate the maximum (plastic) moment,  $M_p$ . (See Sec. 59.19.) This moment cannot be calculated from the elastic moment diagrams in Table 3-22 and Table 3-23 in *AISC Manual Part 3*. The distances to the maximum moment are taken from Table 59.1. Assume the left end span is a beam with a fixed support at one end and a simple support at the other. The other spans are considered fixed-fixed. (See Fig. 59.8.)

**Figure 59.8** Location of Plastic Moments on a Uniformly Loaded Continuous Beam

*step 3:* If beam selection is to be made according to the required plastic section modulus, calculate  $Z_x$ .

$$Z_x = \frac{M_p}{F_y} \quad 59.24$$

*step 4:* Use the Flexural Design Tables in *AISC Manual Part 3* to select an economical beam.

*step 5:* Check that the nominal shear strength,  $V_n$ , based on plastic failure, does not exceed the

design shear strength (calculated from *AISC Specification* Eq. G2-1).

$$V_n = 0.6F_yA_wC_v \quad 59.25$$

*step 6:* Specify web (intermediate) stiffeners at loading points where plastic hinges are expected.

*step 7:* Determine lateral bracing requirements. Compression flange support (lateral bracing) is required at points where plastic hinges will form. In addition, the distance between points of lateral support must be less than or equal to the distance given by Eq. 59.26 [*AISC Specification*, App. 1 Eq. A-1-7].

$$L_{pd} = \left( 0.17 - 0.10 \left( \frac{M'_1}{M_2} \right) \right) \left( \frac{E}{F_y} \right) r_y \geq 0.10 \left( \frac{E}{F_y} \right) r_y \quad 59.26$$

$M'_1$  is the effective moment at the end of the unbraced length, opposite from  $M_2$ , and  $M_2$  is the larger end moment of the unbraced segment. The ratio  $M_1/M_2$  is positive when moments cause reverse curvature and negative for single curvature.

The term *mechanism* (i.e., a mechanical device with its own joints and elbows) is used to describe each of the different ways that the beam can fail plastically. Each of the spans may experience hinges at different locations and/or loadings and represents a distinctly unique mechanism.

## 15. ULTIMATE PLASTIC MOMENTS

Step 2 requires calculating the maximum moment based on plastic theory. This moment is not the same as the moment determined from elastic theory. Table 59.1 can be used in a simple case to determine the ultimate moment,  $M_p$ . Locations of plastic hinges are also indicated in the table.

A uniformly loaded, continuous beam is a case that occurs frequently. The ultimate moments can be derived from the cases in Fig. 59.8. Both ultimate moments should be checked, since the interior hinges will form first if the span lengths are short. (The end span hinges will form first if all spans are the same length.)

$$M_1 = \left( \frac{3}{2} - \sqrt{2} \right) wL_1^2 \approx 0.0858wL_1^2 \quad [uniform\ loading] \quad 59.27$$

$$M_2 = \frac{wL^2}{16} \quad [uniform\ loading] \quad 59.28$$

## 16. ULTIMATE SHEARS

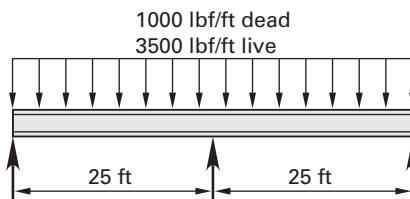

The ultimate shear in step 5 may or may not be the factored shear on the beam. The shear, by definition, is the slope of the moment diagram. In the case of a uniformly loaded beam with built-in ends, the effect of plastic failure is merely to move the baseline without changing the overall shape of the moment diagram. Since there is no change in the slope, the ultimate shear is merely the factored shear.

In the case of continuous beams, however, the effect of plastic failure will change the slope of the lines in the moment diagram. Graphical or analytical means can be used to obtain the maximum slope. For a uniformly loaded continuous beam, as shown in Fig. 59.8, the maximum shear induced will be

$$V_{max} = \frac{wL}{2} + \frac{M_{max}}{L} = 0.5858wL \quad [uniform\ loading] \quad 59.29$$

### Example 59.3

Use plastic design to select a W-shape beam (A992 steel) to support a dead load (including the beam's own weight) of 1000 lbf/ft and a live load of 3500 lbf/ft over the beam shown. The beam is simply supported at all three points. The flange is supported continuously.

*Solution*

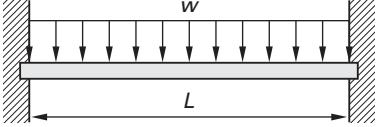

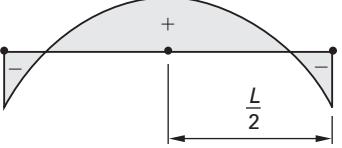

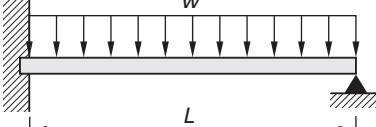

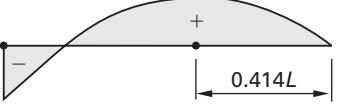

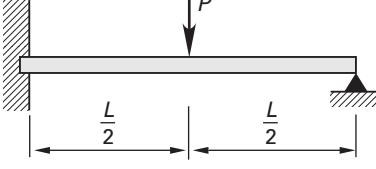

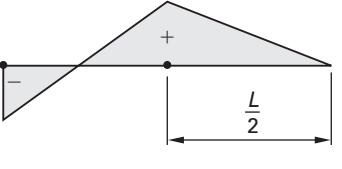

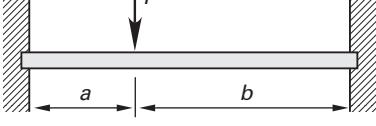

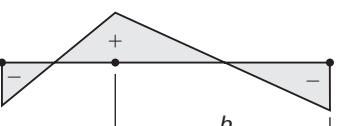

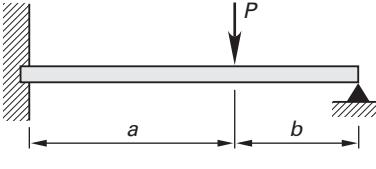

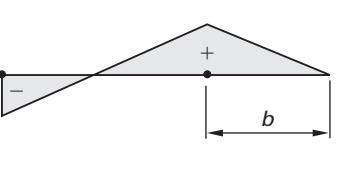

*step 1:* The factored load is

$$\begin{aligned} w_u &= 1.2w_D + 1.6w_L \\ &= (1.2) \left( 1000 \frac{\text{lbf}}{\text{ft}} \right) + (1.6) \left( 3500 \frac{\text{lbf}}{\text{ft}} \right) \\ &= 6800 \text{ lbf/ft} \end{aligned}$$

*step 2:* The maximum moment on an end span of a uniformly loaded continuous beam is given in Table 59.1. From Eq. 59.27 (i.e., the required  $M$ ),

$$\begin{aligned} M_{max} &= 0.0858wL^2 \\ &= (0.0858) \left( 6800 \frac{\text{lbf}}{\text{ft}} \right) (25 \text{ ft})^2 \\ &= 364,650 \text{ ft-lbf} \quad (365 \text{ ft-kips}) \end{aligned}$$

**Table 59.1** Maximum Plastic Moments (plastic hinges shown as •)

loading	moment diagram and location of plastic hinges	governing equations
		$M_{\max} = \frac{wL^2}{16}$
		$M_{\max} = 0.0858wL^2$
		$M_{\max} = \frac{PL}{6}$
		$a + b = L$ $M_{\max} = \frac{abP}{2L}$
		$a + b = L$ $M_{\max} = \frac{abP}{L + b}$

*step 3:* The selection can be made on the basis of required plastic moment. This step is skipped.

*step 4:* Entering the Flexural Design Tables (AISC Table 3-10), a W21 × 50 beam is chosen. The available strength is 413 ft-kips, which is more than required. However, this is the economical beam with a capacity exceeding the requirements. (Plastic design and LRFD methods cannot be used with noncompact shapes. While a W21 × 48 has sufficient capacity of 398 ft-kips, that shape exceeds the compact limit for flexure with  $F_y = 50$  ksi materials. Refer to footnote f of AISC Table 3-2.) (See Sec. 59.18.)

*step 5:* The maximum (required) shear on an end span of a uniformly loaded, continuous beam is given by Eq. 59.29.

$$\begin{aligned} V_{\max} &= 0.5858wL \\ &= (0.5858) \left( 6800 \frac{\text{lbf}}{\text{ft}} \right) (25 \text{ ft}) \\ &= 99,586 \text{ lbf} \end{aligned}$$

From AISC Table 1-1,  $d = 20.8$  in and  $t_w = 0.380$  in. From Eq. 59.18, the available shear is

$$\begin{aligned}\phi V_n &= \phi(0.6F_y A_w C_v) = \phi(0.6F_y d t_w C_v) \\ &= (1.0)(0.6)\left(50,000 \frac{\text{lbf}}{\text{in}^2}\right) \\ &\quad \times (20.8 \text{ in})(0.380 \text{ in})(1.0) \\ &= 237,120 \text{ lbf}\end{aligned}$$

Or, from AISC Table 3-2,  $\phi V_n = 237$  kips.

Since  $V_{\max} < V_{\text{available}}$ , shear is not a problem.

## 17. CONSTRUCTING PLASTIC MOMENT DIAGRAMS

There are several methods of determining the shape of the plastic moment diagram. The method presented in this section is a semigraphical approach that can be used to quickly draw moment diagrams and locate points where plastic hinges will form.

*step 1:* Consider the beam as a series of simply supported spans.

*step 2:* Draw the elastic bending moment on each span.

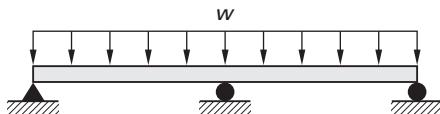

*step 3:* Construct the modified baseline. This is a jointed set of straight lines that meets the following conditions: (a) The baseline meets the horizontal axis at simply supported exterior ends. This is consistent with the requirement that the moment be zero at free and simply supported ends. (It is not necessary for the baseline to reach the horizontal axis at built-in ends. In fact, the moment is usually non-zero at such points.) (b) The slope of the baseline changes only at points of support. (c) The baselines for all spans connect at points of support. The baseline is located to minimize the maximum ordinate along the entire length of the beam (along all spans). Therefore, one span will control. (Do not consider the distance between the baseline and the horizontal axis when minimizing the maximum ordinate.)

*step 4:* The maximum ordinate determines  $M_p$ .

*step 5:* Hinges form at points of maximum ordinates and wherever else required to support full rotation. The moments at hinges that form simultaneously are identical.

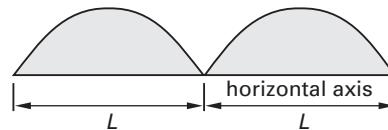

### Example 59.4

Draw the plastic moment diagram for the uniformly loaded, two-span beam shown.

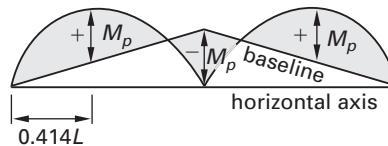

*Solution*

*step 1:* The moment diagram of a simply supported, uniformly loaded single span is drawn twice.

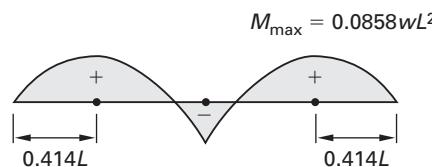

*step 2:* Referring to Table 59.1, the modified baseline is chosen to minimize the distance between the curved line and the baseline.

*step 3:* The maximum ordinate is determined visually to be near the middle of the end spans.

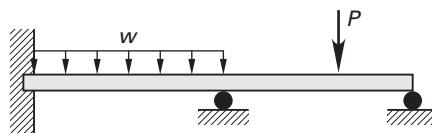

*step 4:* If hinges form near the middle of the end spans, a hinge must also form over the center support. Otherwise, the beam could not rotate in failure.

The final moment diagram is drawn by “straightening out” the modified baseline.

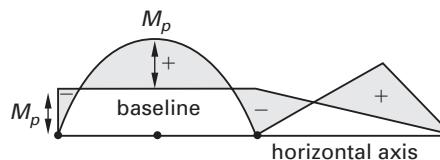

### Example 59.5

Draw the plastic moment diagram for the beam of constant cross section shown.

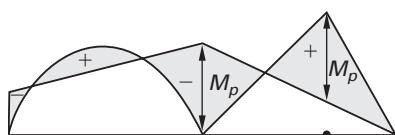

*Solution*

Since the actual numerical loads are unknown, it is not possible to determine which of the two spans controls. If the left span controls, then three hinges must form simultaneously. This forces the baseline to be horizontal along the left span. The baseline along the right span is fixed by its end points.

If the right span controls, then two hinges must form simultaneously. The moments at these two hinge points

are equal. The baseline along the left span is chosen to minimize the positive and negative ordinates.

## 18. UNSYMMETRICAL BENDING

Typically, a wide-flange beam is oriented with its web in the plane of the loading (i.e., the plane of the weak axis), and the bending is said to occur about the strong axis or the  $x$ - $x$  axis of beam cross section. The  $x$ - $x$  and  $y$ - $y$  axes of a beam cross section are known as the *principal axes* for which the product of inertia is zero. A beam is said to be subjected to *unsymmetrical bending* when bending occurs about an axis other than one of the principal axes. When the applied loads are not in a plane with either of the principal axes or when loads are simultaneously applied from more than one direction, unsymmetrical bending (also called *biaxial bending*) is the result.

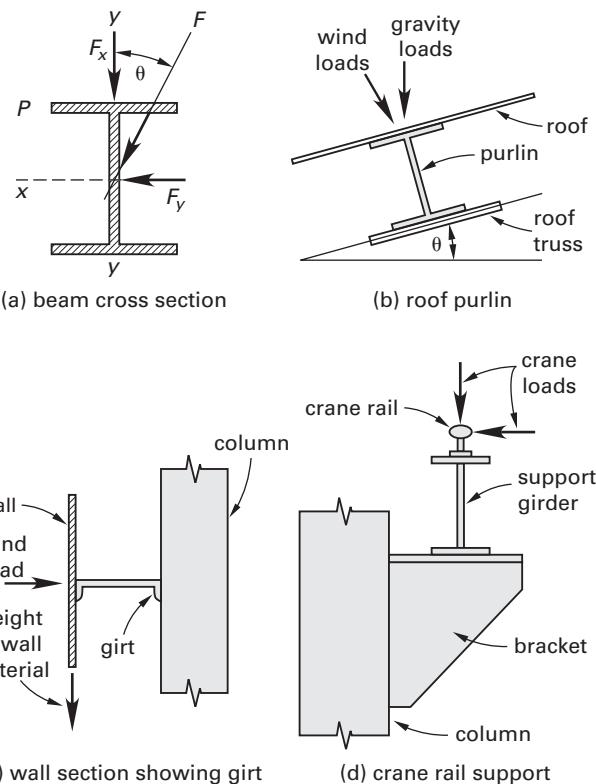

There are two cases of unsymmetrical bending: (1) loads applied through the shear center and (2) loads not applied through the shear center. The *shear center* of a cross section is that point through which the loads must act if there is to be no twisting (torsion) of the beam. The location of the shear center is determined from principles of mechanics of materials by equating the internal resisting torsional moment to the external torque. For a wide-flange section, however, the shear center and the centroid are the same point. In either case, an appropriate interaction equation is used for design or analysis.

In case (1), the load applied through the shear center may be resolved into two mutually perpendicular components along the principal ( $x$ - $x$  and  $y$ - $y$ ) axes. Referring to Fig. 59.9(a), where  $\theta$  is the angle between the applied load  $F$  and the  $y$ - $y$  axis, the components of  $F$  are  $F_x = F \cos \theta$  and  $F_y = F \sin \theta$ . The moments  $M_x$  and  $M_y$  about the principal axes are computed from  $F_x$  and  $F_y$ , respectively. (The force  $F_x$  creates a moment about the  $x$ - $x$  axis and  $F_y$  creates a moment about the  $y$ - $y$  axis.) The stresses due to moments  $M_x$  and  $M_y$  are computed separately for bending about each axis as:  $f_{bx} = M_x/S_x$  and  $f_{by} = M_y/S_y$ .

Finally, to check the adequacy of a section, use the *interaction equation*, Eq. 59.30 (*AISC Specification* Eq. H2-1), which serves as the design criterion since the allowable bending stresses with respect to the  $x$ - $x$  and  $y$ - $y$  axes are different. (AISC uses the subscript  $w$  to relate to the major principal axis bending and  $z$  for the minor principal axis bending, while this book uses  $x$  and  $y$ .)

$$\left| \frac{f_a}{F_a} + \frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \right| \leq 1.0 \quad 59.30$$

**Figure 59.9** Cases of Unsymmetrical Bending

Spiegel, Leonard; Limbrunner, George F., *Applied Structural Steel Design*, 3rd, © 1997. Printed and electronically reproduced by permission of Pearson Education, Inc., New York, New York.

Since the axial stress for a beam in pure bending is zero, the first term of the equation drops out and Eq. 59.30 becomes

$$\frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \leq 1.0 \quad 59.31$$

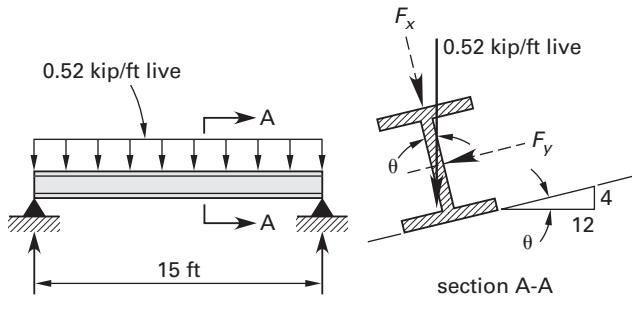

$F_{bx}$  and  $F_{by}$  are most conveniently “reverse” calculated from the beam flexural capacities tabulated as  $\phi M$  in *AISC Manual* Table 3-2 and Table 3-10.

$$F_b = \frac{(\phi M)_{\text{tabulated}}}{S} \quad 59.32$$

Since loads are frequently applied from different directions on the top flange, case (2) (where load does not pass through the shear center) is a common occurrence. The top flange alone is assumed to resist the lateral force component. For a typical wide-flange shape, the section modulus of the top flange is approximately equal to  $S_y/2$ , and the stress due to bending about the  $y$ - $y$  axis becomes  $f_{by} = 2M_y/S_y$ .

**Example 59.6**

A W8 × 21 beam of A992 steel is used as a roof purlin on a simple span of 15 ft. The roof slope is 4:12 (vertical:horizontal). The beam carries a uniformly distributed gravity live load of 0.52 kip/ft that passes through the centroid of the section. Assuming that the beam has full lateral support provided by the roofing above, check the adequacy of the section.

**Solution**

Properties of a W8 × 21 are  $S_x = 18.2 \text{ in}^3$ , and  $S_y = 3.71 \text{ in}^3$ .

Resolve the loads into their components.

$$\theta = \arctan \frac{4}{12} = 18.4^\circ$$

$$w_{x,D} = w \cos \theta = \left( 0.021 \frac{\text{kip}}{\text{ft}} \right) \cos 18.4^\circ = 0.020 \text{ kip/ft}$$

$$w_{y,D} = w \sin \theta = \left( 0.021 \frac{\text{kip}}{\text{ft}} \right) \sin 18.4^\circ = 0.0007 \text{ kip/ft}$$

Disregard the dead loading.

$$w_{x,L} = w \cos \theta = \left( 0.52 \frac{\text{kip}}{\text{ft}} \right) \cos 18.4^\circ = 0.493 \text{ kip/ft}$$

$$w_{y,L} = w \sin \theta = \left( 0.52 \frac{\text{kip}}{\text{ft}} \right) \sin 18.4^\circ = 0.164 \text{ kip/ft}$$

Compute the factored moments.

$$M_{ux} = \frac{w_x L^2}{8} = (1.6) \left( \frac{\left( 0.493 \frac{\text{kip}}{\text{ft}} \right) (15 \text{ ft})^2}{8} \right) \\ = 22.2 \text{ ft-kips}$$

$$M_{uy} = \frac{w_y L^2}{8} = (1.6) \left( \frac{\left( 0.164 \frac{\text{kip}}{\text{ft}} \right) (15 \text{ ft})^2}{8} \right) \\ = 7.4 \text{ ft-kips}$$

Compute the required bending stresses.

$$f_{bx} = \frac{M_{ux}}{S_x} = \frac{(22.2 \text{ ft-kips}) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{18.2 \text{ in}^3} = 14.6 \text{ ksi}$$

$$f_{by} = \frac{M_{uy}}{S_y} = \frac{(7.4 \text{ ft-kips}) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{3.71 \text{ in}^3} = 23.9 \text{ ksi}$$

Determine the available stresses from the available moments.

For bending about the  $x$ - $x$  axis, since the beam has full lateral support, from AISI Table 3-2 or Table 3-10, for a W8 × 21,  $\phi M_n = 76.5 \text{ ft-kips}$ .

$$F_{bx} = \frac{\phi_b M_{nx}}{S_x} = \frac{(76.5 \text{ ft-kips}) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{18.2 \text{ in}^3} = 50.4 \text{ ksi}$$

For bending about the  $y$ - $y$  axis, from AISI Table 3-4,  $\phi M_n = 21.3 \text{ ft-kips}$ .

$$F_{by} = \frac{\phi_b M_{ny}}{S_y} = \frac{(21.3 \text{ ft-kips}) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{3.71 \text{ in}^3} = 68.9 \text{ ksi}$$

Check the interaction equation, Eq. 59.31.

$$\frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \leq 1.0$$

$$\frac{14.6 \frac{\text{kips}}{\text{in}^2}}{50.4 \frac{\text{kips}}{\text{in}^2}} + \frac{23.9 \frac{\text{kips}}{\text{in}^2}}{68.9 \frac{\text{kips}}{\text{in}^2}} = 0.637 < 1.0 \quad [\text{OK}]$$

Therefore, the W8 × 21 section is adequate.

## 19. BRIDGE CRANE MEMBERS

A bridge crane member is a beam that carries a set of moving loads that remain equidistant as they travel across the beam. For a simply supported beam, (a) the absolute maximum moment occurs under one of the concentrated loads when that load and the resultant of the set of loads are equidistant from the centerline of the beam, and (b) the absolute maximum shear will occur just next to one of the supports when the load group is placed such that the resultant is at a minimum distance from the support.

Two other factors that are usually taken into consideration in the design of bridge crane members are fatigue and impact loading. Both factors are complex and require specific information about the installation and usage. Theoretical allowances for impact can be derived from energy methods; however, standards and building

codes prescribe basic allowances for impact.<sup>5</sup> ASCE/SEI7 (to which the *AISC Manual* defers some of its load factor specifications) specifies an allowance for “ordinary impact” of 100% for elevators and elevator machinery, 20% for light shaft- or motor-driven machinery, 50% for reciprocating machinery, and 33% for hangers for floors and balconies [ASCE/SEI7 Sec. 4.6 and ASME A17.1]. Manufacturers’ allowances, if greater, take precedence over these values.

Vertical design loads for bridge and monorail crane runways beams, connections, and support brackets are increased to account for impact and vibration: 25% for powered monorail and cab- and remotely-operated bridge cranes, and 10% for powered pendant-operated bridge cranes. No impact allowance is required for monorail and bridge cranes with hand/geared bridges, trolleys, and hoists. Increases in lateral and longitudinal forces are required for electrically powered trolleys when designing crane runway beams. The increased lateral force is assumed to act horizontally at the traction surface on the beam, in either direction, perpendicular to the beam, and is calculated as 20% of the sum of the rated capacity of the crane and the weight of the hoist and trolley. The increased longitudinal force is assumed to act horizontally at the traction surface on the beam, in either direction, parallel to the beam, and is calculated as 10% of the maximum wheel loads of the crane [ASCE/SEI7 Sec. 4.9]. These increases for impact apply only to the runway beam and its connections, as the deflection of the beam creates a magnifying effect. Consequently, increases for impact do not generally apply to columns and foundations.

## 20. HOLES IN BEAMS

A beam is usually connected to other structural members. If such connections are made with bolts, holes are punched or drilled in the web or flanges of the beam. In addition, to provide space for utilities such as electrical conduits and ventilation ducts, sometimes relatively large holes are cut in the beam webs. Holes in a beam result in capacity reduction. Two such reductions are recognized: (a) holes in beam webs reduce the shear capacity, and (b) holes in beam flanges reduce the moment capacity. In general, web holes should be located at sections of low shear and centered on the neutral axis to avoid high bending stresses, and flange holes should be located at sections of low bending moment.

The effect of flange holes is to reduce the moment of inertia, which reduces moment capacity. The reduced

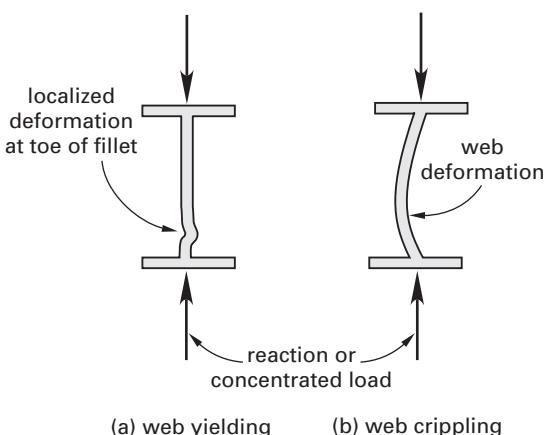

<sup>5</sup>Impact may be referred to and accounted for in various ways. *AASHTO LRFD Bridge Design Specifications* Sec. 3.6.2.2 prescribes a *dynamic load factor*, DLF, or *dynamic load allowance*, IM, 0.33 (33%) (LRFD) for *dynamic effects* for bridge design to account for vehicular movement. NDS specifies a *load duration factor* of 2.0 for short-term loading of timber structures.

moment of inertia is based upon the effective tension flange area given by *AISC Specification* Sec. F13.

## 21. CONCENTRATED WEB FORCES

*Local buckling* is a factor in the vicinity of large concentrated loads. Such loads may occur at a reaction point or where a column frames into a supporting girder. *Web yielding* and *web crippling*, two types of local buckling shown in Fig. 59.10, can be reduced or eliminated by use of *stiffeners*. If the load is applied uniformly over a large enough area (say, along  $l_b$  inches of beam flange or more), no stiffeners will be required.

Figure 59.10 Local Buckling

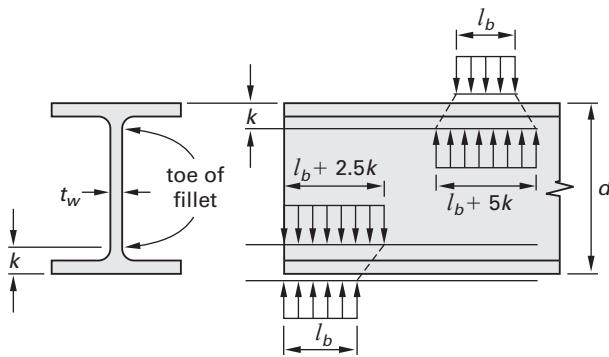

Regarding web yielding, the limit state is determined using  $\phi = 1.00$  (LRFD) or  $\Omega = 1.50$  (ASD). The nominal strength,  $R_n$ , is specified by Eq. 59.33 [AISC Eq. J10-2] for interior loads and Eq. 59.34 [AISC Eq. J10-3] for loads at beam ends. (See Fig. 59.11.)

$$R_n = F_{yw} t_w (5k + l_b) \quad 59.33$$

$$R_n = F_{yw} t_w (2.5k + l_b) \quad 59.34$$

Regarding web crippling, the limit state is determined using  $\phi = 0.75$  (LRFD) or  $\Omega = 2.00$  (ASD). The nominal strength,  $R_n$ , is specified by Eq. 59.35 [AISC Eq. J10-4] for interior loads and by Eq. 59.36 [AISC Eq. J10-5a] and Eq. 59.37 [AISC Eq. J10-5b] for reactions at beam ends.

$$R_n = 0.80 t_w^2 \left( 1 + 3 \left( \frac{l_b}{d} \right) \left( \frac{t_w}{t_f} \right)^{1.5} \right) \sqrt{\frac{E F_{yw} t_f}{t_w}} \quad [AISC Eq. J10-4] \quad 59.35$$

**Figure 59.11** Nomenclature for Web Yielding Calculations

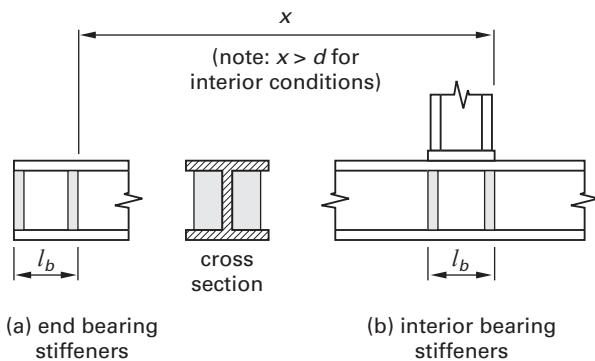

For  $l_b/d \leq 0.2$ ,

$$R_n = 0.40 t_w^2 \left( 1 + 3 \left( \frac{l_b}{d} \right) \left( \frac{t_w}{t_f} \right)^{1.5} \right) \sqrt{\frac{E F_{yw} t_f}{t_w}} \quad [AISC Eq. J10-5a] \quad 59.36$$

For  $l_b/d > 0.2$ ,

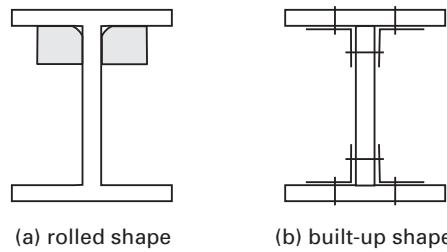

$$R_n = 0.40 t_w^2 \left( 1 + \left( \frac{4l_b}{d} - 0.2 \right) \left( \frac{t_w}{t_f} \right)^{1.5} \right) \sqrt{\frac{E F_{yw} t_f}{t_w}} \quad [AISC Eq. J10-5b] \quad 59.37$$

*Intermediate stiffeners* (i.e., web stiffeners spaced throughout a stock rolled shape) are never needed with rolled shapes but are typically used in plate girders. (For built-up beams, diagonal buckling requirements should also be checked.<sup>6</sup>) *Bearing stiffeners* are typically web stiffening plates welded to the webs and flanges of rolled sections. (See Fig. 59.12.)

**Figure 59.12** Bearing Stiffeners

<sup>6</sup>Diagonal buckling becomes an issue when  $h/t_w > 85$ . Since all rolled shapes have  $h/t_w < 70$ , diagonal buckling is a possibility only for plate girders. The *AISC Manual* prevents diagonal buckling in built-up sections by limiting  $h/t_w$  ratios, limiting shear stress to  $0.4F_y$ , and by requiring intermediate stiffeners.

*Flange stiffeners* are typically angles placed at the web-flange corner used to keep the flange perpendicular to the web. (See Fig. 59.13.) Flange stiffeners cannot be used in place of bearing stiffeners.

**Figure 59.13** Flange Stiffeners

## 22. BEAM BEARING PLATES

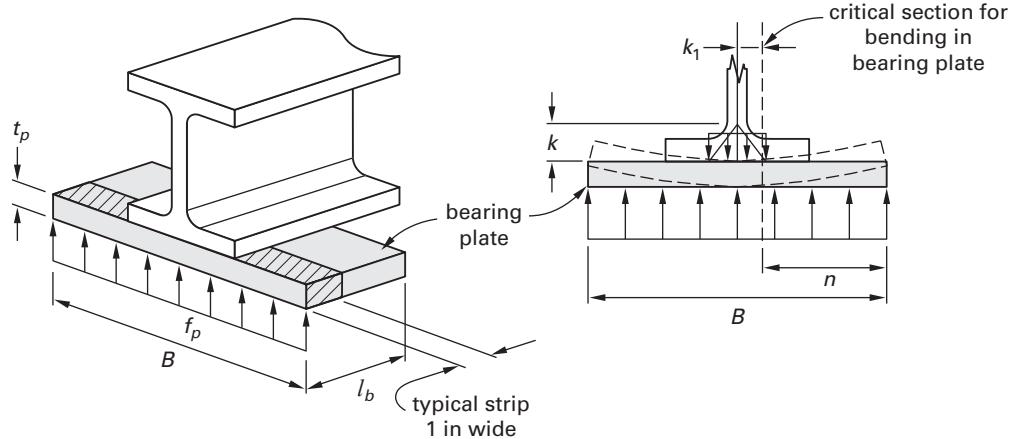

Not all beams are supported by connections to other structural steel members (e.g., beams or columns). Some beams are supported by bearing on concrete or masonry members, such as walls or pilasters. Since masonry and concrete are weaker than steel, the beam reaction must be distributed over a large enough area to keep the average bearing pressure on concrete or masonry within allowable limits. A *bearing plate* is used for this purpose. (See Fig. 59.14.)

The design of a bearing plate is based on *AISC Manual Part 14*, *AISC Specification Sec. J7* and *Sec. J8*, and on the following criteria. (a) It must be long enough so that local web yielding or web crippling of the beam does not occur. (b) It must be large enough to ensure the required bearing strength,  $R_u$  or  $R_a$ , under the plate does not exceed the available bearing strength,  $\phi R_n$  or  $R_n/\Omega$ . (c) It must be thick enough so that the moment in the plate at the critical section is less than the available moment.

A procedure for the design of beam bearing plates on concrete supports is given in *AISC Manual Part 14*. *AISC Specification Sec. J7* gives the nominal bearing strength,  $R_n$ , for various types of bearing. For column bases and bearing on concrete, *AISC Specification Sec. J8* gives provisions so that column loads and moments are properly transferred to the footings and foundations. For a plate covering the full area of a concrete support, where  $P_p$  is the nominal bearing strength and  $A_1$  is the area of steel concentrically bearing on a concrete support,

$$P_p = 0.85 f'_c A_1 \quad [AISC Eq. J8-1] \quad 59.38$$

$\phi_p P_p$  is the *design bearing strength*, and  $P_p/\Omega_p$  is the *allowable bearing strength*. The required bearing area is calculated from the nominal bearing area by introducing the resistance factor for bearing,  $\phi_p = 0.60$  (LRFD) or

**Figure 59.14** Nomenclature for Beam Bearing Plate

the safety factor for bearing,  $\Omega_p = 2.50$  (ASD) [AISC Specification Sec. J8].

$$A_{1,\text{required}} = \frac{P_p}{0.85\phi_p f'_c} \quad [\text{LRFD}] \quad 59.39(a)$$

$$A_{1,\text{required}} = \frac{\Omega_p P_p}{0.85f'_c} \quad [\text{ASD}] \quad 59.39(b)$$

For a plate covering less than the full area of a concrete support, the area of steel concentrically bearing on a concrete support is given by Eq. 59.40. Area  $A_2$  is the maximum area of the portion of the supporting surface that is geometrically similar to and concentric with the loaded area.

$$P_p = 0.85f'_c A_1 \sqrt{\frac{A_2}{A_1}} \leq 1.7f'_c A_1 \quad [\text{AISC Eq. J8-2}] \quad 59.40$$

The minimum bearing length,  $l_b$  (in inches), is obtained as the larger of the two values, using Eq. 59.41 and Eq. 59.42 (corresponding to AISC Manual values found in Table 9-4), based on local web yielding ( $\phi R_n$ ) and web crippling criteria, respectively, as described in AISC Specification Sec. J10.2.

$$l_b = \frac{\phi R_n - \phi R_1}{\phi R_2} \quad 59.41$$

$$l_b = \frac{\phi R_n - \phi R_3}{\phi R_4} \quad 59.42$$

After establishing the bearing length,  $l_b$ , the width,  $B$ , is obtained from Eq. 59.43. Round up to an integral number of inches to provide a shelf for welding the bearing plate to the beam.

$$B = \frac{A_1}{l_b} \quad 59.43$$

The required moment,  $M_u$ , is limited by the pressure developed under the plate,  $f_p$ , from the factored vertical reaction,  $R_u$ , which is assumed to be uniform and is calculated as

$$f_p = \frac{R_u}{A_1} = \frac{R_u}{Bl_b} \quad [\text{ASD}] \quad 59.44(a)$$

$$f_p = \frac{R_u}{A_1} = \frac{R_u}{Bl_b} \quad [\text{LRFD}] \quad 59.44(b)$$

The cantilever dimension,  $n$ , is determined from

$$n = \frac{B}{2} - k_1 \quad 59.45$$

The thickness,  $t$ , is specified in  $1/8$  in increments. The minimum thickness is

$$t = \sqrt{\frac{2R_u n^2 \Omega}{A_1 F_y}} = \sqrt{\frac{2f_p n^2 \Omega}{F_y}} \quad [\text{ASD}] \quad 59.46(a)$$

$$t = \sqrt{\frac{2R_u n^2}{\phi A_1 F_y}} = \sqrt{\frac{2f_p n^2}{\phi F_y}} \quad [\text{LRFD}] \quad 59.46(b)$$

With LRFD, the available moment,  $\phi M_n$ , is limited by  $F_b$ , which, for rectangular plates, is the same as for weak-axis bending:  $F_b = 0.9F_y$ . For ASD,  $\Omega = 1.67$ . For flexure,  $\phi = 0.90$ .

### Example 59.7

A W21 × 68 beam is supported on a 12 in thick concrete wall ( $f'_c = 3500 \text{ lbf/in}^2$ ). The beam reaction,  $\phi R_n$ , is 68 kips, and the length of bearing in the direction of the wall thickness is limited to 8 in. The beam is A992, and the plate is A36 steel. Design the bearing plate using LRFD.

**Solution**

From AISC Manual Table 9-4,  $\phi R_1 = 64$  kips,  $\phi R_2 = 21.5$  kips/in,  $\phi R_3 = 84.3$  kips, and  $\phi R_4 = 5.96$  kips/in. Using Eq. 59.41 and Eq. 59.42,

$$\begin{aligned} l_b &= \frac{\phi R_n - \phi R_1}{\phi R_2} \\ &= \frac{68 \text{ kips} - 64 \text{ kips}}{21.5 \frac{\text{kips}}{\text{in}}} \\ &= 0.2 \text{ in} < 8 \text{ in} \quad [\text{OK}] \end{aligned}$$

$$\begin{aligned} l_b &= \frac{\phi R_n - \phi R_3}{\phi R_4} \\ &= \frac{68 \text{ kips} - 84.3 \text{ kips}}{5.96 \frac{\text{kips}}{\text{in}}} \\ &= -2.74 \text{ in} < 8 \text{ in} \quad [\text{OK}] \end{aligned}$$

Calculate the required area,  $A_1$ , from Eq. 59.39.

$$\begin{aligned} A_{1,\text{required}} &= \frac{P_p}{0.85\phi_f f'_c} = \frac{68 \text{ kips}}{(0.85)(0.6)\left(3.5 \frac{\text{kips}}{\text{in}^2}\right)} \\ &= 38.1 \text{ in}^2 \end{aligned}$$

This requires a minimum width of

$$B_{\min} = \frac{A_1}{l_b} = \frac{38.1 \text{ in}^2}{8 \text{ in}} = 4.76 \text{ in}$$

For a W21 × 68, the flange width is  $b_f = 8.27$  in, so use a bearing plate width of  $B = 10$  in. The area provided by the bearing plate is

$$A_{\text{provided}} = Bl_b = (10 \text{ in})(8 \text{ in}) = 80 \text{ in}^2$$

The plate's aspect ratio is

$$\frac{B}{l_b} = \frac{10 \text{ in}}{8 \text{ in}} = 1.25$$

The maximum possible concrete support width,  $N_2$ , is limited to 12 in by the width of the wall. To be geometrically similar, the maximum plate length is

$$B_2 = (1.25)(12 \text{ in}) = 15 \text{ in}$$

The maximum area of concrete support is

$$A_2 = B_2 N_2 = (15 \text{ in})(12 \text{ in}) = 180 \text{ in}^2$$

Since this is so much greater than required, the plate area can be reduced. The bearing plate width should not be less than the flange width to allow for welding. Try a smaller plate depth.

Try  $l_b = 6$  in.

$$A_{\text{provided}} = Bl_b = (10 \text{ in})(6 \text{ in}) = 60 \text{ in}^2$$

The area of concrete support, rearranging Eq. 59.40, is

$$\begin{aligned} A_2 &= \frac{P_p^2}{(0.85)^2(f'_c)^2 A_1} \\ &= \frac{(68 \text{ kips})^2}{(0.85)^2 \left(3.5 \frac{\text{kips}}{\text{in}^2}\right)^2 (38.1 \text{ in}^2)} \\ &= 13.7 \text{ in}^2 < 60 \text{ in}^2 \end{aligned}$$

Therefore, 6 in bearing depth is adequate.

For a W21 × 68,  $k_1 = 7/8$  in. The plate cantilever dimension is

$$n = \frac{B}{2} - k_1 = \frac{10 \text{ in}}{2} - \frac{7}{8} \text{ in} = 4.125 \text{ in}$$

The required moment,  $M_u$ , is limited by

$$f_p = \frac{R_u}{Bl_b} = \frac{68 \text{ kips}}{60 \text{ in}^2} = 1.133 \text{ kips/in}^2$$

From Eq. 59.46, the plate thickness is

$$\begin{aligned} t &= \sqrt{\frac{2f_p n^2}{\phi F_y}} = \sqrt{\frac{(2)\left(1.133 \frac{\text{kips}}{\text{in}^2}\right)(4.125 \text{ in})^2}{(0.90)\left(36 \frac{\text{kips}}{\text{in}^2}\right)}} \\ &= 1.09 \text{ in} \quad [\text{use } 1^{1/4} \text{ in thick plate}] \end{aligned}$$

The bearing plate is  $1^{1/4} \times 6 \times 10$ .

## 1. INTRODUCTION

Tension members occur in a variety of structures, including bridge and roof trusses, transmission towers, wind bracing systems in multistoried buildings, and suspension and cable-stayed bridges. Wire cables, rods, eyebars, structural shapes, and built-up members are typically used as tension members. (See Fig. 60.1.)

**Figure 60.1** Common Tension Members

## 2. AXIAL TENSILE STRENGTH

The available axial strength,  $P_a$ , of a tensile member is calculated from the nominal strength,  $P_n$ . The available strength must be greater than the required strength.

$$P_a = \phi_t P_n \geq P_u \quad [\text{LRFD; design strength}] \quad 60.1(a)$$

$$P_a = \frac{P_n}{\Omega_t} \geq P \quad [\text{ASD; allowable strength}] \quad 60.1(b)$$

The values of  $\phi_t$  and  $\Omega_t$  depend on the nature of the tensile area under consideration. For calculations of nominal strength based on gross area,  $A_g$ , the values are  $\phi_t = 0.90$  and  $\Omega_t = 1.67$ . For calculations involving nominal strength based on net area,  $A_n$ , or effective area,  $A_e$ , the values are  $\phi_t = 0.75$  and  $\Omega_t = 2.00$ . Both areas must be evaluated, with the minimum value

determining the nominal strength. The concepts of effective and net areas are presented in subsequent sections.

$$P_n = F_y A_g \quad \left[ \begin{array}{l} \text{yielding criterion;} \\ \text{AISC Specification Eq. D2-1} \end{array} \right] \quad 60.2$$

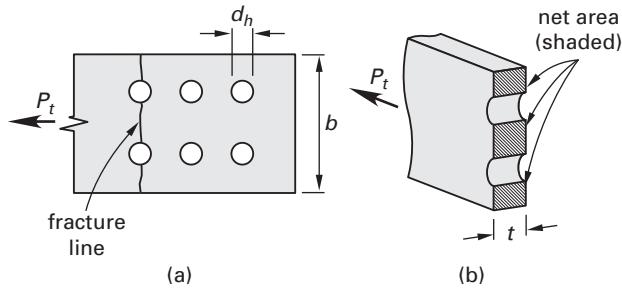

$$P_n = F_u A_e = A_n U F_u \quad \left[ \begin{array}{l} \text{fracture criterion;} \\ \text{AISC Specification Eq. D2-2} \\ \text{and Eq. D3-1} \end{array} \right] \quad 60.3$$

### 3. GROSS AREA

The gross area,  $A_g$ , is the original unaltered cross-sectional area of the member. The gross area for the plate shown in Fig. 60.2 is

$$A_g = b t \quad 60.4$$

**Figure 60.2** Tension Member with Unstaggered Rows of Holes

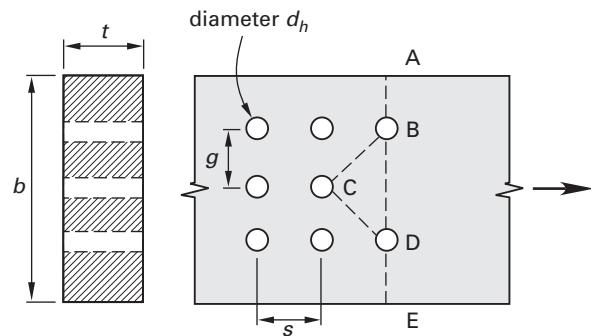

### 4. NET AREA

Plates and shapes are connected to other plates and shapes by means of welds, rivets, and bolts. If rivets or bolts are used, holes must be punched or drilled in the member. As a result, the member's cross-sectional area at the connection is reduced. The load-carrying capacity of the member may also be reduced, depending on the size and location of the holes. The *net area* actually available to resist tension is illustrated in Fig. 60.2(b).

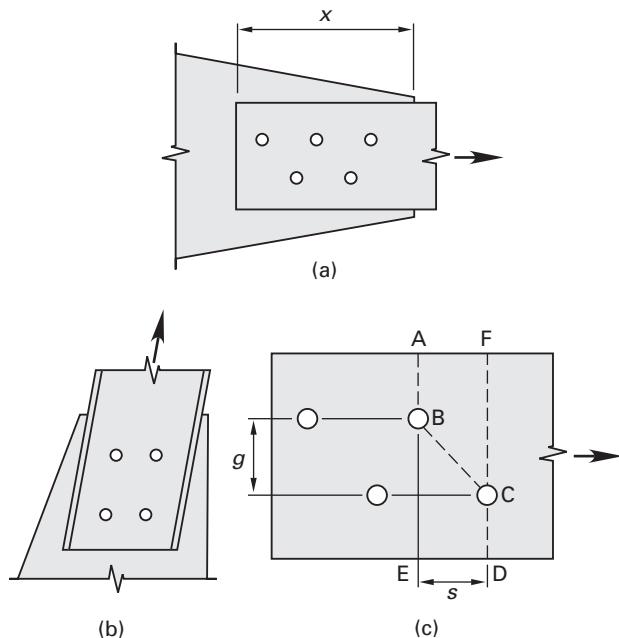

In a multiconnector connection, the *gage spacing*,  $g$ , is the lateral center-to-center spacing of two adjacent holes perpendicular to the direction of the applied load. The *pitch spacing*,  $s$ , is the longitudinal spacing of any two adjacent holes in the direction for the applied load. Gage and pitch spacing are shown in Fig. 60.3.

When space limitations (such as a limit on dimension  $x$  in Fig. 60.4(a), or odd connection geometry as in Fig. 60.4(b)) make it necessary to use more than one row of fasteners, the reduction in cross-sectional area can be minimized by using a staggered arrangement of fasteners. For multiple rows of fasteners (staggered or not) at a connection, more than one potential fracture line may exist. For each possible fracture line, the net width,  $b_n$ , is calculated by subtracting the hole diameters,  $d_h$ , in the potential failure path from the gross

**Figure 60.3** Tension Member with Uniform Thickness and Unstaggered Holes

**Figure 60.4** Tension Members with Staggered Holes

width,  $b$ , and then adding a correction factor,  $s^2/4g$ , for each diagonal leg in the failure path. (There is one diagonal leg, BC, in the failure path ABCD shown in Fig. 60.4(c), so the term  $s^2/4g$  would be added once.)

$$b_n = b - \sum d_h + \sum \frac{s^2}{4g} \quad 60.5$$

Punched bolt holes should be  $1/16$  in larger than nominal fastener dimensions. (This increased diameter is sometimes referred to as a *standard hole* [AISC Specification Sec. B2].) However, due to difficulties in producing uniform punched holes in field-produced assemblies, another  $1/16$  in should be added to the hole diameter. (The additional  $1/16$  in is advised, but not specified, in the AISC Manual.) The hole diameter,  $d_h$ , in Eq. 60.5 is taken as the fastener diameter,  $d$ , plus  $1/8$  in. This does not change the definition of a standard hole, but it does affect the calculation of the net area.

For members of uniform thickness (e.g., plates), the net area,  $A_n$ , is calculated as the net width,  $b_n$ , times the thickness,  $t$ .

$$A_n = b_n t \quad 60.6$$

For members of nonuniform thickness (e.g., channels), a more useful formula for net area,  $A_n$ , is Eq. 60.7.

$$A_n = A_g - \sum d_h t + \left( \sum \frac{s^2}{4g} \right) t \quad 60.7$$

The *critical net area* is the net area having the least value. It is obtained by checking all possible failure paths. For example, in Fig. 60.4(c), paths ABCD and DCF must both be checked. In Fig. 60.3, where the number of bolts is not the same in all rows, both paths ABDE and ABCDE must be checked.

If connectors in a tension lap splice are arranged in two or more unstaggered rows, and if the rows have unequal numbers of fasteners, each fracture line should be checked for tension capacity assuming that the previous fracture lines have absorbed a proportionate share of the load. For example, if three bolts are arranged in two rows—one row with two bolts and the next row with one bolt—the net section of the first fracture line (the width less two bolt diameters) should be checked for tension capacity with two-thirds of the total applied load.

## 5. EFFECTIVE NET AREA

When a tension member frames into a supporting member, some of the load-carrying ability will be lost unless all connectors are in the same plane and all elements of the tension member are connected to the support. (An angle connected to its support only by one of its legs is a case in which load-carrying ability would be lost.) A *shear lag reduction coefficient*,  $U$ , is used to calculate the effective net area.  $U$  can be taken as 1.0 if all cross-sectional elements are connected to the support to transmit the tensile force. When the load is transmitted by bolts through only some of the cross-sectional elements of the tension member, the *effective net area*,  $A_e$ , is computed from Eq. 60.8 [AISC Specification Eq. D3-1].  $U$  is given in Table 60.1.

$$A_e = A_n U \quad 60.8$$

In addition to the reduction in the net area by  $U$ , the effective net area for splice and gusset plates must not exceed 85% of the gross area, regardless of the number of holes. Tests have shown that as few as one hole in a plate will reduce the strength of a plate by at least 15%. It is a good idea to limit the effective net area to 85% of the gross area for all connections (not just splices and gusset plates) with holes in plates.

When the load is transmitted by welds, Table 60.2 can be used to determine the shear lag reduction coefficient. Since there are no holes, the net and gross areas are the

**Table 60.1** Shear Lag Reduction Coefficient ( $U$ ) Values for Bolted Connections<sup>a</sup>

shape	condition	$U$
all tension members where load is transmitted across each cross-sectional element by fasteners	all	1.00
	$b_f \geq \frac{2}{3}d$ , only flange connections, and 3 or more fasteners per line in direction of loading	0.90
	$b_f < \frac{2}{3}d$ , only flange connections, and 3 or more fasteners per line in direction of loading	0.85
	only web connections, and 4 or more fasteners per line in direction of loading	0.70
single angles <sup>b</sup>	4 or more fasteners per line in direction of loading	0.80
	2 or 3 fasteners per line in direction of loading	0.60

<sup>a</sup>When the connection contains only a single fastener or a single row of fasteners (i.e.,  $s = 0$ ), AISC Commentary Sec. J4.3 implies  $U = 1$  when the tension is uniform across the face, and  $U = 0.5$  otherwise; and block shear and bearing may control the connection.

<sup>b</sup> $U$  may also be calculated as  $U = 1 - (\bar{x}/l)$ , and the larger of the two values may be used.  $\bar{x}$  is the connection eccentricity, equal to the distance from the plane of the connection to the centroid of the connected member, often tabulated in shape tables. (See AISC Commentary Fig. C-D3.1 for guidance on establishing  $\bar{x}$ .)  $l$  is the length of the connection in the direction of loading, measured for bolted connections as the center-to-center distance between the two end connectors in a line.

same for transverse weld-connected plates. For transverse weld-connected sections (W, M, S, etc.), the net area is the sum of the gross areas of the connected cross-sectional elements.

$$A_n = \sum_{\text{connected elements}} A_g \quad 60.9$$

## 6. BLOCK SHEAR STRENGTH

For tension members, another possible failure mode exists in addition to yielding and fracture. In this mode, a segment or “block” of material at the end of the member tears out, as shown in Fig. 60.5. Depending on the connection at the end of a tension member, such *block shear failure* can occur in either the tension member itself or in the member to which it is attached (e.g., a gusset plate). Block shear failure represents a combination of two failures—a shear failure along a plane through the bolt holes or welds and a tension failure along a perpendicular plane—occurring simultaneously.

**Figure 60.5** Block Shear Failures

Block shear strength,  $R_n$ , is computed from Eq. 60.10 [AISC Specification Eq. J4-5].  $A_{gv}$  is the gross area subject to shear,  $A_{nt}$  is the net area subject to tension, and  $A_{nv}$  is the net area subject to shear. Where the tension stress is uniform,  $U_{bs} = 1$ , and where the tension stress is nonuniform,  $U_{bs} = 0.5$ .

$$R_n = 0.6F_uA_{nv} + U_{bs}F_uA_{nt}$$

$$\leq 0.6F_yA_{gv} + U_{bs}F_uA_{nt}$$

block shear criterion;  
AISC Specification Eq. J4-5

60.10

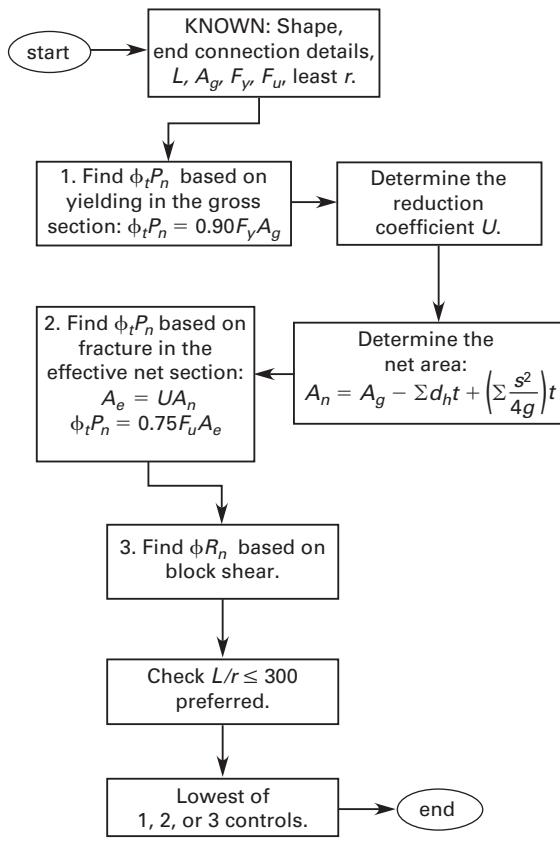

## 7. SLENDERNESS RATIO

Where structural shapes are used in tension, AISC Specification D1 lists a preferred (but not required) maximum slenderness ratio (SR) of 300. Rods and wires are excluded from this recommendation.

$$SR = \frac{L}{r_y} \quad 60.11$$

## 8. ANALYSIS OF TENSION MEMBERS

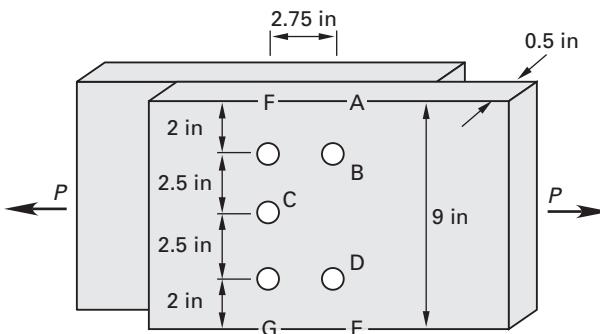

The analysis of a tension member is essentially the determination of its tensile strength,  $P_n$ , as the smallest of the three values obtained from Eq. 60.2, Eq. 60.3, and Eq. 60.10 [AISC Specification Eq. D2-1, Eq. D2-2, and Eq. J5-4]. A flowchart for the LRFD analysis of tension members is shown in Fig. 60.6.

**Figure 60.6** Flowchart for Analysis of Tension Members Using LRFD

Spiegel, Leonard; Limbrunner, George F., *Applied Structural Steel Design*, 3rd, © 1997. Printed and electronically reproduced by permission of Pearson Education, Inc., New York, New York.

### Example 60.1

A long tensile member is constructed by connecting two plates as shown. Each plate is  $\frac{1}{2}$  in  $\times$  9 in, A572 grade 50 steel with an ultimate strength of 65 ksi. The fasteners are  $\frac{1}{2}$  in diameter bolts. Using LRFD, determine the maximum tensile load the connection can support. Disregard the shear strength of the bolts, and disregard eccentricity.

### Solution

The gross area of the plate is

$$A_g = (0.5 \text{ in})(9 \text{ in}) = 4.5 \text{ in}^2$$

The effective hole diameter includes  $\frac{1}{8}$  in allowance for clearance and manufacturing tolerances.

$$d_h = 0.5 \text{ in} + 0.125 \text{ in} = 0.625 \text{ in}$$

The net area of the connection must be evaluated in three ways: paths ABDE, ABCDE, and FCG. Path ABDE does not have any diagonal runs. The net area is given by Eq. 60.7.

$$\begin{aligned} A_{n,ABDE} &= A_g - \sum d_h t + \left( \sum \frac{s^2}{4g} \right) t \\ &= (0.5 \text{ in}) \left( 9 \text{ in} - (2 \text{ holes}) \left( 0.625 \frac{\text{in}}{\text{hole}} \right) \right) \\ &= 3.875 \text{ in}^2 \end{aligned}$$

To determine the net area of path ABCDE, the quantity  $s^2/4g$  must be calculated. The *pitch*,  $s$ , is shown as 2.75 in, and the *gage*,  $g$ , is shown as 2.5 in.

$$\frac{s^2}{4g} = \frac{(2.75 \text{ in})^2}{(4)(2.5 \text{ in})} = 0.756 \text{ in}$$

There are two diagonals in path ABCDE. Again using Eq. 60.7, the net area is

$$\begin{aligned} A_{n,ABCDE} &= (0.5 \text{ in}) \left( 9 \text{ in} - (3 \text{ holes}) \left( 0.625 \frac{\text{in}}{\text{hole}} \right) \right. \\ &\quad \left. + (2 \text{ diagonals}) \left( 0.756 \frac{\text{in}}{\text{diagonal}} \right) \right) \\ &= 4.319 \text{ in}^2 \end{aligned}$$

The net area of path FCG is

$$\begin{aligned} A_{n,FCG} &= (0.5 \text{ in}) \left( 9 \text{ in} - (3 \text{ holes}) \left( 0.625 \frac{\text{in}}{\text{hole}} \right) \right) \\ &= 3.5625 \text{ in}^2 \end{aligned}$$

The smallest area is  $A_{n,FCG}$ , which is less than 85% of  $A_g$ . The design tensile strength,  $\phi_t P_n$ , of the connection based on the gross section is found with Eq. 60.2.  $\phi_t$  is 0.90.

$$\begin{aligned} \phi_t P_n &= \phi_t F_y A_g = (0.90) \left( 50 \frac{\text{kips}}{\text{in}^2} \right) (4.5 \text{ in}^2) \\ &= 202.5 \text{ kips} \end{aligned}$$

Since all of the connections are in the same plane,  $U = 1$ . Based on the net section, the design tensile strength is determined from Eq. 60.3 and Eq. 60.8.  $\phi_t$  is 0.75.

$$A_e = A_n U = (3.5625 \text{ in}^2)(1) = 3.5625 \text{ in}^2$$

$$\phi_t P_n = \phi_t F_u A_e = (0.75) \left( 65 \frac{\text{kips}}{\text{in}^2} \right) (3.5625 \text{ in}^2)$$

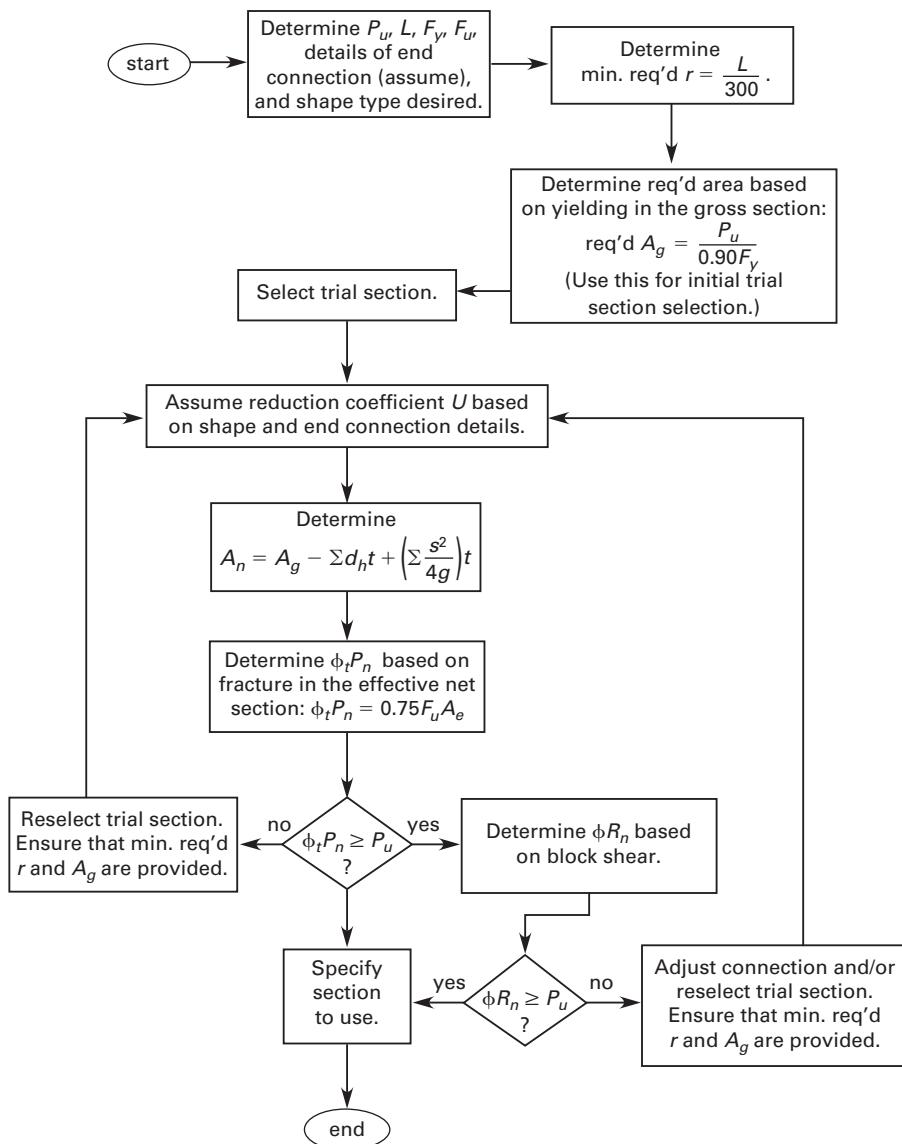

$$= 173.7 \text{ kips}$$

The design tensile strength is the smaller value of 173.7 kips.

## 9. DESIGN OF TENSION MEMBERS

The design of a tension member involves selection of a cross-sectional shape that is suitable for simple connections and has adequate gross area, net area, block shear strength, and radius of gyration (for a preferred limit on slenderness ratio). A flowchart for LRFD tension member design is shown in Fig. 60.7.

**Figure 60.7** Flowchart for the Design of Tension Members Using LRFD

Spiegel, Leonard; Limbrunner, George F., *Applied Structural Steel Design*, 3rd, © 1997. Printed and electronically reproduced by permission of Pearson Education, Inc., New York, New York.

### Example 60.2

Using LRFD, select a 25 ft long W shape of A992 steel to carry factored dead and live tensile loads of 468 kips. The shape will be used as a main member with loads transmitted to framing members through the bolted flanges only.

*Solution*

Assume the design strength is limited by the net area remaining after deductions for bolt holes. The design tensile strength in the effective (net) area of the member is determined using Eq. 60.3.  $\phi_t$  is 0.75.

$$\begin{aligned}\phi_t P_n &= \phi_t F_u A_e = (0.75) \left( 65 \frac{\text{kips}}{\text{in}^2} \right) A_e \\ &= (48.75 \text{ kips/in}^2) A_e\end{aligned}$$

Since the web does not transmit the tensile strength,  $U = 0.90$  is used, and  $A_e = A_n U$ . The required area is

$$\begin{aligned}A_n &= \frac{P_u}{0.75F_u U} = \frac{468 \text{ kips}}{(0.75) \left( 65 \frac{\text{kips}}{\text{in}^2} \right) (0.90)} \\ &= 10.67 \text{ in}^2\end{aligned}$$

From AISC Table 5-1, a W21 × 44 member has a gross area of 13.0 in<sup>2</sup>. The minimum radius of gyration is  $r_y = 1.26$  in. Using Eq. 60.11, the maximum slenderness ratio is

$$\begin{aligned}SR &= \frac{L}{r_y} = \frac{(25 \text{ ft}) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{1.26 \text{ in}} \\ &= 238.1\end{aligned}$$

The slenderness ratio is less than the suggested limit of 300. The yield limit state should be checked when the bolt size and arrangement are designed.

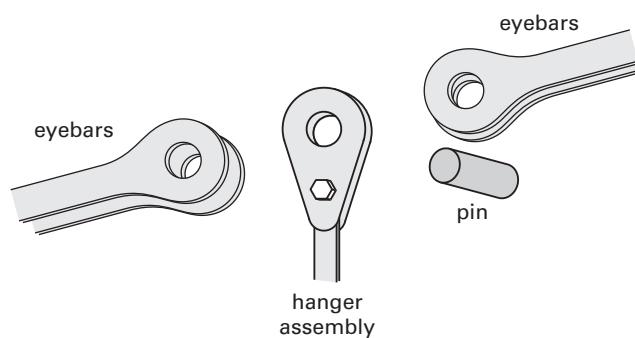

### 10. THREADED MEMBERS IN TENSION

Nominal tensile stress on threaded parts made from approved steels may not exceed  $0.75F_u$  [AISC Specification Table J3.2]. This limit applies to static loading, regardless of whether or not threads are present in the shear plane. The area to be used when calculating the maximum tensile load is the gross or nominal area, as determined from the outer extremity of the threaded section. The nominal area of bolts is calculated from the nominal bolt diameter [AISC Specification Table J3.1].

### 11. EYEBARS AND PIN-CONNECTED PLATES IN BRIDGES

*Eyebars* and pin-connected plates have historically been used in steel bridges as tension members and in tension connections.<sup>1</sup> An eyebar typically looks like a dog-bone with a circular head at each end, as shown in Fig. 60.8. Each end has a circular opening through which a steel connecting pin is inserted. *Connection plates* can be also used in conjunction with eyebars to distribute loads on the rest of the structure.

Figure 60.8 Elements of Eyebar Assemblies

AASHTO LRFD Eq. 6.8.7.2-1 determines the factored bearing resistance,  $P_r$ , on pin plates. The projected bearing area on the plate,  $A_b$ , is equal to the pin diameter multiplied by the plate thickness. AASHTO LRFD Sec. 6.5.4.2 defines the resistance factor for bearing on pins,  $\phi_b$ , as 1.00.

$$P_r = \phi_b P_n = \phi_b A_b F_y$$

Eyebar assemblies should be detailed to avoid corrosion. To ensure that eyebars do not fail in the region of the holes when the strength limit state is experienced in the plates and bars away from the hole, AASHTO LRFD Sec. 6.8.6.2 specifies proportions for the pin-plate assembly.<sup>2</sup>

- The eyebar thickness must not be less than 0.5 in or more than 2.0 in.
- The center of the pin hole must be located on the longitudinal axis of the plate.
- The pin hole diameter must not be more than  $1/32$  in larger than the pin diameter.
- The thickness of the plate away from the hole must not be less than 12% of the required plate width.

<sup>1</sup>Due to the dramatic failures of the Silver Bridge over the Ohio River in 1967 and the Mianus River Bridge over the Mianus River in Connecticut in 1983, and due to observed eyebar cracking in the San Francisco-Oakland Bay Bridge in 2009, eyebar usage is relatively rare in new bridge construction.

<sup>2</sup>Refer to AASHTO LRFD for a complete list.

y	yield or weak axis

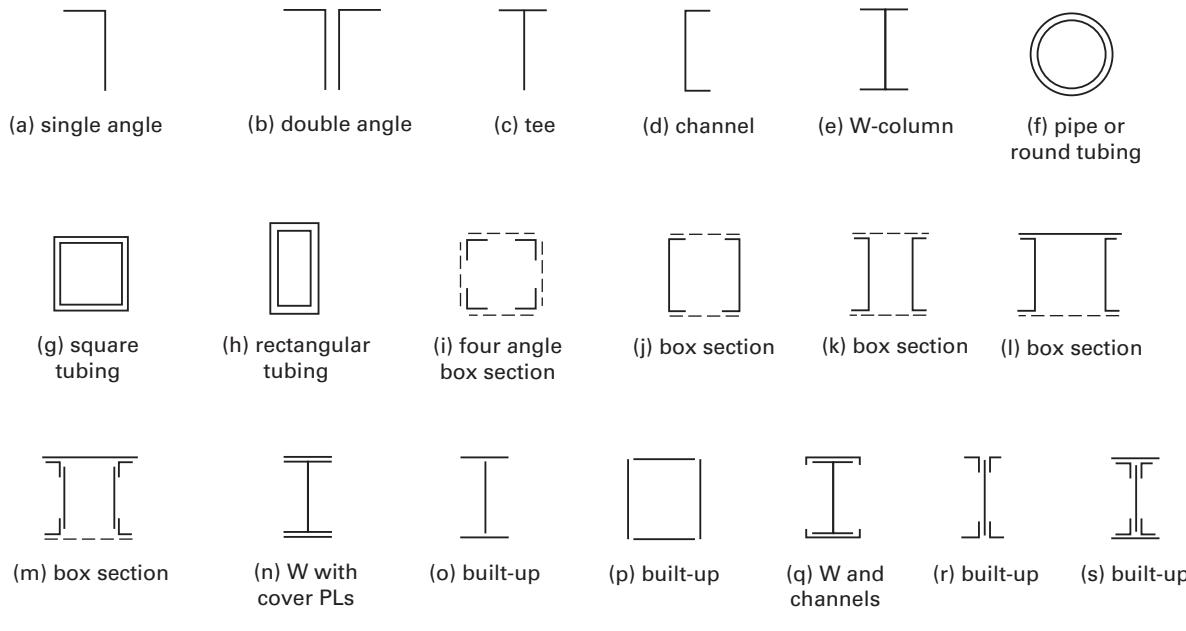

### 1. INTRODUCTION

Structural members subjected to axial compressive loads are often called by names identifying their functions. Of these, the best-known are *columns*, the main vertical compression members in a building frame. Other common compression members include *chords* in trusses and *bracing members* in frames.

The selection of a particular shape for use as a compression member depends on the type of structure, the availability, and the connection methods. Load-carrying capacity varies approximately inversely with the slenderness ratio, so stiff members are generally required. Rods, bars, and plates, commonly used as tension members, are too slender to be used as compression members unless they are very short or lightly loaded.

For building columns, *W-shapes* having nominal depths of 14 in or less are commonly used. These sections, being rather square in shape, are more efficient than others for carrying compressive loads. (Deeper sections are more efficient as beams.) *Pipe sections* are satisfactory for small or medium loads. Pipes are often used as columns in long series of windows, in warehouses, and in basements and garages. In the past, square and *rectangular tubing* saw limited use, primarily due to the difficulty in making bolted or riveted connections at the ends. Modern welding techniques have essentially eliminated this problem.

*Built-up sections* are needed in large structures for very heavy loads that cannot be supported by individual rolled shapes. For bracing and compression members in light trusses, *single-angle members* are suitable. However, *equal-leg angles* may be more economical than *unequal-leg angles* because their least radius of gyration values are greater for the same area of steel. For *top chord* members of bolted roof trusses, a pair of angles (usually unequal legs, with long legs back-to-back) to give a better balance between the radius of gyration values about the x- and

**Figure 61.1** Typical Compression Members' Cross Sections

*y*-axes) are used with or without gusset plates. In welded roof trusses, where gusset plates are unnecessary, *structural tees* are used as top chord members.

Box sections have large radii of gyration. The section shown in Fig. 61.1(i) is often seen in towers and crane booms. In Fig. 61.1(i) through Fig. 61.1(m), solid lines represent the main elements of *box sections* that are continuous for the full length of the compression member. Dashed lines represent discontinuous elements—typically plates, *lacing* or *lattice bars*, or *perforated cover plates*.<sup>1</sup> The discontinuous elements do not usually contribute to load-carrying capacity; they serve only to space the continuous elements. Depending on the design, *cover plates* may or may not contribute load-carrying capacity.

Single *channels* are not satisfactory for the average compression member because the radii of gyration about their weak axes are almost negligible unless additional lateral support in the weak direction is provided.

There are three general modes by which axially loaded compression members can fail. These are flexural buckling, local buckling, and torsional buckling. *Flexural buckling* (also called *Euler buckling*) is the primary type of buckling. *Local buckling* is where one or more parts of a member's cross section fail in a small region, before the other modes of failure can occur. This type of failure is a function of the width-thickness ratios of the parts of the cross-section. *Torsional buckling*, which is not covered in this chapter, occurs in some members (e.g., single angles and tees) but is not significant in a majority of cases.

<sup>1</sup>*Lacing bars* differ from *lattice bars* in that a *laced column* has bars oriented in the same diagonal direction, as if the bars spiral up the column, while a *latticed column* has crossed bars oriented in both directions.

## 2. EULER'S COLUMN BUCKLING THEORY

Column design and analysis are based on the Euler buckling load theory. However, specific factors of safety and slenderness ratio limitations distinguish design and analysis procedures from purely theoretical concepts.

An *ideal column* is initially perfectly straight, isotropic, and free of residual stresses. When loaded to the *buckling* (or *Euler*) *load*, a column will fail by sudden buckling (bending). The Euler column buckling load for an ideal, pin-ended, concentrically loaded column is given by Eq. 61.1. The modulus of elasticity term, *E*, implies that Eq. 61.1 is valid as long as the loading remains in the elastic region.

$$P_e = \frac{\pi^2 EI}{L^2} \quad 61.1$$

The *buckling stress*, *F<sub>e</sub>*, is derived by dividing both sides of Eq. 61.1 by the area, *A*, and using the relationship *I* = *Ar*<sup>2</sup>, where *r* is the radius of gyration.

$$F_e = \frac{P_e}{A} = \frac{\pi^2 E}{\left(\frac{L}{r}\right)^2} \quad 61.2$$

As Eq. 61.2 shows, the buckling stress is not a function of the material strength. Rather, it is a function of the ratio *L/r*, known as the *slenderness ratio*, SR. As the slenderness ratio increases, the buckling stress decreases, meaning that as a column becomes longer and more slender, the load that causes buckling becomes smaller. Equation 61.2 is convenient for design and is valid for all types of cross sections and all grades of steel.

### 3. EFFECTIVE LENGTH

Real columns usually do not have pin-connected ends. The restraints placed on a column's ends greatly affect its stability. Therefore, an *effective length factor*,  $K$  (also known as an *end-restraint factor*), is used to modify the unbraced length. The product,  $KL$ , of the effective length factor and the unbraced length is known as the *effective length* of the column. The effective length approximates the length over which a column actually buckles. The effective length can be longer or shorter than the actual unbraced length.

$$F_e = \frac{\pi^2 E}{\left(\frac{KL}{r}\right)^2} \quad [\text{AISC Specification Eq. E3-4}] \quad 61.3$$

Values of the effective length factor depend upon the rotational restraint at the column ends as well as on the resistance provided against any lateral movement along the column length (i.e., whether or not the column is braced against sidesway). Theoretically, restraint at each end can range from complete *fixity* (though this is impossible to achieve in practice) to zero fixity (e.g., as with a freestanding signpost or flagpole end). Table 61.1 lists recommended values of  $K$  for use with steel columns. For braced columns (sidesway inhibited),  $K \leq 1$ , whereas for unbraced columns (sidesway uninhibited),  $K > 1$ .

**Table 61.1** Effective Length Factors\*

end no. 1	end no. 2	$K$
built-in	built-in	0.65
built-in	pinned	0.80
built-in	rotation fixed, translation free	1.2
built-in	free	2.1
pinned	pinned	1.0
pinned	rotation fixed, translation free	2.0

\*These are slightly different from the theoretical values often quoted for use with Euler's equation.

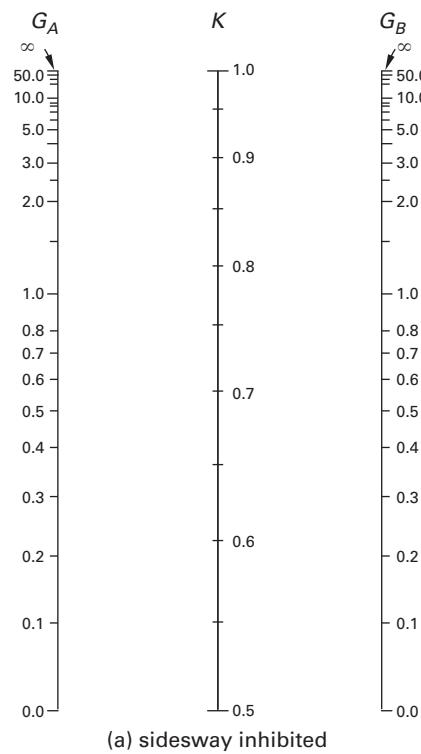

Copyright © American Institute of Steel Construction, Inc. Reprinted with permission. All rights reserved.

The values of  $K$  in Table 61.1 do not require prior knowledge of the column size or shape. However, if the columns and beams of an existing design are known, the alignment charts in Fig. 61.2 can be used to obtain a more accurate effective length factor.

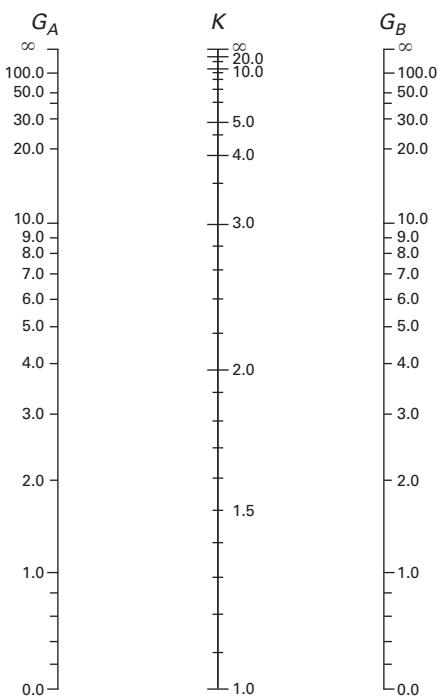

To use Fig. 61.2 [AISC Commentary Fig. C-A-7.1 and Fig. C-A-7.2], the *end condition coefficients*,  $G_A$  and  $G_B$ , are first calculated from Eq. 61.4 for the two column ends. (The alignment charts are symmetrical. Either end can be designated *A* or *B*.)

$$G = \frac{\sum \left(\frac{I}{L}\right)_c}{\sum \left(\frac{I}{L}\right)_b} \quad 61.4$$

**Figure 61.2** Effective Length Factor Alignment Charts

(a) sidesway inhibited

(b) sidesway uninhibited

Copyright © American Institute of Steel Construction, Inc. Reprinted with permission. All rights reserved.

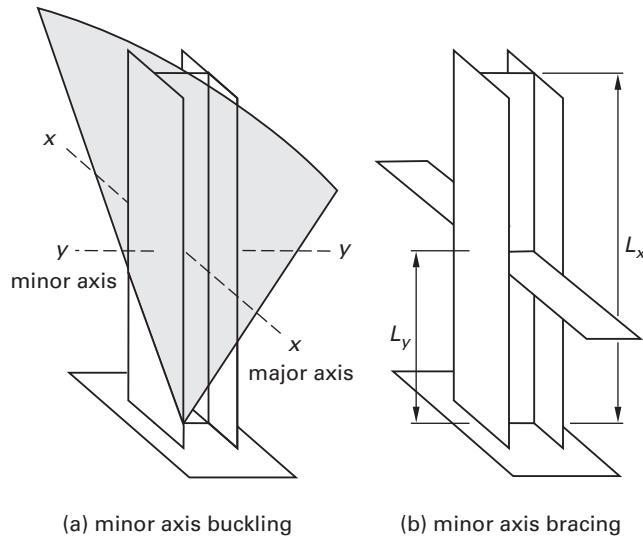

In calculating  $G$ , only beams and columns in the plane of bending (i.e., those that resist the tendency to buckle) are included in the summation. Also, only rigidly attached beams and columns are included, since pinned

connections do not resist moments. For ground-level columns, one of the column ends will not be framed to beams or other columns. In that case,  $G = 10$  (theoretically,  $G = \infty$ ) will be used for pinned ends, and  $G = 1$  (theoretically,  $G = 0$ ) will be used for rigid footing connections.

#### 4. GEOMETRIC TERMINOLOGY

Figure 61.3 shows a W-shape used as a column. The  $I_y$  moment of inertia is smaller than  $I_x$ . In this case, the column is said to “buckle about the minor axis” if the failure (buckling) mode is as shown.

**Figure 61.3** Minor Axis Buckling and Bracing

Since buckling about the minor axis is the expected buckling mode, bracing for the minor axis is usually provided at intermediate locations to reduce the unbraced length. Associated with each column are two unbraced lengths,  $L_x$  and  $L_y$ . In Fig. 61.3(b),  $L_x$  is the full column height. However,  $L_y$  is half the column height, assuming that the brace is placed at midheight.

Another important geometric characteristic is the *radius of gyration*. Since there are two moments of inertia, there are also two radii of gyration. Since  $I_y$  is smaller than  $I_x$ ,  $r_y$  will be smaller than  $r_x$ .  $r_y$  is known as the *least radius of gyration*.

#### 5. SLENDERNESS RATIO

Steel columns are categorized as long columns and intermediate columns, depending on their slenderness ratios, SR. Since there are two values of the radius of gyration,  $r$  (and two values of  $K$  and  $L$ ), corresponding to the  $x$ - and  $y$ -directions, there will be two slenderness ratios.

$$SR = \frac{KL}{r} \quad 61.5$$

The SR of compressive members preferably should not exceed 200 [AISC Specification Sec. E2].

#### 6. BUCKLING OF REAL COLUMNS

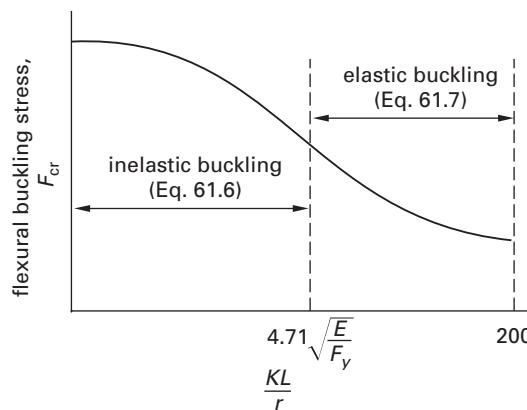

Euler's buckling load formula assumes concentrically loaded, perfect columns—conditions that are difficult to achieve in the real world. Real columns always have some flaws—curvature, variations in material properties, and residual stresses (of 10 ksi to 15 ksi, mainly due to uneven cooling after hot-rolling). Furthermore, concentric loading is not possible.

Residual stresses are of particular importance with slenderness ratios of 40 to 120—a range that includes a very large percentage of columns. Because of the residual stresses, early localized yielding occurs at points in the column cross section, and buckling strength is appreciably reduced.

#### 7. DESIGN COMPRESSIVE STRENGTH

The available column strength varies with the slenderness ratio. Figure 61.4 shows two different regions, representing *inelastic buckling* and *elastic buckling*, which are separated by the limit  $4.71\sqrt{E/F_y}$ . (Very short compression members—those with effective lengths less than about 2 ft (0.6 m)—are governed by different requirements.)

**Figure 61.4** Available Compressive Stress Versus Slenderness Ratio

For intermediate columns ( $KL/r \leq 4.71\sqrt{E/F_y}$ ) that fail by inelastic buckling, Eq. 61.6 gives the design stress [AISC Specification Eq. E3-2].

$$F_{cr} = (0.658^{F_y/F_e})F_y \quad 61.6$$

The parabolic curve of Eq. 61.6 accounts for the inelastic behavior due to residual stresses and initial crookedness in a real column.

For long columns ( $KL/r > 4.71\sqrt{E/F_y}$ ) that fail by elastic buckling, Eq. 61.7 [AISC Specification Eq. E3-3] must be used. Although Eq. 61.6 is a function of  $F_y$ ,

Eq. 61.7 is independent of  $F_y$ .  $F_e$  is the elastic critical buckling stress. (See Eq. 61.3.)

$$F_{cr} = 0.877F_e \quad 61.7$$

## 8. ANALYSIS OF COLUMNS

Columns are analyzed by verifying that the required strength,  $P_u$  or  $P_a$ , does not exceed the design strength,  $\phi_c P_n$ , or the allowable strength,  $P_n/\Omega_c$ . The nominal axial compressive strength,  $P_n$ , is

$$P_n = F_{cr}A_g \quad [AISC Specification Eq. E3-1] \quad 61.8$$

*step 1:* Determine the shape properties  $A$ ,  $r_x$ , and  $r_y$  from the *AISC Manual*. Determine the unbraced lengths,  $L_x$  and  $L_y$ .

*step 2:* Obtain  $K_x$  and  $K_y$  from Table 61.1 or from the alignment chart, Fig. 61.2.

*step 3:* Calculate the maximum slenderness ratio as

$$SR = \text{larger of } \left\{ \frac{\frac{K_x L_x}{r_x}}{\frac{K_y L_y}{r_y}} \right\} \quad 61.9$$

*step 4:* Calculate the limit,  $4.71\sqrt{E/F_y}$ .

*step 5:* Using SR, determine the design stress,  $F_{cr}$ , from either AISC Table 4-1 or Table 4-22. Alternatively, calculate the design stress,  $F_{cr}$ , from either Eq. 61.6 or Eq. 61.7, depending on the value of SR.

*step 6:* Compute the allowable strength or the design compressive strength and compare against the required strength.

$$P_a = \frac{P_n}{\Omega_c} = \frac{F_{cr}A_g}{1.67} \quad [\text{ASD}] \quad 61.10(a)$$

$$\phi_c P_n = 0.90F_{cr}A_g \quad [\text{LRFD}] \quad 61.10(b)$$

## 9. DESIGN OF COLUMNS

Trial-and-error column selection is difficult. Accordingly, Part 4 of the *AISC Manual* contains column-selection tables [AISC Table 4-2] that make it fairly easy to select a column based on the required column capacity. These tables assume that buckling will occur first about the minor axis. Steps 4 through 7 in the following procedure accommodate the case where buckling occurs first about the major axis.

*step 1:* Determine the load to be carried. Include an allowance for the column weight.

*step 2:* Determine the effective length factors,  $K_y$  and  $K_x$ , for the column. (If Eq. 61.4 is to be used, an initial column may need to be assumed.)

Calculate the effective length assuming that buckling will be about the minor axis.

$$\text{effective length} = K_y L_y \quad 61.11$$

*step 3:* Enter the table and locate a column that will support the required load with an effective length of  $K_y L_y$ .

*step 4:* Check for buckling in the strong direction. Calculate  $K_x L'_x$  from Eq. 61.12. (The ratio  $r_x/r_y$  is tabulated in the column tables.)

$$K_x L'_x = \frac{K_x L_x}{\frac{r_x}{r_y}} \quad 61.12$$

*step 5:* If  $K_x L'_x < K_y L_y$ , the column is adequate and the procedure is complete. Go to step 8.

*step 6:* If  $K_x L'_x > K_y L_y$  but the column chosen can support the load at a length of  $K_x L'_x$ , the column is adequate, and the procedure is complete. Go to step 8.

*step 7:* If  $K_x L'_x > K_y L_y$  but the column chosen cannot support the load at a length of  $K_x L'_x$ , choose a larger member that will support the load at a length of  $K_x L'_x$ . (The ratio  $r_x/r_y$  is essentially constant.)

*step 8:* If sufficient information on other members framing into the column is available, use the alignment charts to check the values of  $K$ . (See Fig. 61.2.)

### Example 61.1

Select an A992 steel W14 shape to support a 2000 kip concentric live load. The unbraced length is 11 ft in both directions. Use  $K_y = 1.2$  and  $K_x = 0.80$ . Use the LRFD method.

*Solution*

*step 1:* Assume the weight of the column is approximately 500 lbf/ft. The load to be carried is

$$P_u = (1.6)(2000 \text{ kips}) + (1.2) \left( \frac{(500 \frac{\text{lbf}}{\text{ft}})(11 \text{ ft})}{1000 \frac{\text{lbf}}{\text{kip}}} \right) \\ = 3207 \text{ kips}$$

*step 2:* From Eq. 61.11, the effective length for minor axis bending is

$$K_y L_y = (1.2)(11 \text{ ft}) = 13.2 \text{ ft} \quad [\text{say } 13 \text{ ft}]$$

*step 3:* From AISC Table 4-1 for 50 ksi steel, select a W14 × 283 shape with an available strength,  $\phi_c P_n$ , of 3380 kips.

*step 4:* From the column table,  $r_x/r_y = 1.63$ . Using Eq. 61.12,

$$K_x L'_x = \frac{K_x L_x}{\frac{r_x}{r_y}} = \frac{(0.80)(11 \text{ ft})}{1.63} = 5.40 \text{ ft}$$

*step 5:*  $5.40 \text{ ft} < 13 \text{ ft}$ ; therefore, the column selected is adequate.

### Example 61.2

Select a 25 ft A992 W12 shape column to support a live load of 375 kips. The base is rigidly framed in both directions. The top is rigidly framed in the weak direction and fixed against rotation in the strong direction, but translation in the strong direction is possible.

*Solution*

*step 1:* Assume the column weight is approximately 80 lbf/ft. The required axial strength is

$$P_u = (1.6)(375 \text{ kips}) + (1.2) \left( \frac{\left( 80 \frac{\text{lbf}}{\text{ft}} \right) (25 \text{ ft})}{1000 \frac{\text{lbf}}{\text{kip}}} \right) = 602 \text{ kips}$$

*step 2:* From Table 61.1, the end restraint coefficients are  $K_y = 0.65$  and  $K_x = 1.2$ . The effective lengths are

$$K_y L_y = (0.65)(25 \text{ ft}) = 16.25 \text{ ft}$$

$$K_x L_x = (1.2)(25 \text{ ft}) = 30 \text{ ft}$$

*step 3:* From AISC Table 4-1 for 50 ksi steel, find a column capable of supporting 602 kips with an effective length of 16 ft. Try a W12 × 65 shape with a capacity of 639 kips.

*step 4:* From AISC Table 4-1,  $r_x/r_y = 1.75$ . Using Eq. 61.12,

$$K_x L'_x = \frac{K_x L_x}{\frac{r_x}{r_y}} = \frac{30 \text{ ft}}{1.75} = 17.1 \text{ ft}$$

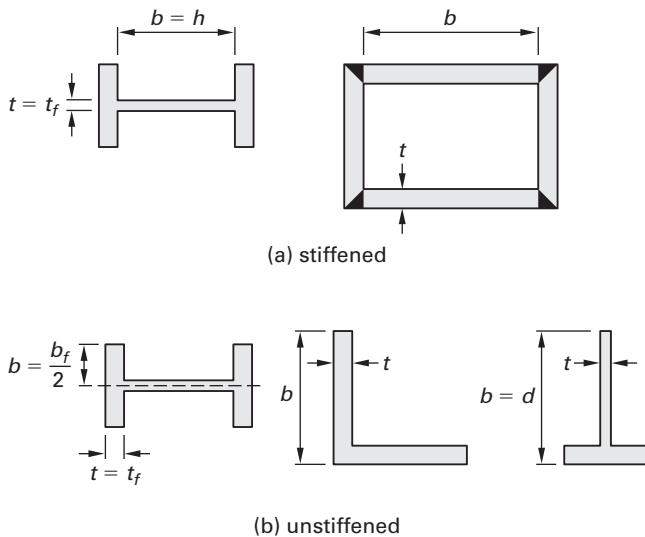

*step 5:* Since  $17.1 \text{ ft} > 16.25 \text{ ft}$ , the strong-axis buckling controls. Use AISC Table 4-1 to find an effective length of 17.1 ft. The column capacity is found by interpolation to be 613 kips. Since  $613 \text{ kips} > 602 \text{ kips}$ , this column is adequate.

### 10. LOCAL BUCKLING

Local buckling of a plate element in a rolled shape, built-up, or hollow structural section (HSS) compression member may occur before Euler buckling. The ability of plate sections to carry compressive loads without buckling is determined by the *width-thickness ratio*,  $b/t$ . If a shape is selected from the AISC column-selection tables, the width-thickness ratios do not generally need to be evaluated. However, compression members constructed from structural tees, structural tubing, and plates must be checked.

For the purpose of specifying limiting width-thickness ratios, compression elements are divided into stiffened elements and unstiffened elements. (See Fig. 61.5.) *Stiffened elements* are supported along two parallel edges. Examples are webs of W-shapes and the sides of box beams. *Unstiffened elements* are supported along one edge only. Flanges of W-shapes and legs of angles are unstiffened elements.

**Figure 61.5** Stiffened and Unstiffened Compressive Elements

For the purpose of local buckling, the *AISC Manual* classifies sections (e.g., rolled I-shaped members) into three categories. *Compact sections* have flanges that are continuously connected to their webs, and webs and flanges satisfy Eq. 61.13. Compact sections are expected to fail plastically. *Noncompact sections* satisfy Eq. 61.14. Noncompact sections are expected to fail inelastically. *Slender-element sections* are described by Eq. 61.15. Slender-element sections are expected to fail elastically. Values of  $\lambda_p$  and  $\lambda_r$  are specified in Table 61.2 and Table 61.3.

$$\frac{b}{t} \leq \lambda_p \quad [\text{compact}] \quad 61.13$$

$$\lambda_p < \frac{b}{t} \leq \lambda_r \quad [\text{noncompact}] \quad 61.14$$

$$\frac{b}{t} > \lambda_r \quad [\text{slender-element}] \quad 61.15$$

**Table 61.2** Limiting Width-to-Thickness Ratios for Elements in Axial Compression

element	ratio	$\lambda_r$ (nonslender/slender)
flanges of rolled I-shaped sections; plates projecting from rolled I-shaped sections; outstanding legs of pairs of angles connected with continuous contact; flanges of channels; and flanges of tees	$b/t$	$0.56\sqrt{E/F_y}$
flanges of built-up I-shaped sections and plates or angle legs projecting from built-up I-shaped sections	$b/t$	$0.64\sqrt{k_c E/F_y}^*$
legs of single angles, legs of double angles with separators, and all other unstiffened elements	$b/t$	$0.45\sqrt{E/F_y}$
stems of tees	$d/t$	$0.75\sqrt{E/F_y}$
webs of doubly symmetric I-shaped sections and channels	$h/t_w$	$1.49\sqrt{E/F_y}$
walls of rectangular HSS and boxes of uniform thickness	$b/t$	$1.40\sqrt{E/F_y}$
flange cover plates and diaphragm plates between lines of fasteners or welds	$b/t$	$1.40\sqrt{E/F_y}$
all other stiffened elements	$b/t$	$1.49\sqrt{E/F_y}$
round HSS	$D/t$	$0.11E/F_y$

\* $k_c = 4/\sqrt{h/t_w}$ ; but,  $0.35 \leq k_c \leq 0.76$ .

Source: Adapted from AISC Specification Table B4.1a.

**Table 61.3** Limiting Width-to-Thickness Ratios for Elements in Flexure

element	ratio	$\lambda_p$ (compact/ noncompact)	$\lambda_r$ (noncompact/ slender)
flanges of rolled I-shaped sections, channels, and tees	$b/t$	$0.38\sqrt{E/F_y}$	$1.0\sqrt{E/F_y}$
flanges of doubly and singly symmetric I-shaped built-up sections	$b/t$	$0.38\sqrt{E/F_y}$	$0.95\sqrt{k_c E/F_y}^{a,b}$
legs of single angles	$b/t$	$0.54\sqrt{E/F_y}$	$0.91\sqrt{E/F_y}$
flanges of all I-shaped sections and channels in flexure about the weak axis	$b/t$	$0.38\sqrt{E/F_y}$	$1.0\sqrt{E/F_y}$
stems of tees	$d/t$	$0.84\sqrt{E/F_y}$	$1.03\sqrt{E/F_y}$
webs of doubly symmetric I-shaped sections and channels	$h/t_w$	$3.76\sqrt{E/F_y}$	$5.70\sqrt{E/F_y}$
webs of singly symmetric I-shaped sections	$h_c/t_w$	$\frac{h_c/h_p\sqrt{E/F_y}}{(0.54 M_p/M_y - 0.09)^2} \leq \lambda_r^c$	$5.70\sqrt{E/F_y}$
flanges of rectangular HSS and boxes of uniform thickness	$b/t$	$1.12\sqrt{E/F_y}$	$1.40\sqrt{E/F_y}$
flange cover plates and diaphragm plates between lines of fasteners or welds	$b/t$	$1.12\sqrt{E/F_y}$	$1.40\sqrt{E/F_y}$
webs of rectangular HSS and boxes	$h/t$	$2.42\sqrt{E/F_y}$	$5.70\sqrt{E/F_y}$
round HSS	$D/t$	$0.07E/F_y$	$0.31E/F_y$

<sup>a</sup> $k_c = 4/\sqrt{h/t_w}$ ; but,  $0.35 \leq k_c \leq 0.76$ .

<sup>b</sup> $F_L = 0.7F_y$  for major axis bending of compact and noncompact web built-up I-shaped members with  $S_{xt}/S_{xc} \geq 0.7$ ;  $F_L = F_y S_{xt}/S_{xc} \geq 0.5F_y$  for major-axis bending of compact and noncompact web built-up I-shaped members with  $S_{xt}/S_{xc} < 0.7$ .

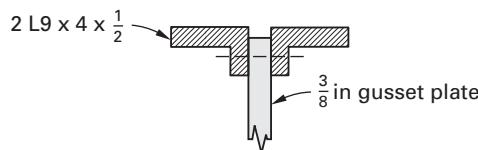

<sup>c</sup> $M_y$  is the moment at yielding of the extreme fiber.  $M_p$  = plastic bending moment, kip-in (N·mm).  $E$  = modulus of elasticity of steel = 29,000 ksi (200 000 MPa).  $F_y$  = specified minimum yield stress, ksi (MPa).

Source: Adapted from AISC Specification Table B4.1b.

For compression members with slender elements that exceed width-thickness requirements, the boundary between elastic and inelastic buckling and the inelastic buckling stress are modified by a reduction factor,  $Q$ , as defined in *AISC Specification* Sec. E7. For slender unstiffened compression elements, a reduction factor,  $Q_s$ , is computed, and for slender stiffened compression elements, a reduction factor,  $Q_a$ , is computed based on the effective area of the cross section. The reduction factor,  $Q$ , is the product of  $Q_s$  and  $Q_a$ . The critical buckling stress is reduced by the  $Q$  factor.

### Example 61.3

Two A36 L9 × 4 × 1/2 angles are used with a 3/8 in gusset plate to create a truss compression member. The short legs are back to back, making the long legs unstiffened elements. Can the combination fully develop compressive stresses?

#### Solution

From *AISC Specification* Table B4.1, the limitation on the unstiffened separated double angles is given by

$$0.45 \sqrt{\frac{E}{F_y}} = 0.45 \sqrt{\frac{29,000 \text{ kips}}{36 \text{ kips}}} = 12.77$$

The actual width-thickness ratio is

$$\frac{b}{t} = \frac{9 \text{ in}}{0.5 \text{ in}} = 18$$

Since  $18 > 12.77$ , local buckling will control. A reduced stress factor must be used when calculating the allowable compressive load on the truss member.

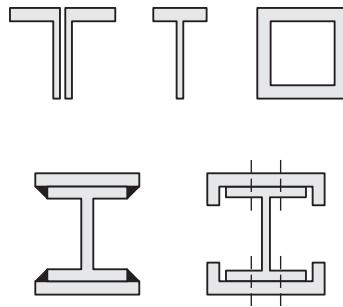

## 11. MISCELLANEOUS COMBINATIONS IN COMPRESSION

Miscellaneous shapes, including round and rectangular tubing, single and double angles, and built-up sections, can be used as compression members, as shown in Fig. 61.6.

Generally, sections with distinct strength advantages in one plane (e.g., double angles or tees) should be used when bending is confined to that plane. For example, a double-angle member could be used as a compression strut in a roof truss or as a spreader bar for hoisting large loads.

Design and analysis of these miscellaneous compression members is similar to the design and analysis of W-shape columns. The same equations are used for calculating the

**Figure 61.6** Miscellaneous Compression Members

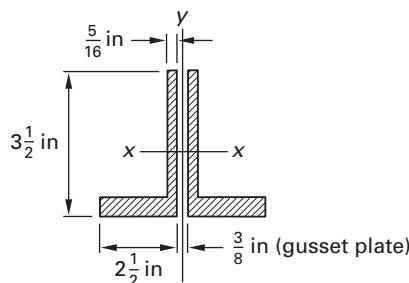

design stress,  $F_{cr}$ . It is essential to check the width-thickness ratios for all elements in the compression members, including both flanges and stems of tees.

Where spot welding or stitch riveting is used to combine two shapes into one (as is done with double angles), the spacing of the connections must be sufficient to prevent premature buckling of one of the shapes. The  $KL/r$  value affected by the spacing of intermediate connectors must be modified by the equations given in Sec. E6 of the *AISC Specification*.

Column load tables have been prepared for many combinations of double angles, tees, round pipe, and structural tubing. Single-angle compression members are difficult to load concentrically, and special attention is required when designing the connections.

### Example 61.4

Design a 10 ft long A36 double-angle strut to support an axial compressive load of 40 kips. Assume  $K = 1$  in both directions. Gusset plates at the ends are 3/8 in thick.

#### Solution

(Slightly different answers will be obtained if AISC Table 4-22 is used.)

#### ASD Method

Self-weight is disregarded since the weight of the strut will be insignificant compared to the axial load.

From AISC Table 4-9, try two L3 1/2 × 2 1/2 × 3/8. This combination of two angles has an available strength,  $P_n/\Omega$ , of 48.8 kips in the  $x$ -direction and 44.4 kips in the  $y$ -direction. The available strength is the lesser of these two values. Since 44.4 kips > 40 kips, the angle is OK.

The available strength about the  $x$ -axis can be computed from Eq. 61.6 or Eq. 61.7 as follows. From the table, the properties are

$$A = 4.22 \text{ in}^2$$

$$r_x = 1.10 \text{ in}$$

The slenderness ratio,  $KL/r$ , is

$$\frac{K_x L}{r_x} = \frac{(1)(10 \text{ ft})(12 \frac{\text{in}}{\text{ft}})}{1.10 \text{ in}} = 109$$

The limiting slenderness ratio between inelastic and elastic buckling is

$$4.71 \sqrt{\frac{E}{F_y}} = 4.71 \sqrt{\frac{29,000 \frac{\text{kips}}{\text{in}^2}}{36 \frac{\text{kips}}{\text{in}^2}}} = 134$$

Since  $109 < 134$ , Eq. 61.6 controls. The Euler stress is calculated from Eq. 61.3.

$$F_e = \frac{\pi^2 E}{\left(\frac{KL}{r}\right)^2} = \frac{\pi^2 \left(29,000 \frac{\text{kips}}{\text{in}^2}\right)}{(109)^2} = 24.09 \text{ kips/in}^2$$

The flexural buckling stress,  $F_{cr}$ , is

$$F_{cr} = (0.658^{F_y/F_e}) F_y = \left(0.658^{\frac{36 \text{ kips/in}^2}{24.09 \text{ kips/in}^2}}\right) \left(36 \frac{\text{kips}}{\text{in}^2}\right) = 19.26 \text{ kips/in}^2$$

The available strength is

$$\frac{P_n}{\Omega} = \frac{A_g F_{cr}}{\Omega} = \frac{(4.22 \text{ in}^2) \left(19.26 \frac{\text{kips}}{\text{in}^2}\right)}{1.67} = 48.7 \text{ kips}$$

The value given for the available strength in the  $y$ -direction is a function of connector spacing and is computed from a modified  $KL/r$  determined from equations in AISC Specification Sec. E6.

#### LRFD Method

Since the dead load is neglected, the required strength,  $P_u$ , is

$$P_u = (1.6)(40 \text{ kips}) = 64 \text{ kips}$$

From AISC Table 4-9, try two  $L3\frac{1}{2} \times 2\frac{1}{2} \times \frac{3}{8}$ . This combination of two angles has an available strength,  $\phi P_n$ , equal to 73.4 kips in the  $x$ -direction and 66.8 kips in the  $y$ -direction. The available strength is the lesser of

these two values. Since  $66.8 \text{ kips} > 64 \text{ kips}$ , the angle is OK.

The flexural buckling stress with respect to the  $x$ -axis is computed as in the ASD solution. The available strength is given by

$$\begin{aligned} \phi P_n &= \phi A_g F_{cr} = (0.9)(4.22 \text{ in}^2) \left(19.26 \frac{\text{kips}}{\text{in}^2}\right) \\ &= 73.1 \text{ kips} \end{aligned}$$

## 12. COLUMN BASE PLATES

The design of axially-loaded column base plates is covered in *AISC Manual* Chap. 14, while bearing on concrete is covered in *AISC Specification* Sec. J8. The allowable bearing strength,  $P_a$ , and design bearing strength,  $P_u$ , are

$$P_a = \frac{P_p}{\Omega_c} \quad [\text{ASD}; \Omega_c = 2.50] \quad 61.16(a)$$

$$P_u = \phi_c P_p \quad [\text{LRFD}; \phi_c = 0.60] \quad 61.16(b)$$

The pressure beneath the column base plate must not exceed the available bearing strength,  $F_p$ , of the foundation material (e.g., concrete or masonry). If the geometrically-similar and concentric supporting area of the foundation,  $A_2$ , exceeds the area of the column base plate,  $A_1$ , the available bearing stress may be increased by  $\sqrt{A_2/A_1}$ , but not by more than a factor of 2.

Base plate design is a two-step process. In the first step, the area of the base plate,  $A_1$ , is calculated from the allowable bearing stress.

$$A_1 = \frac{\text{unfactored column load}}{F_p} \quad 61.17$$

$$F_p = 0.85 f'_c \sqrt{\frac{A_2}{A_1}} \leq 1.7 f'_c \quad 61.18$$

The nominal bearing strength,  $P_p$ , is

$$P_p = F_p A_1 = 0.85 f'_c A_1 \sqrt{\frac{A_2}{A_1}} \leq 1.7 f'_c A_1 \quad 61.19$$

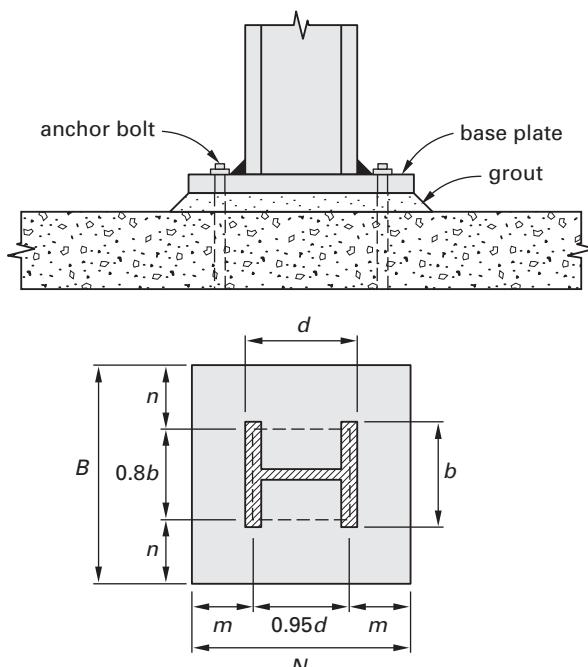

The dimensioning procedure may be iterative. The base plate dimensions are determined,  $N$  and  $B$  (as shown in Fig. 61.7), may be known, or they may need to be calculated from the column dimensions. The dimension may be limited by web yielding or crippling. In some installations, one or both dimensions may be limited by the supporting structure dimensions.

For rectangular columns, using the dimensions of the critical section defined in the second step,

$$N = 2m + 0.95d \quad 61.20$$

$$B = \frac{A_1}{N} \quad 61.21$$

**Figure 61.7** Column Base Plate

Base plate dimensions are typically specified in whole inches. Therefore, the actual plate area will often be larger than the required plate area. The actual bearing pressure will be

$$f_p = \frac{\text{unfactored column load}}{BN} \quad 61.22$$

It is generally desirable to have  $m = n$ . If  $B$  and  $N$  are established, these dimensions may be calculated from the base plate dimensions.

$$m = \frac{N - 0.95d}{2} \quad 61.23$$

$$n = \frac{B - 0.80b_f}{2} \quad 61.24$$

In the second step, after the base plate dimensions are determined, the base plate thickness is determined based on the flexural demand on a critical section of the base plate acting as a uniformly loaded, double cantilevered beam. The *base plate critical section* is defined as the  $0.95 \times 0.8b_f$  rectangular section for wide-flanged beams, as 0.80 times the outer diameter for round tube sections, and as 0.95 times the outside dimension of rectangular tube sections.

The uniform loading of the cantilever section extending outward from the rectangle results in an actual bending stress,  $f_b$ , at the critical section. For ASD, the allowable bending strength of the plate is equal to  $0.75F_{y,\text{plate}}$ , and the elastic section modulus,  $S$ , is used. For LRFD, the

design strength is  $0.90F_{y,\text{plate}}$ , and the plastic section modulus,  $Z$ , is used.

$$M_n = F_y S \quad [\text{ASD}] \quad 61.25(a)$$

$$M_n = F_y Z \quad [\text{LRFD}] \quad 61.25(b)$$

Depending on which direction controls, the critical cross-section for bending is either an  $N \times t$  or a  $B \times t$  rectangle, so the section modulus is

$$Z = \frac{\{N \text{ or } B\}t^2}{4} \quad 61.26$$

$$S = \frac{\{N \text{ or } B\}t^2}{6} \quad 61.27$$

The length of the critical section is the larger of  $m$ ,  $n$ , or  $\lambda n'$ , where  $n'$  is defined by Eq. 61.28, and  $\lambda$  is the *base plate cantilever factor* defined by Eq. 61.29.  $\lambda$  is always less than 1.0 and may be conservatively estimated as 1.0.

$$n' = \frac{\sqrt{db_f}}{4} \quad 61.28$$

$$\lambda = \frac{2\sqrt{X}}{1 + \sqrt{1 - X}} \leq 1.0 \quad 61.29$$

$$X = \left( \frac{4db_f}{(d + b_f)^2} \right) \left( \frac{P_{u,\text{req'd}}}{\phi_c P_p} \right) \quad [\text{LRFD}; \phi_c = 0.6] \quad 61.30(a)$$

$$X = \left( \frac{4db_f}{(d + b_f)^2} \right) \left( \frac{\Omega_u P_{a,\text{req'd}}}{P_p} \right) \quad [\text{ASD}; \Omega_c = 2.50] \quad 61.30(b)$$

The pressure,  $f_p$ , under the base plate for axial loading is uniform, so the applied moment is

$$M_n = \frac{1}{2}l^2 \{B \text{ or } N\} f_p \quad 61.31$$

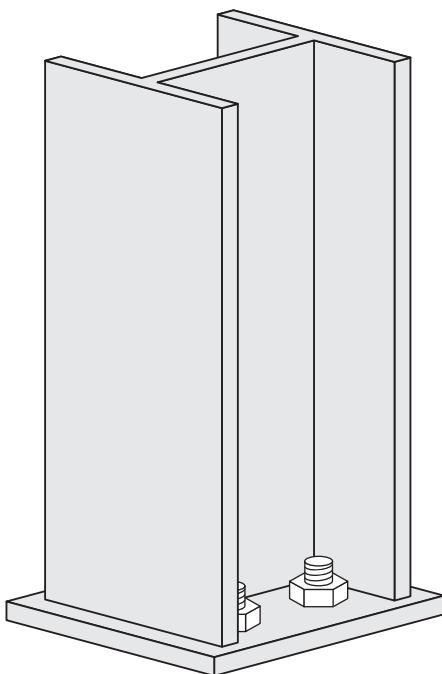

Equation 61.32 can be used to calculate the minimum plate thickness. Thicknesses should be specified in  $1/8$  in increments up to  $1\frac{1}{4}$  in, and in  $1/4$  in increments thereafter.

$$t_{\min} = l \sqrt{\frac{2P_u}{0.9F_y BN}} \quad [\text{LRFD}] \quad 61.32(a)$$

$$t_{\min} = l \sqrt{\frac{3.33P_a}{F_y BN}} \quad [\text{ASD}] \quad 61.32(b)$$

In the past, for the purpose of erection, small columns were often anchored to the supporting substructure with only two anchor bolts, a practice that sometimes proved inadequate. (See Fig. 61.8.) The Occupational Safety and Health Administration (OSHA) now requires that a minimum of four anchor bolts (or rods or embedded studs) be used during erection [OSHA 1926.755(a)(1)]. Since it is difficult to squeeze two anchor bolts into the free space between the flanges of W4, W6, and W8 beams, round and rectangular sections are preferred over these smaller sections.

$x$	strong axis
$y$	weak axis or yield

## 1. INTRODUCTION

A member that is acted upon by a compressive force and a bending moment is known as a *beam-column*. The bending moment can be due to an eccentric load or a true lateral load.

For pure beams and columns, second-order effects are neglected. Only first-order effects based on undeformed geometry need to be considered (i.e., for a member subjected to a moment only, or when the same member carries an axial compressive load alone).

When a member is acted upon by both bending moment and an axial load, the two stresses cannot be added directly to obtain the so-called combined stresses. Additional stresses resulting from a secondary moment must be taken into account, especially when the axial compressive load is large. The secondary moment is caused by the *P-Δ effect* and has a magnitude of  $P\Delta$ . The deflection,  $\Delta$ , results from the initial lateral deflection due to the bending moment, but causes further bending of its own and produces secondary stresses.

The secondary moment and the associated stress are known as *second-order effects*, since they are dependent on the deformed geometry of the member. *Moment amplification factors* are used to account for the second-order effects. An equation for maximum combined stress can be written as Eq. 62.1.  $f_{bx}$  and  $f_{by}$  are the maximum bending stresses caused by bending moments about  $x$ - and  $y$ -axes, respectively.  $(AF)_x$  and  $(AF)_y$  are the corresponding amplification factors.

$$f_{\max} = f_a + (AF)_x f_{bx} + (AF)_y f_{by} \quad 62.1$$

Unfortunately, even with the inclusion of secondary moment effects, computed values of combined stresses

are not particularly useful, since there are no code-specified allowable combined stresses for beam-columns. Design and analysis of beam-columns generally attempt to transform moments into equivalent axial loads (i.e., the *equivalent axial compression method*) or make use of interaction equations. Interaction-type equations are best suited for beam-column analysis and validation, since so much (e.g., area, moment of inertia) needs to be known about a shape. Equivalent axial compression methods are better suited for design.

Equation 62.1 is converted to an *interaction equation* by dividing both sides by  $f_{\max}$  and then by substituting applicable allowable stresses for  $f_{\max}$ . In Eq. 62.2, if one or more applied stresses is zero, the member acts as an axially loaded column, a beam bending about one or both axes, or a beam-column bending about one axis only.

$$\frac{f_a}{F_a} + (\text{AF})_x \left( \frac{f_{bx}}{F_{bx}} \right) + (\text{AF})_y \left( \frac{f_{by}}{F_{by}} \right) = 1.0 \quad 62.2$$

## 2. FLEXURAL/AXIAL COMPRESSION

The flexural/compressive force relationships (also known as flexural/force interaction equations) are presented in the *AISC Specification* Sec. H1.1.

For  $P_r/P_c \geq 0.2$ , AISC Eq. H1-1a is

$$\frac{P_r}{P_c} + \left( \frac{8}{9} \right) \left( \frac{M_{rx}}{M_{cx}} + \frac{M_{ry}}{M_{cy}} \right) \leq 1.0 \quad 62.3$$

For  $P_r/P_c < 0.2$ , AISC Eq. H1-1b is

$$\frac{P_r}{2P_c} + \frac{M_{rx}}{M_{cx}} + \frac{M_{ry}}{M_{cy}} \leq 1.0 \quad 62.4$$

$P_r$  is the required axial compressive strength,  $P_c$  is the available axial compressive strength,  $M_r$  is the required flexural strength,  $M_c$  is the available flexural strength,  $x$  relates to the strong-axis bending, and  $y$  relates to the weak-axis bending.

For doubly symmetric members in flexural/compressive forces mainly in one plane, the two independent limit states (i.e., in-plane stability and out-of-plane buckling or flexural torsional buckling) can be considered separately.

According to *AISC Specification* Sec. H1.3, analysis of in-plane instability uses AISC Eq. H1-1a and Eq. H1-1b with  $P_c$ ,  $M_r$ , and  $M_c$  determined in the plane of bending. For out-of-plane buckling, AISC Eq. H1-2 applies, where  $P_{cy}$  is the available compressive strength out of the plane of bending, and  $M_{cx}$  is the available flexural torsional strength for strong-axis flexure determined from *AISC Specification* Chap. F using  $C_b = 1.0$ .

$$\frac{P_r}{P_{cy}} \left( 1.5 - 0.5 \frac{P_r}{P_{cy}} \right) + \left( \frac{M_{rx}}{C_b M_{cx}} \right)^2 \leq 1.0 \quad 62.5$$

[AISC Eq. H1-2]

If bending occurs only in the weak axis, the moment ratio may be neglected.

The lateral-torsional buckling coefficient,  $C_b$ , accounts for beams and girders being restrained against rotation about their longitudinal axis when both ends of the unsupported segment are braced.

$$C_b = \frac{12.5 M_{\max}}{2.5 M_{\max} + 3M_A + 4M_B + 3M_C} \quad 62.6$$

[AISC Eq. F1-1]

## 3. SECOND-ORDER EFFECTS

In frames and structures subject to sway, the *effect of deflection* (i.e., *second-order effects*) on the required strengths of members subjected to both axial and bending loads is accounted for by a multiplicative *flexural amplification factor* (*flexural magnifier*),  $B_1$ , applied to the required elastic nominal moment strength.  $B_1$  is not applied to the axial strength. *AISC Specification* Sec. C and App. 8 specify two such factors:  $B_1$  for use between points of bracing, and  $B_2$  for use at points of bracing. This accounts for the nickname, “ $B_1$ - $B_2$  procedure” given to this method.  $B_2$  is used to account for frame deflections such as drift, while  $B_1$  is used to account for member deflections. In Eq. 62.8,  $C_m$  can be conservatively taken as 1.0 for beam-columns subjected to transverse loading between the supports, or evaluated based on end moments.  $\alpha$  is 1.0 for LRFD and is 1.6 for ASD.  $P_{el}$  is the Euler buckling load calculated with  $K = 1$  for the end restraint factor in the plane of buckling and assuming zero sidesway. (See *AISC Specification* App. 8.)

$$M_r = B_1 M_{nt} + B_2 M_{lt} \quad [\text{AISC Eq. A-8-1}] \quad 62.7$$

$$B_1 = \frac{C_m}{1 - \frac{\alpha P_r}{P_{el}}} \geq 1 \quad [\text{AISC Eq. A-8-3}] \quad 62.8$$

$$B_2 = \frac{1}{1 - \frac{\alpha P_{\text{story}}}{P_{e,\text{story}}}} \geq 1 \quad [\text{AISC Eq. A-8-6}] \quad 62.9$$

## 4. ANALYSIS OF BEAM-COLUMNS

The following procedure can be used for beam-column analysis.

*step 1:* Use appropriate load combinations to calculate the required axial compression strength,  $P_r$

*step 2:* Calculate the slenderness ratios for both bending modes.

*step 3:* Based on the larger slenderness ratio, determine the design axial compressive strength,  $P_n$ , using the procedure described in Chap. 61.

*step 4:* Calculate the ratio  $P_r/P_c$ .

- step 5:* Calculate the flexural amplification factors  $B_1$  and  $B_2$ .
- step 6:* Calculate the required flexural strengths  $M_{rx}$  and  $M_{ry}$ .
- step 7:* Calculate the design flexural strengths,  $M_{cx}$  and  $M_{cy}$ , using the procedure described in Chap. 59.
- step 8:* Determine the adequacy of the design using the applicable interactions equation. If  $P_r/P_c \geq 0.2$ , use Eq. 62.3. If  $P_r/P_c < 0.2$ , use Eq. 62.4.

### Example 62.1

A W14 × 120 A992 shape has been chosen to carry an unfactored axial live compressive load of 200 kips and a 250 ft-kips live moment about its strong axis. The unsupported length is 20 ft, sidesway is permitted in the direction of bending, and  $K = 1$ . Determine if the column is adequate.

#### Solution

Assume the dead load is negligible.

#### LRFD Method

$$P_u = (1.6)(200 \text{ kips}) = 320 \text{ kips}$$

$$M_u = (1.6)(250 \text{ kips}) = 400 \text{ ft-kips}$$

$$KL = 20 \text{ ft}$$

$$P_c = \phi_c P_n = 1180 \text{ kips}$$

$$L_b = 20 \text{ ft}$$

From AISC Table 3-10,

$$M_{cx} = \phi M_{nx} = 743 \text{ ft-kips}$$

$$\frac{P_u}{\phi_c P_n} = \frac{320 \text{ kips}}{1180 \text{ kips}} = 0.271$$

Since  $0.27 > 0.20$ , use Eq. 62.3.

$$\begin{aligned} \frac{P_r}{P_c} + \left(\frac{8}{9}\right) \left( \frac{M_{rx}}{M_{cx}} + \frac{M_{ry}}{M_{cy}} \right) &\leq 1.0 \\ = \frac{320 \text{ kips}}{1180 \text{ kips}} + \left(\frac{8}{9}\right) \left( \frac{400 \text{ ft-kips}}{743 \text{ ft-kips}} + 0 \right) &\leq 1.0 \\ 0.750 \leq 1.0 \quad [\text{OK}] & \end{aligned}$$

#### ASD Method

$$P_r = 200 \text{ kips}$$

$$M_{rx} = 250 \text{ ft-kips}$$

$$KL = 20 \text{ ft}$$

$$P_c = \frac{P_n}{\Omega} = 783 \text{ kips}$$

From AISC Table 3-10,

$$M_{cx} = \frac{M_{nx}}{\Omega} = 495 \text{ ft-kips}$$

$$\frac{P_r}{P_c} = \frac{200 \text{ kips}}{783 \text{ kips}} = 0.255$$

Since  $0.255 > 0.20$ , use Eq. 62.3.

$$\frac{P_r}{P_c} + \left(\frac{8}{9}\right) \left( \frac{M_{rx}}{M_{cx}} + \frac{M_{ry}}{M_{cy}} \right) \leq 1.0$$

$$= \frac{200 \text{ kips}}{783 \text{ kips}} + \left(\frac{8}{9}\right) \left( \frac{250 \text{ ft-kips}}{495 \text{ ft-kips}} + 0 \right) \leq 1.0$$

$$0.70 \leq 1.0 \quad [\text{OK}]$$

## 5. DESIGN OF BEAM-COLUMNS

In order to minimize the trial-and-error process of selecting a shape for combined axial and bending loads, Eq. 62.3 and Eq. 62.4 can be modified to allow the use of the tables in Combined Flexure and Axial Force tables in Part 6 of the *AISC Manual*. From AISC Table 6-1, the values of  $p$ ,  $b_x$ , and  $b_y$  can be used to solve the modified forms of Eq. 62.3 and Eq. 62.4 [AISC Eq. H1-1a and Eq. H1-1b].

For  $P_r/P_c \geq 0.2$ ,

$$pP_r + b_x M_{rx} + b_y M_{ry} \leq 1.0 \quad [\text{large axial loads}] \quad 62.10$$

For  $P_r/P_c < 0.2$ ,

$$\frac{pP_r}{2} + \left(\frac{9}{8}\right) (b_x M_{rx} + b_y M_{ry}) \leq 1.0 \quad [\text{small axial loads}] \quad 62.11$$

The following procedure can be used to determine an equivalent axial load.

*step 1:* Determine the effective length,  $KL$ , based on weak-axis bending and bracing.

*step 2:* Use AISC Table 6-1 to select a trial shape.

*step 3:* From AISC Table 6-1, select  $p$ ,  $b_x$ , and  $b_y$  corresponding to  $KL$  for that shape.

*step 4:* An estimate of the adequacy of the shape is given by Eq. 62.10 and Eq. 62.11.

*step 5:* Repeat steps 2 through 4 until a reasonable shape is found.

*step 6:* Determine the adequacy of the design using the applicable interactions equation. If  $P_r/P_c \geq 0.2$ , use Eq. 62.3. If  $P_r/P_c < 0.2$ , use Eq. 62.4.

This procedure tends to oversize beam-columns. More economical members can be found if the member initially selected is used as a starting point for a subsequent trial-and-error solution.

**Example 62.2**

Select a 50 ksi shape to carry an axial live load of 200 kips and a maximum live moment of 250 ft-kips about the strong axis. The unsupported length is 20 ft. Assume  $K = 1$ .

*Solution*

*LRFD Method*

$$P_u = (1.6)(200 \text{ kips}) = 320 \text{ kips}$$

$$M_u = (1.6)(250 \text{ ft-kips}) = 400 \text{ ft-kips}$$

Try a W14 × 132. From AISC Table 6-1,

$$p = 0.771 \times 10^{-3} \text{ 1/kips}$$

$$b_x = 1.08 \times 10^{-3} \text{ 1/ft-kips}$$

Assuming a large axial load, an estimate of the adequacy of the shape is given by Eq. 62.10.

$$\begin{aligned} pP_r + b_x M_{rx} + b_y M_{ry} &\leq 1.0 \\ &= \left(0.771 \times 10^{-3} \frac{1}{\text{kips}}\right)(320 \text{ kips}) \\ &\quad + \left(1.08 \times 10^{-3} \frac{1}{\text{ft-kips}}\right)(400 \text{ ft-kips}) \leq 1.0 \\ &= 0.679 \leq 1.0 \quad [\text{OK}] \end{aligned}$$

From AISC Table 1-1 and AISC Table 3-2, a W14 × 132 has properties of

$$A = 38.8 \text{ in}^2$$

$$S_x = 209 \text{ in}^3$$

$$I_x = 1530 \text{ in}^4$$

$$Z_x = 234 \text{ in}^3$$

$$L_p = 13.3 \text{ ft}$$

$$L_r = 56.0 \text{ ft}$$

$$P_c = \phi_c P_n = 1300 \text{ kips}$$

The Euler buckling load is

$$\begin{aligned} P_{e1} &= \frac{\pi^2 EI_x}{(KL_x)^2} = \frac{\pi^2 \left(29,000 \frac{\text{kips}}{\text{in}^2}\right)(1530 \text{ in}^4)}{\left((1)(20 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)\right)^2} \\ &= 7603 \text{ kips} \end{aligned}$$

The  $x$ - $x$  axis flexural magnifier is

$$\begin{aligned} B_1 &= \frac{C_m}{1 - \frac{\alpha P_r}{P_{e1}}} = \frac{1.0}{1 - \frac{(1.0)(320 \text{ kips})}{7603 \text{ kips}}} \\ &= 1.044 \end{aligned}$$

$$\begin{aligned} M_{ux} &= B_1 M_n = (1.044)(400 \text{ ft-kips}) \\ &= 417.6 \text{ ft-kips} \end{aligned}$$

The yielding limit state is

$$\begin{aligned} M_{nx} &= M_p = F_y Z_x = \frac{\left(50 \frac{\text{kips}}{\text{in}^2}\right)(234 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}} \\ &= 975 \text{ ft-kips} \end{aligned}$$

The lateral-torsional buckling limit state is

$$L_p < L_b < L_r = 13.3 \text{ ft} < 20 \text{ ft} < 56.0 \text{ ft}$$

From App. 59.A or AISC Table 3-1,  $C_b$  is 1.14. Use Eq. 59.15.

$$\begin{aligned} M_{nx} &= C_b \left( M_p - (M_p - 0.7F_y S_x) \left( \frac{L_b - L_p}{L_r - L_p} \right) \right) \leq M_p \\ &= (1.14) \left( \begin{array}{c} 975 \text{ ft-kips} \\ - \left( \begin{array}{c} 975 \text{ ft-kips} \\ - \frac{(0.7)\left(50 \frac{\text{kips}}{\text{in}^2}\right)(209 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}} \end{array} \right) \\ \times \left( \frac{20 \text{ ft} - 13.3 \text{ ft}}{56 \text{ ft} - 13.3 \text{ ft}} \right) \end{array} \right) \\ &= 1046 \text{ ft-kips} > 975 \text{ ft-kips} \quad [M_p \text{ controls}] \end{aligned}$$

$$\phi_b = 0.90$$

$$M_{cx} = \phi_b M_{nx} = (0.9)(975 \text{ ft-kips}) = 877.5 \text{ ft-kips}$$

$$\frac{P_u}{\phi_c P_n} = \frac{320 \text{ kips}}{1300 \text{ kips}} = 0.246$$

Since  $0.246 > 0.2$ , use Eq. 62.3.

$$\begin{aligned} \frac{P_r}{P_c} + \left(\frac{8}{9}\right) \left( \frac{M_{rx}}{M_{cx}} + \frac{M_{ry}}{M_{cy}} \right) &\leq 1.0 \\ \frac{320 \text{ kips}}{1300 \text{ kips}} + \left(\frac{8}{9}\right) \left( \frac{417.6 \text{ ft-kips}}{877.5 \text{ ft-kips}} + 0 \right) &\leq 1.0 \\ 0.67 &\leq 1.0 \quad [\text{OK}] \end{aligned}$$

ASD Method

$$\begin{aligned} P_a &= 200 \text{ kips} \\ M_{ax} &= 250 \text{ kips} \end{aligned}$$

Try a W14 × 132. From AISC Table 6-1,

$$\begin{aligned} p &= 1.16 \times 10^{-3} \text{ 1/kips} \\ b_x &= 1.62 \times 10^{-3} \text{ 1/ft-kips} \end{aligned}$$

Assuming a large axial load, an estimate of the adequacy of the shape is given by Eq. 62.10.

$$\begin{aligned} pP_r + b_xM_{rx} + b_yM_{ry} &\leq 1.0 \\ = \left(1.16 \times 10^{-3} \frac{1}{\text{kips}}\right)(200 \text{ kips}) \\ + \left(1.62 \times 10^{-3} \frac{1}{\text{ft-kips}}\right)(250 \text{ ft-kips}) &\leq 1.0 \\ = 0.637 &\leq 1.0 \quad [\text{OK}] \end{aligned}$$

From AISC Table 1-1 and AISC Table 3-2, a W14 × 132 has properties of

$$A = 38.8 \text{ in}^2$$

$$S_x = 209 \text{ in}^3$$

$$I_x = 1530 \text{ in}^4$$

$$Z_x = 234 \text{ in}^3$$

$$L_p = 13.3 \text{ ft}$$

$$L_r = 56.0 \text{ ft}$$

$$P_c = \frac{P_n}{\Omega_c} = 862 \text{ kips}$$

The Euler buckling load is

$$\begin{aligned} P_{e1} &= \frac{\pi^2 EI_x}{(KL_x)^2} = \frac{\pi^2 \left(29,000 \frac{\text{kips}}{\text{in}^2}\right) (1530 \text{ in}^4)}{\left((1)(20 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)\right)^2} \\ &= 7603 \text{ kips} \end{aligned}$$

The  $x$ - $x$  axis flexural magnifier is

$$\begin{aligned} B_1 &= \frac{C_m}{1 - \frac{\alpha P_r}{P_{e1}}} = \frac{1.0}{1 - \frac{(1.0)(320 \text{ kips})}{7603 \text{ kips}}} \\ &= 1.044 \end{aligned}$$

$$\begin{aligned} M_{ux} &= B_1 M_n = (1.044)(250 \text{ ft-kips}) \\ &= 261.0 \text{ ft-kips} \end{aligned}$$

The yielding limit state is

$$\begin{aligned} M_{nx} &= M_p = F_y Z_x = \frac{\left(50 \frac{\text{kips}}{\text{in}^2}\right)(234 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}} \\ &= 975 \text{ ft-kips} \end{aligned}$$

The lateral-torsional buckling limit state is

$$L_p < L_b < L_r = 13.3 \text{ ft} < 20 \text{ ft} < 56.0 \text{ ft}$$

From App. 59.A or AISC Table 3-1,  $C_b$  is 1.14. Use Eq. 59.15.

$$\begin{aligned} M_{nx} &= C_b \left( M_p - (M_p - 0.7F_y S_x) \left( \frac{L_b - L_p}{L_r - L_p} \right) \right) \leq M_p \\ &= (1.14) \left( \begin{array}{l} 975 \text{ ft-kips} \\ - \left( \begin{array}{l} 975 \text{ ft-kips} \\ - \frac{(0.7) \left( 50 \frac{\text{kips}}{\text{in}^2} \right) (209 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}} \end{array} \right) \\ \times \left( \frac{20 \text{ ft} - 13.3 \text{ ft}}{56 \text{ ft} - 13.3 \text{ ft}} \right) \end{array} \right) \\ &= 1046 \text{ ft-kips} > 975 \text{ ft-kips} \quad [M_p \text{ controls}] \end{aligned}$$

$$\Omega_b = 1.67$$

$$M_{cx} = \frac{M_{nx}}{\Omega_b} = \frac{975 \text{ kips}}{1.67} = 584 \text{ kips}$$

$$\frac{P_a}{P_n} = \frac{200 \text{ kips}}{862 \text{ kips}} = 0.232$$

Since  $0.237 > 0.2$ , use Eq. 62.3.

$$\frac{P_r}{P_c} + \left(\frac{8}{9}\right) \left( \frac{M_{rx}}{M_{cx}} + \frac{M_{ry}}{M_{cy}} \right) \leq 1.0$$

$$\frac{200 \text{ kips}}{862 \text{ kips}} + \left(\frac{8}{9}\right) \left( \frac{261 \text{ ft-kips}}{584 \text{ ft-kips}} + 0 \right) \leq 1.0$$

$$0.63 \leq 1.0 \quad [\text{OK}]$$

## 1. INTRODUCTION

*Built-up sections* (previously and commonly referred to in the *AISC Specification* as *plate girders*) are used when beams with moments of inertia larger than standard mill shapes are required. Figure 63.1 illustrates two different methods of constructing plate girders. One is built up by bolting or riveting. The other is by welding. A *hybrid girder* is a plate girder that uses stronger steel for the flanges than for the web. Hybrid girders can be less expensive than traditional plate girders.

**Figure 63.1** Elements of a Built-Up Section

Two different definitions of “depth” are encountered with plate girders: the *web depth*, *h*, and the *girder depth*, *d*. Unlike for rolled shapes, only the web depth, *h*, is used for shear stress calculations. For depth thickness (*h/t*) ratios, the *AISC Specification* requires *h* to be the clear distance between flanges. For bolted or riveted

flanges, this distance is the separation between the last rows of fasteners. For welded flanges, the distinction is not made.

The girder depth,  $d$ , is generally chosen to be approximately one-tenth of the span, although the ratio can vary from 1:5 to 1:15.

## 2. DEPTH-THICKNESS RATIOS

The required web thickness,  $t_w$ , depends on the spacing of intermediate stiffeners. If intermediate stiffeners are spaced no more than  $1.5h$  (i.e., 150% of the girder depth), then Eq. 63.1 gives the maximum permissible depth-thickness ratio. If  $h$  is known, the required thickness,  $t_w$ , can be obtained from Eq. 63.1 [AISC Specification Eq. F13-3].

$$\left(\frac{h}{t_w}\right)_{\max} \leq 12.0 \sqrt{\frac{E}{F_y}} \quad 63.1$$

If intermediate stiffeners are spaced more than  $1.5h$ , then Eq. 63.2 governs the depth-thickness ratio [AISC Specification Eq. F13-4].

$$\left(\frac{h}{t_w}\right)_{\max} \leq \frac{0.40E}{F_y} \quad 63.2$$

If  $h/t_w$  satisfies Eq. 63.2, is less than 260, with a ratio of web area to flange area less than 10, and if the shear stress is less than the allowable value, no intermediate stiffeners are required. (Bearing stiffeners are still required at reaction and loading points, however.) In other cases, actual stiffener spacing will depend on the shear stress [AISC Specification Sec. E6].

## 3. SHEAR STRENGTH

The AISC Specification gives two methods for calculating shear strength. The first method, which is presented in this book, does not utilize the post buckling strength of the member (*tension field action*). Tension field action is presented in Sec. G3 of the AISC Specification.

The design or available shear strength,  $\phi_v V_n$  or  $V_n/\Omega$ , must equal or exceed the required shear strength,  $V_u$  or  $V_a$ . AISC Specification Chap. G covers the design of members for shear. The nominal shear strength,  $V_n$ , for stiffened or unstiffened webs, in accordance with the limit states of shear yielding and buckling is

$$V_n = 0.6F_y A_w C_v \quad [\text{AISC Specification Eq. G2-1}] \quad 63.3$$

$A_w$  is the web area (the clear distance between flanges multiplied by the web thickness,  $ht_w$ ), and  $C_v$  is the web shear coefficient. (See Fig. 63.1.) For webs of I-shaped members, where  $h/t_w \leq 2.24\sqrt{E/F_y}$ ,  $C_v = 1.0$  [AISC Specification Eq. G2-2]. For webs of all other singly or

doubly symmetric members (except round HSS),  $C_v$  is determined as follows. For  $h/t_w \leq 1.10\sqrt{k_v E/F_y}$ ,

$$C_v = 1.0 \quad [\text{AISC Specification Eq. G2-3}] \quad 63.4$$

$$\text{For } 1.10\sqrt{k_v E/F_y} < h/t_w \leq 1.37\sqrt{k_v E/F_y},$$

$$C_v = \frac{1.10\sqrt{\frac{k_v E}{F_y}}}{\frac{h}{t_w}} \quad [\text{AISC Specification Eq. G2-4}] \quad 63.5$$

$$\text{For } h/t_w > 1.37\sqrt{k_v E/F_y},$$

$$C_v = \frac{1.51k_v E}{\left(\frac{h}{t_w}\right)^2 F_y} \quad [\text{AISC Specification Eq. G2-5}] \quad 63.6$$

$a$  is the clear distance between intermediate stiffeners. When  $a$  is very large (i.e.,  $a/h > 3.0$ ), or when there are no stiffeners, the web plate buckling coefficient,  $k_v$ , is 5. Equation 63.12 gives the formula for  $k_v$  (Refer to AISC Specification Sec. G2 for more cases.)

Determining the shear strength using these equations is time consuming, and the AISC Manual provides two tables to simplify the process. AISC Manual Table 3.16a and Table 3.16b give the available shear stress,  $F_v = V_n/\Omega A_w = \phi V_n/A_w$ , for both the tension field action not included and included, respectively, for 36 ksi steel, while AISC Table 3.17a and Table 3.17b do the same for 50 ksi steel. The allowable shear stress is read as a function of the  $a/h$  and  $h/t_w$  ratios, and the available capacity,  $V_n/\Omega$  or  $\phi V_n$ , is calculated by multiplying allowable shear stress by the web area,  $A_w = ht_w$ .

## 4. DESIGN OF GIRDER WEBS AND FLANGES

Generally, plate girder webs are designed based on shear stress using AISC Manual Table 3-16 and Table 3-17. The available shear stress is a function of  $a/h$  and  $h/t_w$ . The design of girder flanges depends on an assumption regarding flexural strength. Flexural strength is a function of the web thickness. If  $h/t < 640/\sqrt{F_y}$ , then the flexural strength equals  $F_y Z_x$ ; otherwise, a smaller moment must be assumed.

The plastic section modulus,  $Z_x$ , for a plate girder is calculated as

$$Z_x = A_f(h + t_f) + \frac{t_w h^2}{4} \quad 63.7$$

Equation 63.8, derived from basic mechanics principles, gives an initial estimate of the required flange area. Since the moment varies along the beam length, girder flanges do not have to be the same thickness along the entire plate girder length. It is possible to substitute

thinner flanges near the ends of beams or to add cover plates where additional flexural capacity is needed.

$$A_f = \frac{M_p}{F_y h} - \frac{ht}{4} \quad 63.8$$

Once the flange area is known, trial flange widths and thicknesses can be evaluated.

$$A_f = b_f t_f \quad 63.9$$

The limitations in available plate thicknesses should be considered when choosing  $t_f$ . Alternatively,  $b_f$  can be chosen based on  $b_f/d$  ratios, which typically vary between 0.2 and 0.3. Flange plate widths are typically rounded up to a convenient value, often to the nearest 2 in.

## 5. WIDTH-THICKNESS RATIOS

The width-thickness ratios specified in Chap. 61 apply to plate girders as well. Specifically, for unstiffened plates such as plate girder flanges, case 11, *AISC Specification* Table B4.1, should be used.

For compact sections,

$$\frac{b_f}{2t_f} \leq \frac{64.7}{\sqrt{F_{yf}}} \quad 63.10$$

For noncompact sections,

$$\frac{b_f}{2t_f} \leq 162 \sqrt{\frac{k_c}{F_L}} \quad 63.11$$

$F_L$  may be taken to equal  $0.7F_y$  for symmetrical members.

For stiffened plates, such as plate girder webs, Eq. 63.1 and Eq. 63.2 [*AISC Specification* Eq. F13-3 and Eq. F13-4] must be satisfied also.

## 6. REDUCTION IN FLANGE STRENGTH

Once a trial design of the plate girder has been determined, the flexural strength can be computed. There are several possible limit states for girders, including yielding, inelastic lateral-torsional buckling, elastic lateral-torsional buckling, and local buckling. For members with compact webs and flanges and with adequate lateral support, the flexural strength,  $M_n$ , is given by  $F_y Z_x$ . As the distance between lateral supports increases, flexural strength is given by *AISC Specification* Eq. F2-2 and Eq. F2-3.

For members with compact webs and noncompact flanges, flexural strength is given by the equations listed in Sec. F3 of the *AISC Specification*; for members with noncompact webs and flanges, flexural strength is given by the equations in *AISC Specification* Sec. F4.

## 7. LOCATION OF FIRST (OUTBOARD) STIFFENERS

The first intermediate stiffeners can be located where the shear stress exceeds Eq. 63.3 [*AISC Specification* Eq. G2-1]. In practice, a trial distance  $a$  such that  $a/h < 1.0$  is selected as the separation between the end panel and the first intermediate stiffener. The design shear strength,  $\phi_v V_n$ , and the available shear strength,  $V_n/\Omega_v$ , are calculated and compared to the required shear strength. If  $\phi_v V_n$  is greater than  $V_w$  or if  $V_n/\Omega_v$  is greater than  $V_a$ , the location is adequate. Otherwise, a smaller value of the spacing,  $a$ , should be tried.

## 8. LOCATION OF INTERIOR STIFFENERS

If  $h/t_w \leq 2.46\sqrt{E/F_y}$ , or where required shear strength is less than or equal to available shear strength, then intermediate (i.e., transverse) stiffeners are not required [*AISC Specification* Sec. G2.2]. Otherwise, the horizontal spacing,  $a$ , of interior intermediate stiffeners should not exceed the value determined from Eq. 63.13 [*AISC Specification* Sec. G2.1]. For unstiffened webs of doubly symmetric shapes with  $h/t_w < 260$ ,  $k_v = 5$ . For stiffened webs,

$$k_v = 5 + \frac{5}{\left(\frac{a}{h}\right)^2} \quad 63.12$$

$k_v = 5$  applies when  $a/h > 3.0$ , or

$$\frac{a}{h} > \left(\frac{260}{\frac{h}{t_w}}\right)^2 \quad 63.13$$

With the value of  $k_v$  calculated from Eq. 63.12, the coefficient  $C_v$  can be calculated from Eq. 63.4, Eq. 63.5, and Eq. 63.6. The shear strength can be computed from Eq. 63.3. In beams where the maximum shear occurs near the ends, the spacing chosen for the first interior stiffener will be adequate for the entire beam length.

If Eq. 63.13 is met and if  $C_v \leq 1.0$ , then Eq. 63.14 can be used in place of Eq. 63.3 [*AISC Specification* Eq. G2-1]. This is the *tension field action equation*. Use of Eq. 63.14 places an additional restraint on the allowable bending stress in the girder web.

For  $h/t_w > 1.10\sqrt{k_v E/F_y}$ ,

$$V_n = 0.6F_y A_w \left( C_v + \frac{1 - C_v}{1.15\sqrt{1 + \left(\frac{a}{h}\right)^2}} \right) \quad [AISC Specification Eq. G3-2] \quad 63.14$$

For  $h/t_w \leq 1.10\sqrt{k_v E/F_y}$ ,

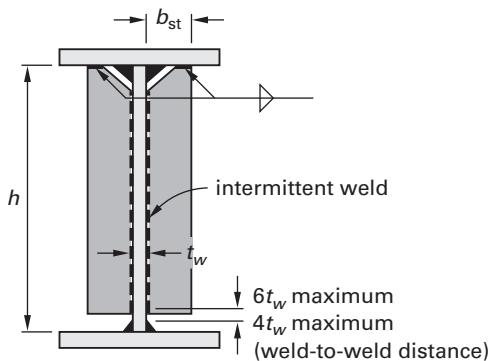

$$V_n = 0.6F_y A_w \quad 63.15$$

In lieu of equations, Table 3-17a and Table 3-17b of the *AISC Manual* can be used.

## 9. DESIGN OF INTERMEDIATE STIFFENERS

*Intermediate stiffeners*, as shown in Fig. 63.2, are used to support the compression flange and prevent buckling. They may be constructed from plates or angles and may be used either singly or in pairs. Unlike stiffeners that transmit reactions and loads, intermediate stiffeners do not need to extend completely from the top to bottom flanges, but they must be fastened to the compression flange to resist uplift. The *AISC Specification* contains limitations on weld and rivet spacing.

Figure 63.2 Intermediate Stiffeners

Intermediate stiffeners are sized by their moment of inertia, as calculated from the stiffener dimensions per *AISC Specification* Sec. G2.2. In addition to meeting *AISC Specification* Sec. G2.2, the following two limitations must also be met when designing intermediate stiffeners, as per *AISC Specification* Sec. G3.3.

$$I_{st} \geq I_{st1} + (I_{st2} - I_{st1}) \left( \frac{V_r - V_{cl}}{V_{c2} - V_{cl}} \right) \quad 63.16$$

$$\left( \frac{b}{t} \right)_{st} \leq 0.56 \sqrt{\frac{E}{F_{y,st}}} \quad 63.17$$

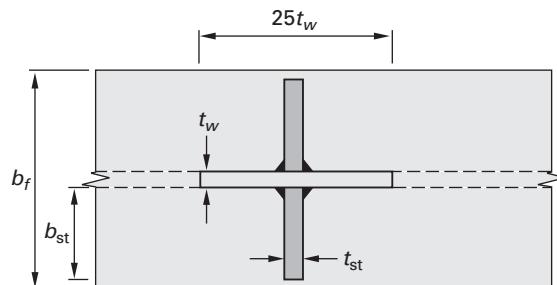

$(b/t)_{st}$  is the stiffener's width-thickness ratio and  $F_{y,st}$  is the specified minimum yield stress of the stiffener as defined by *AISC Specification* Sec. G3.3.  $V_r$  is the larger of the required shear strengths in the adjacent web panels, and  $V_c$  is the available shear strength as defined in *AISC Specification* Sec. G3.3.

## 10. DESIGN OF BEARING STIFFENERS

*Bearing stiffeners* are used to transmit loads and reactions from one flange to the other. (See Fig. 63.3.) Bearing stiffeners that transmit loads and reactions may

extend from flange to flange. There is no single formula for calculating the thickness of bearing stiffeners. Rather, stiffener thickness is the maximum thickness determined from evaluations of the bearing stress, width-thickness ratio, column stress, and compression yield criteria.

Figure 63.3 Bearing Stiffener (top view)

The bearing pressure on bearing stiffeners is limited to  $0.90F_y$  [*AISC Specification* Sec. J10.8]. Such stiffeners must essentially extend from the web to the edge of the flanges. Therefore, this criterion establishes one method of determining the bearing stiffener thickness. However, other criteria must also be met. (See Sec. 63.11.) The width is essentially fixed by the flange dimension. So only the thickness needs to be determined. Also, bearing stiffeners should have close contact with the flanges.

Since the stiffener is loaded as a column, it must satisfy the width-thickness ratio for an unstiffened element.

$$\frac{b_{st}}{t_{st}} \leq \frac{95}{\sqrt{F_y}} \quad 63.18$$

The stiffener should be designed as a column with an effective length equal to  $0.75h$ , with a cross section composed of a pair of stiffeners, and with a strip of the web having a width of either (a)  $25t_w$  at interior concentrated loads or (b)  $12t_w$  at the ends of members [*AISC Specification* Sec. J10.8].

For the purpose of determining the slenderness ratio, the radius of gyration,  $r$ , can be determined exactly or it can be approximated as 0.25 times the stiffener edge-to-edge distance.

$$\frac{l}{r} = \frac{0.75h}{0.25(2b_{st} + t_w)} \quad 63.19$$

Once the  $l/r$  ratio is known, it can be used (as  $Kl/r$ ) to determine the flexural buckling stress,  $F_{cr}$ . However, some of the web supports the load. Specifically, 25 times the web thickness is the contributing area at an interior concentrated load. Therefore, the required stiffener thickness based on column stress is

$$t_{st} = \frac{\frac{\text{load}}{\phi F_{cr}} - 25t_w^2}{2b_{st}} \quad 63.20$$

Compression yielding of stiffeners should also be considered when determining stiffener thickness. Available compressive strength is limited to  $0.90F_y$ . Therefore, the thickness is

$$t_{st} = \frac{\text{load}}{0.90F_y} \quad 63.21$$

$$t_{st} = \frac{2b_{st}}{\text{load}}$$

If column stability is not the factor controlling stiffener thickness, the larger thickness could conceivably increase the slenderness ratio and reduce the allowable compressive stress even further. This should be checked, but it is not likely to be a factor.

## 11. SPECIAL DESIGN CONSIDERATIONS FOR CONCENTRATED FORCES

The *AISC Specification* Sec. J10 contains provisions to determine if the web is capable of supporting the concentrated forces (loads or reactions) without experiencing local web yielding, web crippling, or sidesway web buckling. The need for bearing stiffeners to preclude local web yielding is determined from *AISC Specification* Eq. J10-2 and Eq. J10-3. AISC Eq. J10-4, Eq. J10-5a, and Eq. J10-5b determine the maximum load that can be applied before stiffeners are required from web-crippling criteria. If stiffeners are provided and extend at least one-half the web depth, Eq. J10-4, Eq. J10-5a, and Eq. J10-5b need not be checked. AISC Eq. J10-6 and Eq. J10-7 are used to check if bearing stiffeners are needed to prevent sidesway web buckling. If the term  $(h/t_w)/(L_b/b_f)$  in Eq. J10-6 and Eq. J10-7 exceeds 2.3 or 1.7, respectively, then these two equations need not be checked.

## 12. DESIGN PROCESS SUMMARY

The following steps summarize plate girder design. Using *AISC Manual* Table 3-16 and Table 3-17 will help design the web.

*step 1:* Select the overall depth.

*step 2:* Select a trial web size using the required shear strength.

*step 3:* Select a trial flange size using the required flexural strength.

*step 4:* Check the available flexural strength of the trial section.

*step 5:* Check for tension field action.

*step 6:* Design the intermediate stiffeners (if any).

*step 7:* Check for web resistance to applied concentrated loads and/or support reactions and design bearing stiffeners if needed.

*step 8:* Design all required welds.

### Example 63.1

Design a symmetrical welded plate girder of A992 steel with no intermediate stiffeners to carry a load of 2.5 kips/ft on a simple span of 60 ft. The depth of the girder is restricted to 50 in. The compression flange is laterally supported throughout the girder span.

#### Solution

##### LRFD Method

Assume the dead load is 0.5 kip/ft.

The required shear is

$$V_u = (1.2)(15 \text{ kips}) + (1.6)(75 \text{ kips}) = 138 \text{ kips}$$

The required flexural strength is

$$w_u = (1.2)\left(0.5 \frac{\text{kip}}{\text{ft}}\right) + (1.6)\left(2.5 \frac{\text{kips}}{\text{ft}}\right) = 4.6 \text{ kips/ft}$$

$$M_u = \frac{w_u L^2}{8} = \frac{\left(4.6 \frac{\text{kips}}{\text{ft}}\right)(60 \text{ ft})^2}{8}$$

$$= 2070 \text{ ft-kips}$$

Try a  $44 \times \frac{3}{8}$  in plate for a web and two  $16 \times \frac{3}{4}$  in plates for the flanges.

The material and geometric properties for ASTM A992 steel are

$$F_y = 50 \text{ kips/in}^2$$

$$F_u = 65 \text{ kips/in}^2$$

$$t_w = 0.375 \text{ in}$$

$$t_f = 0.75 \text{ in}$$

$$b_f = 16 \text{ in}$$

$$h = 44 \text{ in}$$

$$d = 44 \text{ in} + (2)(0.75 \text{ in}) = 45.5 \text{ in}$$

The required shear strength is

$$R_u = \left( (1.2)\left(0.5 \frac{\text{kip}}{\text{ft}}\right) + (1.6)\left(2.5 \frac{\text{kips}}{\text{ft}}\right) \right)(30 \text{ ft})$$

$$= 138 \text{ kips}$$

Determine if stiffeners are required.

$$A_w = dt_w = (45.5 \text{ in})(0.375 \text{ in}) = 17.06 \text{ in}^2$$

$$\frac{h}{t_w} = \frac{44 \text{ in}}{0.375 \text{ in}} = 117 < 260 \quad \begin{matrix} \text{[per } AISC \text{ Specification]} \\ \text{Sec. G2.1(b)(i)} \end{matrix}$$

$$k_v = 5$$

Then, from *AISC Specification* Sec. G2.1(b)(iii),

$$1.37 \sqrt{\frac{k_v E}{F_y}} = 1.37 \sqrt{\frac{(5)(29,000 \text{ kips})}{50 \frac{\text{kips}}{\text{in}^2}}} = 73.8$$

Since  $h/t_w = 117 > 73.8$ , use *AISC Specification* Eq. G2-5 to calculate the web shear coefficient,  $C_v$ .

$$C_v = \frac{1.51 k_v E}{\left(\frac{h}{t_w}\right)^2 F_y} = \frac{(1.51)(5)(29,000 \frac{\text{kips}}{\text{in}^2})}{(117)^2 \left(50 \frac{\text{kips}}{\text{in}^2}\right)} = 0.320$$

Calculate the nominal shear strength,  $V_n$ .

$$\begin{aligned} V_n &= 0.6 F_y A_w C_v = (0.6) \left(50 \frac{\text{kips}}{\text{in}^2}\right) (17.06 \text{ in}^2) (0.320) \\ &= 163.8 \text{ kips} \end{aligned}$$

Check the design shear strength without stiffeners.

$$\phi_v = 0.90$$

$$\phi_v V_n = (0.90)(163.8 \text{ kips}) = 147 \text{ kips}$$

$$147 \text{ kips} > 138 \text{ kips}$$

Since the design shear strength is greater than the required shear strength, stiffeners are not required.

Check the bending moment and the required flexural strength.

Calculate  $I_{gr}$  using the following table.

section	dimension	$A$ (in <sup>2</sup> )	$y$ (in)	$Ay^2$ (in <sup>4</sup> )	$I_o$ (in <sup>4</sup> )	$I_{gr}$ (in <sup>4</sup> )
web	$\frac{3}{8} \times 44$	16.5	0	0	2662	2662
flange	$\frac{3}{4} \times 16$	12.0	22.375	6007.7	0.5625	6008.3
flange	$\frac{3}{4} \times 16$	12.0	22.375	6007.7	0.5625	6008.3
				total	14,679	

$$c = \frac{d}{2} = \frac{45.5 \text{ in}}{2} = 22.75 \text{ in}$$

Calculate  $S_x$ .

$$S_x = \frac{I_{gr}}{c} = \frac{14,679 \text{ in}^4}{22.75 \text{ in}} = 645.2 \text{ in}^3$$

$$\frac{M_u}{S_x} = \frac{(2070 \text{ ft-kips}) \left(12 \frac{\text{in}}{\text{ft}}\right)}{645.2 \text{ in}^3} = 38.5 \text{ kips/in}^2$$

$$M_{yc} = M_{yt} = M_y = F_y S_x$$

$$= \frac{\left(50 \frac{\text{kips}}{\text{in}^2}\right) (645.2 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}} = 2688 \text{ kips}$$

Compute  $Z_x$ .

$$\begin{aligned} Z_x &= A_f(h + t_f) + \frac{t_w h^2}{4} \\ &= (16 \text{ in})(0.75 \text{ in})(44 \text{ in} + 0.75 \text{ in}) \\ &\quad + \frac{(0.375 \text{ in})(44 \text{ in})^2}{4} \\ &= 718.5 \text{ in}^3 \end{aligned}$$

$$\begin{aligned} M_p &= F_y Z_x = \frac{\left(50 \frac{\text{kips}}{\text{in}^2}\right) (718.5 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}} \\ &= 2994 \text{ ft-kips} \end{aligned}$$

Check for compactness.

For the flange,

$$\lambda_f = \frac{b_f}{2t_f} = \frac{16 \text{ in}}{(2)(0.75 \text{ in})} = 10.67$$

Since  $\lambda_p < \lambda_f < \lambda_r$ , as given in Sec. B4 of the *AISC Specification*, the flange is noncompact.

For the web,

$$\lambda_w = \frac{h}{t_w} = \frac{44 \text{ in}}{0.375 \text{ in}} = 117.3$$

Since  $\lambda_p < \lambda_f < \lambda_r$ , as given in Sec. B4 of the *AISC Specification*, the web is noncompact.

Since both the web and flange are noncompact, the flexural strength is given by Sec. F4 of the *AISC Specification*.

$$h_c = h \quad [\text{welded built-up shapes}]$$

$$\lambda = \frac{h_c}{t_w} = \frac{44 \text{ in}}{0.375 \text{ in}} = 117.3$$

The cross-section is symmetric, so *AISC Specification* Table B4.1, case 15 applies.

$$\lambda_{pw} = 3.76 \sqrt{\frac{E}{F_y}} = 3.76 \sqrt{\frac{29,000 \frac{\text{kips}}{\text{in}^2}}{50 \frac{\text{kips}}{\text{in}^2}}} = 90.55$$

$$\lambda_{rw} = 5.70 \sqrt{\frac{E}{F_y}} = 5.70 \sqrt{\frac{29,000 \frac{\text{kips}}{\text{in}^2}}{50 \frac{\text{kips}}{\text{in}^2}}} = 137.27$$

The web plastification factor,  $R_{pc}$ , is found from *AISC Specification* Eq. F4-9b.

$$\begin{aligned} R_{pc} &= \frac{M_p}{M_{yc}} - \left( \frac{M_p}{M_{yc}} - 1 \right) \left( \frac{\lambda - \lambda_{pw}}{\lambda_{rw} - \lambda_{pw}} \right) \leq \frac{M_p}{M_{yc}} \\ &= \frac{2994 \text{ ft-kips}}{2688 \text{ ft-kips}} - \left( \frac{2994 \text{ ft-kips}}{2688 \text{ ft-kips}} - 1 \right) \\ &\quad \times \left( \frac{117.3 - 90.55}{137.27 - 90.55} \right) \leq \frac{2994 \text{ ft-kips}}{2688 \text{ ft-kips}} \\ &= 1.049 \leq 1.11 \quad [\text{OK}] \end{aligned}$$

The flexural strength,  $M_n$ , as limited by compression flange yielding is given by Eq. F4-1 in the *AISC Specification*. For compression flange yielding,

$$M_n = R_{pc} M_{yc} = (1.049)(2688 \text{ ft-kips}) = 2820 \text{ ft-kips}$$

Lateral-torsional buckling is not a limit state since the compression flange is fully supported laterally.

The flexural strength,  $M_n$ , as limited by compression flange local buckling is given by Eq. F4-13 in the *AISC Specification*. Use the following process to evaluate AISC Eq. F4-13.

Determine  $F_L$ . The plate girder is symmetrical, so

$$\begin{aligned} \frac{S_{xt}}{S_{xc}} &= 1 \\ F_L &= 0.7F_y = (0.7) \left( 50 \frac{\text{kips}}{\text{in}^2} \right) = 35 \text{ kips/in}^2 \end{aligned}$$

Determine  $k_c$  as it is defined in *AISC Specification* Table B4.1, footnote (a).

$$\begin{aligned} k_c &= 0.35 \leq \frac{4}{\sqrt{\frac{h}{t_w}}} \leq 0.76 = 0.35 \leq \frac{4}{\sqrt{\frac{44 \text{ in}}{0.375 \text{ in}}}} \\ &= 0.369 \leq 0.76 \end{aligned}$$

Since  $0.369 \leq 0.76$ , 0.369 controls.

From *AISC Specification* Table B4.1, case 11,

$$\begin{aligned} \lambda_{pf} &= 0.38 \sqrt{\frac{E}{F_y}} = 0.38 \sqrt{\frac{29,000 \frac{\text{kips}}{\text{in}^2}}{50 \frac{\text{kips}}{\text{in}^2}}} \\ &= 9.15 \\ \lambda_{rf} &= 0.95 \sqrt{\frac{k_c E}{F_L}} = 0.95 \sqrt{\frac{(0.369)(29,000 \frac{\text{kips}}{\text{in}^2})}{35 \frac{\text{kips}}{\text{in}^2}}} \\ &= 16.61 \end{aligned}$$

From *AISC Specification* Eq. F4-13,

$$\begin{aligned} M_n &= \left( R_{pc} M_{yc} - (R_{pc} M_{yc} - F_L S_{xc}) \left( \frac{\lambda - \lambda_{pf}}{\lambda_{rf} - \lambda_{pf}} \right) \right) \\ &\quad (1.049)(2688 \text{ ft-kips}) \\ &= \left( - \left( \frac{(1.049)(2688 \text{ ft-kips})}{-\frac{\left( 35 \frac{\text{kips}}{\text{in}^2} \right) (645.2 \text{ in}^3)}{12 \frac{\text{in}}{\text{ft}}}} \right) \right. \\ &\quad \left. \times \frac{\left( \frac{10.67 - 9.15}{16.61 - 9.15} \right)}{2629 \text{ ft-kips}} \right) \end{aligned}$$

$2629 \text{ ft-kips} < 2820 \text{ ft-kips}$ , so the lower value will control.

$$M_n = 2629 \text{ ft-kips} \quad [\text{controls}]$$

The design flexural strength,  $\phi M_n$ , is given by

$$\phi M_n = (0.9)(2629 \text{ ft-kips}) = 2366 \text{ ft-kips}$$

Since  $M_u < \phi M_n$ , flexural strength is adequate.

Check live load deflection.

$$\begin{aligned} \Delta_{\max} &= \frac{L}{360} = \frac{(60 \text{ ft})(12 \frac{\text{in}}{\text{ft}})}{360} = 2.0 \text{ in} \\ I_{s,\text{req'd}} &= \frac{5wL^4}{384E\Delta_{\max}} \\ &= \frac{(5)(2.5 \frac{\text{kips}}{\text{ft}})(60 \text{ ft})^4 (12 \frac{\text{in}}{\text{ft}})^3}{(384)(29,000 \frac{\text{kips}}{\text{in}^2})(2.0 \text{ in})} \\ &= 12,569 \text{ in}^4 \end{aligned}$$

Check the minimum section modulus required.

$$S_{\text{req'd}} = \frac{I}{c} = \frac{12,569 \text{ in}^4}{22.75 \text{ in}} = 552 \text{ in}^3$$

Since the actual section modulus is greater than the required section modulus, a  $44 \times 3/8$  web PL with two  $16 \text{ in} \times 3/4 \text{ in}$  flanges is adequate.

*ASD Method*

Assume the dead load is 0.5 kip/ft.

The required shear is

$$V_a = 15 \text{ kips} + 75 \text{ kips} = 90 \text{ kips}$$

The required flexural strength is

$$w_a = 0.5 \frac{\text{kip}}{\text{ft}} + 2.5 \frac{\text{kips}}{\text{ft}} = 3.0 \text{ kips/ft}$$

$$M_a = \frac{w_a L^2}{8} = \frac{\left(3 \frac{\text{kips}}{\text{ft}}\right)(60 \text{ ft})^2}{8} = 1350 \text{ ft-kips}$$

Try a  $44 \times \frac{3}{8}$  in plate for a web and two  $16 \times \frac{3}{4}$  in plates for the flanges.

The material and geometric properties for ASTM A992 steel are

$$F_y = 50 \text{ kips/in}^2$$

$$F_u = 65 \text{ kips/in}^2$$

$$t_w = 0.375 \text{ in}$$

$$t_f = 0.75 \text{ in}$$

$$b_f = 16 \text{ in}$$

$$h = 44 \text{ in}$$

$$d = 44 \text{ in} + (2)(0.75 \text{ in}) = 45.5 \text{ in}$$

The required shear strength is

$$R_a = \left(0.5 \frac{\text{kip}}{\text{ft}} + 2.5 \frac{\text{kips}}{\text{ft}}\right)(30 \text{ kips}) = 90 \text{ kips}$$

Determine if stiffeners are required.

$$A_w = dt_w = (45.5 \text{ in})(0.375 \text{ in}) = 17.06 \text{ in}^2$$

$$\frac{h}{t_w} = \frac{44 \text{ in}}{0.375 \text{ in}} = 117.3 < 260 \quad \begin{bmatrix} \text{per AISC Specification} \\ \text{Sec. G2.1(b)(i)} \end{bmatrix}$$

$$k_v = 5$$

Then, from *AISC Specification* Sec. G2.1(b)(iii),

$$1.37 \sqrt{\frac{k_v E}{F_y}} = 1.37 \sqrt{\frac{(5)\left(29,000 \frac{\text{kips}}{\text{in}^2}\right)}{50 \frac{\text{kips}}{\text{in}^2}}} = 73.8$$

Since  $h/t_w = 117 > 73.8$ , use *AISC Specification* Eq. G2-5 to calculate the web shear coefficient,  $C_v$ .

$$C_v = \frac{1.51 k_v E}{\left(\frac{h}{t_w}\right)^2 F_y} - \frac{(1.51)(5)\left(29,000 \frac{\text{kips}}{\text{in}^2}\right)}{(117.3)^2 \left(50 \frac{\text{kips}}{\text{in}^2}\right)} = 0.318$$

Calculate the nominal shear strength,  $V_n$ .

$$V_n = 0.6 F_y A_w C_v = (0.6) \left(50 \frac{\text{kips}}{\text{in}^2}\right) (17.06 \text{ in}^2) (0.318)$$

$$= 162.8 \text{ kips}$$

Check the available shear strength without stiffeners.

$$\Omega_v = 1.67$$

$$\frac{V_n}{\Omega_v} = \frac{162.8 \text{ kips}}{1.67} = 97.5 \text{ kips}$$

$$97.5 \text{ kips} > 90 \text{ kips}$$

Since the allowable shear strength is greater than the required shear strength, stiffeners are not required.

Check the bending moment and the required flexural strength.

$$w_a = 0.5 \frac{\text{kip}}{\text{ft}} + 2.5 \frac{\text{kips}}{\text{ft}} = 3 \text{ kips/ft}$$

$$M_a = \frac{w_a L^2}{8} = \frac{\left(3 \frac{\text{kips}}{\text{ft}}\right)(60 \text{ ft})^2}{8} = 1350 \text{ ft-kips}$$

As was shown with the LRFD method, the flange and web are noncompact, and the flexural strength,  $M_n$ , is

$$M_n = 2629 \text{ ft-kips}$$

The available flexural strength,  $M_n/\Omega$ , is given by

$$\frac{M_n}{\Omega} = \frac{2629 \text{ ft-kips}}{1.67} = 1574 \text{ ft-kips}$$

Since  $M_a < M_n/\Omega$ , flexural strength is adequate.

Check live load deflection.

$$\Delta_{\max} = \frac{L}{360} = \frac{(60 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{360} = 2.0 \text{ in}$$

$$I_{s,\text{req'd}} = \frac{5wL^4}{384E\Delta_{\max}}$$

$$= \frac{(5)\left(2.5 \frac{\text{kips}}{\text{ft}}\right)(60 \text{ ft})^4\left(12 \frac{\text{in}}{\text{ft}}\right)^3}{(384)\left(29,000 \frac{\text{kips}}{\text{in}^2}\right)(2.0 \text{ in})}$$

$$= 12,569 \text{ in}^4$$

Check the minimum section modulus required.

$$S_{\text{req'd}} = \frac{I_{s,\text{req'd}}}{c} = \frac{12,569 \text{ in}^4}{22.75 \text{ in}} = 552 \text{ in}^3$$

Since the actual section modulus is greater than the required section modulus, a  $44 \times \frac{3}{8}$  web PL with two  $16 \text{ in} \times \frac{3}{4}$  in flanges is adequate.

## 1. INTRODUCTION

Composite construction usually refers to a construction method in which a cast-in-place concrete slab is bonded to steel beams, girders, or decking below, such that the two materials act as a single unit. Although there are varying degrees of composite action, the concrete usually becomes the compression flange of the composite beam, and the steel carries the tension. (See Fig. 64.1.)

**Figure 64.1** Typical Composite Beam Cross Section

There are two types of composite beams: (a) steel beams fully encased in concrete so that the natural bond between the two materials holds them together, and (b) unencased steel beams attached to the concrete slab (solid or on formed steel deck) by mechanical anchorage (i.e., shear connectors). In this chapter, only the more common second type is discussed.

Composite construction is often used for bridge decks and building floors. In general, a composite floor system is stronger and stiffer than its noncomposite counterpart using the same size beams. For a given steel member cross section, the advantages of composite construction are increased load capacity and span length. Although

there are no major disadvantages in composite construction, two limitations—the effect of continuity and long-term deflection (creep)—should be recognized.

Composite construction is carried out with or without temporary *shoring*. If the steel is erected and concrete is poured without temporary shoring (i.e., construction is unshored), the combination will act compositely to carry only the loads that are applied after the concrete cures. Conversely, in fully shored construction, a temporary support carries both the steel and concrete weights until the concrete has cured. When the shore is removed, the beam acts compositely to carry the steel and concrete weights in addition to live loads applied later.

The design of steel beams/girders can be based on the assumption of composite action in accordance with *AISC Specification* Chap. I, provided that (a) the concrete slab supported by the steel beams is adequate to effectively serve as the flange of a composite T-beam, and (b) the concrete and steel are adequately tied together with mechanical anchorage (shear connectors) to act as one unit with no relative slippage. Development of full or partial composite action depends on the quantity of shear connectors. However, usually it is not necessary, and sometimes it is not feasible, to provide full composite action.

## 2. EFFECTIVE WIDTH OF CONCRETE SLAB

In a composite beam, the bending stresses in the concrete slab depend on the spacing of the steel beams. The slab bending stresses are uniformly distributed across the compression zone for closely spaced beams. However, the stresses vary considerably and nonlinearly across the compression flange when beams are placed far apart. The farther away a part of the slab is from the steel beam, the smaller the stress in it will be.

*AISC Specification* Sec. I3.1a simplifies this issue of varying stresses by replacing the actual slab with an “equivalent” narrower or “effective” slab that has a constant stress. This equivalent slab is considered to carry the same total compression as that supported by the actual slab. For an interior beam with slab extending on both sides, the *effective width*,  $b$ , of the concrete slab is given by Eq. 64.1, where  $L$  is the beam span and  $s$  is the spacing between beam centerlines. (For an exterior beam,  $s$  is replaced by  $e + s/2$ , where  $e$  is the distance from the beam centerline to the edge of the slab.)

$$b = \text{smaller of } \left\{ \frac{L}{4}, \frac{s}{s} \right\} \quad [\text{interior beams}] \quad 64.1$$

## 3. SECTION PROPERTIES

For serviceability limit states, the estimated moment of inertia,  $I$ , must be calculated. It is difficult to calculate an accurate value, so approximate methods are used to determine an effective moment of inertia of the composite

section. Deflection tests have shown that 75% of the equivalent moment of inertia,  $I_{\text{equiv}}$ , determined from linear elastic theory, is a reasonable estimate of the effective moment of inertia,  $I_{\text{eff}}$  [*AISC Commentary* Sec. I3.1]. Alternatively, a lower bound may be used. A lower bound value is given in *AISC Manual* Table 3-20. Section I3 of the *AISC Commentary* describes the process used to compute the lower bound value. For W-shapes used as composite beams, the lower bound moment of inertia,  $I_{\text{LB}}$ , is given by

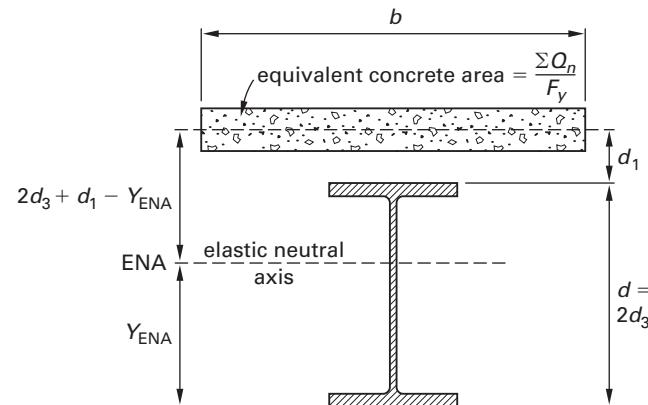

$$I_{\text{LB}} = I_s + A_s(Y_{\text{ENA}} - d_3)^2 + \left( \frac{\sum Q_n}{F_y} \right) (2d_3 + d_1 - Y_{\text{ENA}})^2$$

[*AISC Commentary* Eq. C-I3-1]      64.2

The nomenclature is illustrated in Fig. 64.2.

$Y_{\text{ENA}}$	$\frac{A_s d_3 + \left( \frac{\sum Q_n}{F_y} \right) (2d_3 + d_1)}{A_s + \frac{\sum Q_n}{F_y}}$
$d_1$	distance from the compression force in the concrete to the top of the steel section
$d_3$	distance from the resultant steel tension force for full section tension yield to the top of the steel section
$\sum Q_n$	sum of the shear strength of the studs
$\sum Q_n/F_y$	equivalent concrete area

**Figure 64.2** Deflection Design Model for Composite Beams (*AISC Manual* Fig. 3-4)\*

\**AISC Manual* Fig. 3-4 uses  $Y_2$  for  $d_1$  and  $d + Y_2 - Y_{\text{ENA}}$  for  $2d_3 + d_1 - Y_{\text{ENA}}$ . Copyright © American Institute of Steel Construction, Inc. Reprinted with permission. All rights reserved.

#### 4. AVAILABLE FLEXURAL STRENGTH

When shoring is provided, the composite section composed of the slab and beam acts as a single unit and carries the entire dead and live load. If shoring is not provided, then the dead load of the steel and concrete is resisted by the steel beam alone, and the composite beam resists only the live load.

The maximum available flexural strength,  $M_n$ , for a composite beam is based on plastic analysis and depends on the location of the *plastic neutral axis*, PNA. The maximum available flexural strength,  $M_n$ , for a composite beam occurs when the PNA is at the top of the flange; therefore, the steel shape is all in tension, and the concrete is all in compression. The value for  $M_n$  is given by Eq. 64.3.  $A_g$  is the gross steel area, and  $d$  is the total beam depth.

$$M_n = A_g F_y \left( \frac{d}{2} + Y_2 \right) \quad 64.3$$

Equation 64.3 requires that there be sufficient shear capacity in the studs to transfer the tension force in the steel,  $A_g F_y$ , to the concrete. This is called *full composite action*. If sufficient shear capacity is not provided, then the PNA drops into the steel flange or web as shown in Fig. 64.3.  $Y_1$  is the distance from the top of the flange to the PNA. Then, only a portion of the steel section is in tension, and a portion shares the compressive force with the concrete, and the available flexural strength is reduced. This is called *partial composite action*. This may be useful when the full capacity of the composite beam is not necessary to resist the required moment. Cost savings may be made in the reduction of the number of required shear studs.

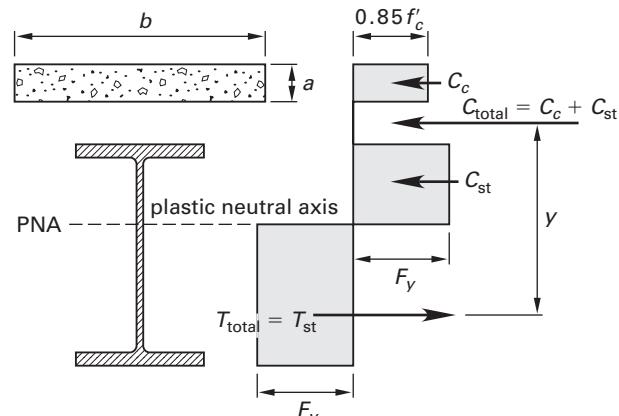

*AISC Manual* Table 3-19 lists available flexural strengths for various values of  $Y_1$ .

#### 5. SHEAR STUD CONNECTORS

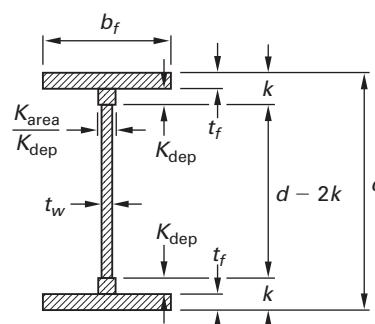

The American Welding Society's *Structural Welding Code* (AWS D1.1) contains material and performance specifications for *studs* (*shear-stud connectors*, *headed studs*), as well as guidance for documentation, inspection, quality control, installation, and testing. Stud manufacturer certification may be relied on to satisfy conformance to AWS D1.1 material and performance specifications [*AISC Specification* Sec. A3.6].

Studs for use with composite construction must be manufactured from ASTM A108 steel (ultimate tensile strength, 65 ksi) [*AISC Manual* Part 2]. Diameters of  $\frac{3}{8}$  in,  $\frac{1}{2}$  in,  $\frac{5}{8}$  in,  $\frac{3}{4}$  in,  $\frac{7}{8}$  in, and 1 in are commonly available, with the smaller sizes used more often. Stud diameter should not be greater than 2.5 times the thickness of the flange to which studs are welded, unless studs are located directly over the web [*AISC Specification* Sec. I8.1]. Studs must be of uniform diameter, be headed

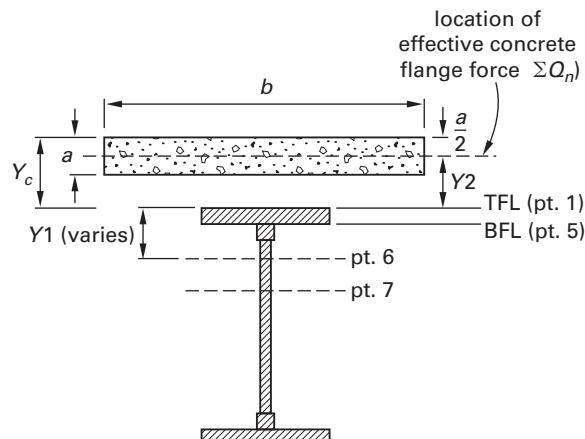

**Figure 64.3** Strength Design Models for Composite Beams\*

(a) partial composite action

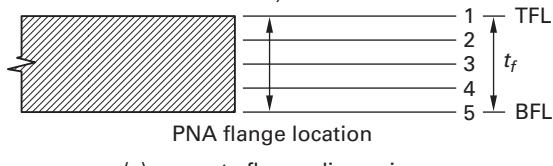

(b) steel beam dimensions

$Y_1$  = distance from top of steel flange to an of the seven tabulated PNA locations

$$\Sigma Q_n(@ pt. 6) = \frac{\Sigma Q_n(@ pt. 5) + \Sigma Q_n(@ pt. 7)}{2}$$

$$\Sigma Q_n(@ pt. 7) = 0.25 F_y A_s$$

(c) concrete flange dimension

\*From *AISC Manual* Fig. 3-3.

Copyright © American Institute of Steel Construction, Inc. Reprinted with permission. All rights reserved.

(i.e., be *Type B studs*), have heads concentric to the shaft, and have chamfered weld ends.

Studs are installed with solid flux. The welded ends of studs are flux-loaded. During welding, the stud and flux are protected by a *ceramic ferrule* (arc shield) that is subsequently removed after stud installation. Surfaces of members to receive studs must be cleaned to remove oil, scale, rust, dirt, and other materials that would interfere with welding. Surfaces may be cleaned by scaling, brushing, or grinding. Surfaces should not be shop-painted, galvanized, or plated prior to installation of studs. Surfaces must be dry and free of snow and ice, and the air temperature should not be lower than 32–35°F without the design engineer's approval.

Installation may be direct to girders or through formed galvanized metal decking (either through pre-punched holes in the decking or directly through the decking itself). Welding normally uses automatic arc welding. Fillet welding of headed studs is not normally permitted without approval from the design engineer. Stud length decrease (burn-off) after installation is approximately  $\frac{1}{8}$  in to  $\frac{3}{8}$  in, depending on stud diameter. Minimum installed length is 1.5 in plus the deck height [*AISC Manual* Table 3-21].

Center-to-center stud spacing should normally be greater than 6 stud diameters along the longitudinal axis of the supporting composite beam and greater than 4 stud diameters in the transverse direction. For studs installed in the ribs of formed steel decks oriented perpendicularly to the steel beam, the minimum spacing is four diameters in any direction. The maximum spacing in any direction cannot exceed the minimum of eight times the slab thickness and 36 in [*AISC Specification* I8.2d].

After welding, ceramic ferrules and any substance that interferes with stud function, or that would prevent concrete bonding, must be removed. After installation, sufficient expelled (melted and solidified) metal must be observed 360° around the stud base. Installed studs must be tested to ensure satisfactory welding. Testing typically involves striking the first two studs that have been installed with a hammer and bending them to 45° before continuing. Additional studs may also be tested. Studs exhibiting no signs of failure after bending are left in the bent position. Studs failing inspection or testing must be replaced. Before welding a new stud, where a defective stud has been removed, the area must be ground smooth and flush. Where there is a pullout of metal, the pocket must be filled with weld metal (using the shielded metal-arc process with low-hydrogen welding electrodes) and then ground flush. Where a stud fails inspection of testing, a new stud may be welded adjacent to the defective stud. However, this should be done only in areas of compression or where permitted by the design engineer.

Although a natural bond is created between a steel beam and a concrete slab, this bond cannot be relied upon to ensure composite action. Mechanical *shear connectors* (also called *stud connectors*) attached to the top

of the steel beam must be provided to create a positive connection between the steel beam and the concrete slab. *AISC Specification* Sec. I gives the material, placing, and spacing requirements, and specifies that the entire horizontal shear at the junction of the steel beam and the concrete slab is assumed to be transferred by shear connectors. Steel stud connectors must conform to the AWS D1.1.

The connectors required on each side of the point of maximum moment in an area of positive moment may be uniformly distributed between that point and adjacent points of zero moment.

*AISC Specification* Sec. I3.2d requires that the number of shear connectors between the maximum positive or negative bending moment and the adjacent zero moment section be equal to the horizontal shear force,  $\Sigma Q_n$ , for shear connectors, divided by the nominal strength of one shear connector. The nominal shear strength,  $Q_n$ , of one of the connectors is given in *AISC Specification* Sec. I8.2. *AISC Manual* Table 3-21 also gives the tabulated values for  $Q_n$ .

$$N = \frac{\sum Q_n}{Q_n} \quad 64.4$$

## 6. DESIGN OF COMPOSITE BEAMS

Design of composite beams is based on the criteria of bending stress, shear stress, and deflection. Table 3-19 and Table 3-20 in Part 3 of the *AISC Manual* are useful in design. Table 3-19 lists available flexural strength, and Table 3-20 lists lower bounds on the moment of inertia.

These tables can be used for full and partial composite action with a solid slab or a slab on formed steel deck without restriction on concrete strength, modular ratio, or effective width.

### Example 64.1

Check the adequacy of a simply supported interior floor beam of composite construction, assuming shored construction and sufficient shear transfer to result in full composite action. The deflection checked during construction considers the weight of concrete as contributing to construction dead load (DL), and limits deflection to a  $2\frac{1}{2}$  in maximum to facilitate concrete placement. Use the LRFD method and the following data.

ASTM A992 steel strength beam	$F_y = 50 \text{ kips/in}^2$
beam span	$L = 40 \text{ ft}$
beam spacing	$s = 8 \text{ ft}$
concrete strength	$f'_c = 3 \text{ kips/in}^2$
unit weight	$150 \text{ lbf/ft}^3$
slab thickness	$t = 4 \text{ in}$
floor live load	$100 \text{ lbf/ft}^2$
partition load	$20 \text{ lbf/ft}^2$

**Solution**

From the *AISC Manual* Table 1-1, for a W21 × 62,  $A = 18.3 \text{ in}^2$ ,  $d = 21.0 \text{ in}$ , and  $t_w = 0.4 \text{ in}$ .

The loading from the 4 in slab is

$$\left( \frac{4 \text{ in}}{12 \frac{\text{in}}{\text{ft}}} \right) (8 \text{ ft}) \left( 150 \frac{\text{lbf}}{\text{ft}^3} \right) = 400 \text{ lbf/ft}$$

The loading from the W21 × 62 steel beam is 62 lbf/ft.

The total dead load is

$$w_D = \frac{400 \frac{\text{lbf}}{\text{ft}} + 62 \frac{\text{lbf}}{\text{ft}}}{1000 \frac{\text{lbf}}{\text{kip}}} = 0.462 \text{ kip/ft}$$

The dead load moment is

$$M_D = \frac{w_DL^2}{8} = \frac{\left(0.462 \frac{\text{kip}}{\text{ft}}\right)(40 \text{ ft})^2}{8} = 92.4 \text{ ft-kips}$$

After the concrete has hardened, the loading from the live load and partition will be  $100 \text{ lbf/in}^2 + 20 \text{ lbf/in}^2 = 120 \text{ lbf/in}^2$ .

$$w_L = \frac{(120 \frac{\text{lbf}}{\text{ft}^2})(8 \text{ ft})}{1000 \frac{\text{lbf}}{\text{kip}}} = 0.96 \text{ kip/ft}$$

$$M_L = \frac{w_LL^2}{8} = \frac{\left(0.96 \frac{\text{kip}}{\text{ft}}\right)(40 \text{ ft})^2}{8} = 192 \text{ ft-kips}$$

The maximum moment is

$$M_{\max} = M_D + M_L = 92.4 \text{ ft-kips} + 192 \text{ ft-kips} = 284.4 \text{ ft-kips}$$

The maximum shear is

$$V_{\max} = \frac{(w_D + w_L)L}{2} = \frac{\left(0.462 \frac{\text{kip}}{\text{ft}} + 0.96 \frac{\text{kip}}{\text{ft}}\right)(40 \text{ ft})}{2} = 28.44 \text{ kips}$$

The effective width of the concrete slab is the smaller of

$$b = \frac{L}{4} = \frac{(40 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{4} = 120 \text{ in}$$

$$b = s = (8 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right) = 96 \text{ in} \quad [\text{governs}]$$

**LRFD Method**

$$w_u = (1.2)\left(0.462 \frac{\text{kip}}{\text{ft}}\right) + (1.6)\left(0.96 \frac{\text{kip}}{\text{ft}}\right) = 2.09 \text{ kips/ft}$$

$$M_u = \frac{w_u L^2}{8} = \frac{\left(2.09 \frac{\text{kips}}{\text{ft}}\right)(40 \text{ ft})^2}{8} = 418 \text{ ft-kips}$$

Use *AISC Manual* Table 3-19, Table 3-20, and Table 3-21.

Assuming  $a = 1 \text{ in}$ ,

$$Y2 = t_{\text{slab}} - \frac{a}{2} = 4 \text{ in} - \frac{1 \text{ in}}{2} = 3.5 \text{ in}$$

With a PNA location 5 (i.e., at the bottom of the flange, BFL),

$$\phi M_n = 816 \text{ ft-kips} > 418 \text{ ft-kips}$$

Check the beam deflection and the available shear strength. The construction dead load is

$$w_D = \frac{(8 \text{ ft})\left(\frac{4 \text{ in}}{12 \frac{\text{in}}{\text{ft}}}\right)\left(150 \frac{\text{lbf}}{\text{ft}^3}\right)}{1000 \frac{\text{lbf}}{\text{kip}}} = 0.4 \text{ kip/ft}$$

The moment of inertia required to limit deflection,  $\Delta_{\max}$ , during construction to 2.5 in is

$$I_{\text{req'd}} = \frac{5w_DL^4}{384E\Delta_{\max}} = \frac{(5)\left(0.4 \frac{\text{kip}}{\text{ft}}\right)(40 \text{ ft})^4\left(12 \frac{\text{in}}{\text{ft}}\right)^3}{(384)\left(29,000 \frac{\text{kips}}{\text{in}^2}\right)(2.5 \text{ in})} = 318 \text{ in}^4$$

From *AISC Manual* Table 3-20, a W21 × 62 has

$$I_x = 1330 \text{ in}^4 > 318 \text{ in}^4 \quad [\text{OK}]$$

From *AISC Manual* Table 3-19,

$$\sum Q_n = 408 \text{ kips}$$

Check  $a$ .

$$a = \frac{\sum Q_n}{0.85 f_c b} = \frac{408 \text{ kips}}{(0.85) \left( 3 \frac{\text{kips}}{\text{in}^2} \right) (8 \text{ ft}) \left( 12 \frac{\text{in}}{\text{ft}} \right)} = 1.66 \text{ in} > 1.0 \text{ in assumed [NG]}$$

Recalculate  $Y_2$  with the new value of  $a$ .

$$Y_2 = 4 - \frac{1.66 \text{ in}}{2} = 3.17 \text{ in}$$

For a  $Y_2 \approx 3.0$  and a PNA location of 5,

$$\phi M_n = 801 \text{ ft-kips} > 418 \text{ ft-kips} \quad [\text{OK}]$$

Determine the maximum live load deflection.

$$\Delta_{L,\max} = \frac{L}{360} = \frac{(40 \text{ ft}) \left( 12 \frac{\text{in}}{\text{ft}} \right)}{360} = 1.33 \text{ in}$$

A lower bound moment of inertia for composite beams is found in *AISC Manual* Table 3-20.

For a W21 × 62, with  $Y_2 = 3.0$  and a PNA at location 7,  $I_{LB} = 2000 \text{ in}^4$ .

Then,

$$\Delta_L = \frac{5w_L L^4}{384EI_{LB}} = \frac{(5) \left( 0.96 \frac{\text{kip}}{\text{ft}} \right) (40 \text{ ft})^4 \left( 12 \frac{\text{in}}{\text{ft}} \right)^3}{(384) \left( 29,000 \frac{\text{kips}}{\text{in}^2} \right) (2000 \text{ in}^4)} = 0.95 \text{ in} < 1.33 \text{ in} \quad [\text{OK}]$$

Determine if the beam has sufficient shear strength.

$$V_u = \left( \frac{40 \text{ ft}}{2} \right) \left( (1.2) \left( 0.462 \frac{\text{kip}}{\text{ft}} \right) + (1.6) \left( 0.96 \frac{\text{kip}}{\text{ft}} \right) \right) = 41.8 \text{ kips}$$

From *AISC Specification* Eq. G2-1,

$$V_n = 0.6 F_y A_w C_v = (0.6) \left( 50 \frac{\text{kips}}{\text{in}^2} \right) ((0.40 \text{ in})(21 \text{ in})) (1) = 252 \text{ kips}$$

Per *AISC Sec. G2.1(a)*, for webs of rolled shapes,  $\phi_v = 1.00$ .

$$\phi_v V_n = (1.00)(252 \text{ kips}) = 252 \text{ kips} > 41.8 \text{ kips}$$

Since the shear strength is greater than the required shear strength, shear capacity is sufficient.

Determine the number of shear stud connectors required to carry the full horizontal shear load (full composite action).

From *AISC Manual* Table 3-21, with 3 ksi concrete, conservatively assume a perpendicular deck with one  $3/4$  in diameter weak stud per rib.

$$Q_n = 17.2 \text{ kips/stud}$$

Per *AISC Specification* Sec. I3.2d(1),

$$\frac{\sum Q_n}{Q_n} = \frac{408 \text{ kips}}{17.2 \frac{\text{kips}}{\text{stud}}} = 23.7 \text{ studs}$$

[24 on each side of the beam centerline]

The total number of studs per beam is 48.

*ASD Method*

Check for adequacy using the following information and determine the flexural strength.

$$w_a = 0.462 \frac{\text{kip}}{\text{ft}} + 0.96 \frac{\text{kip}}{\text{ft}} = 1.422 \text{ kips/ft}$$

$$M_a = \frac{w_a L^2}{8} = \frac{\left( 1.422 \frac{\text{kips}}{\text{ft}} \right) (40 \text{ ft})^2}{8} = 284 \text{ ft-kips}$$

Use *AISC Manual* Table 3-19, Table 3-20, and Table 3-21.

Assuming  $a = 1 \text{ in}$ ,

$$Y_2 = t_{\text{slab}} - \frac{a}{2} = 4 \text{ in} - \frac{1 \text{ in}}{2} = 3.5 \text{ in}$$

With a PNA location 5 (i.e., at the bottom of the flange, BFL),

$$\frac{M_n}{\Omega_b} = 543 \text{ kips} \geq 284 \text{ kips}$$

Check the beam deflection and the available shear strength. The construction dead load is

$$w_D = \frac{(8 \text{ ft}) \left( \frac{4 \text{ in}}{12 \frac{\text{ft}}{\text{in}}} \right) \left( 150 \frac{\text{lbf}}{\text{ft}^3} \right)}{1000 \frac{\text{lbf}}{\text{kip}}} = 0.4 \text{ kip/ft}$$

The moment of inertia required to limit deflection,  $\Delta_{\max}$ , during construction to 2.5 in is

$$I_{\text{req'd}} = \frac{5w_DL^4}{384E\Delta_{\max}} = \frac{(5)(0.4 \frac{\text{kip}}{\text{ft}})(40 \text{ ft})^4(12 \frac{\text{in}}{\text{ft}})^3}{(384)(29,000 \frac{\text{kips}}{\text{in}^2})(2.5 \text{ in})} = 318 \text{ in}^4$$

From *AISC Manual* Table 3-20, a W21 × 62 has

$$I_x = 1330 \text{ in}^4 > 318 \text{ in}^4 \quad [\text{OK}]$$

From *AISC Manual* Table 3-19,

$$\sum Q_n = 408 \text{ kips}$$

Check  $a$ .

$$a = \frac{\sum Q_n}{0.85f_c b} = \frac{408 \text{ kips}}{(0.85)(3 \frac{\text{kips}}{\text{in}^2})(8 \text{ ft})(12 \frac{\text{in}}{\text{ft}})} = 1.66 \text{ in} > 1.0 \text{ in assumed} \quad [\text{NG}]$$

Recalculate  $Y_2$  with the new value of  $a$ .

$$Y_2 = 4 - \frac{1.66 \text{ in}}{2} = 3.17 \text{ in}$$

For a  $Y_2 \approx 3.0$  and a PNA of 5,

$$\frac{M_n}{\Omega_b} = 533 \text{ ft-kips} > 284 \text{ ft-kips} \quad [\text{OK}]$$

Determine the maximum live load deflection.

$$\Delta_{L,\max} = \frac{L}{360} = \frac{(40 \text{ ft})(12 \frac{\text{in}}{\text{ft}})}{360} = 1.33 \text{ in}$$

A lower bound moment of inertia for composite beams is found in *AISC Manual* Table 3-20.

For a W21 × 62, with  $Y_2 = 3.0$  and a PNA at location 7,  $I_{LB} = 2000 \text{ in}^4$ .

Then,

$$\begin{aligned} \Delta_L &= \frac{5w_L L^4}{384EI_{LB}} \\ &= \frac{(5)(0.96 \frac{\text{kip}}{\text{ft}})(40 \text{ ft})^4(12 \frac{\text{in}}{\text{ft}})^3}{(384)(29,000 \frac{\text{kips}}{\text{in}^2})(2000 \text{ in}^4)} \\ &= 0.95 \text{ in} < 1.33 \text{ in} \quad [\text{OK}] \end{aligned}$$

Determine if the beam has sufficient available shear strength.

$$\begin{aligned} V_a &= \left(\frac{40 \text{ ft}}{2}\right)\left(1.422 \frac{\text{kips}}{\text{ft}}\right) = 28.4 \text{ kips} \\ \frac{V_n}{\Omega} &= \frac{240 \text{ kips}}{1.67} = 143.7 \text{ kips} \\ 143.7 \text{ kips} &> 28.4 \text{ kips} \end{aligned}$$

Since the available shear strength is greater than the required shear strength, shear capacity is sufficient.

Determine the number of shear stud connectors required to carry the full horizontal shear load (full composite action).

From *AISC Manual* Table 3-21, with 3 ksi concrete, conservatively assume a perpendicular deck with one  $3/4$  in diameter weak stud per rib.

$$Q_n = 17.2 \text{ kips/stud}$$

Per *AISC Specification* Sec. I3.2d(5),

$$\frac{\sum Q_n}{Q_n} = \frac{408 \text{ kips}}{17.2 \frac{\text{kips}}{\text{stud}}} = 23.7 \text{ studs}$$

[24 on each side of the beam centerline]

The total number of studs per beam is 48.

## 1. INTRODUCTION

There are two types of structural *connectors* (also referred to as *fasteners*): rivets and bolts. *Rivets*, however, have become virtually obsolete because of their low strength, high cost of installation, installed variability, and other disadvantages. The two types of *bolts* generally used in the connections of steel structures are common bolts and high-strength bolts. *Common bolts* are classified by ASTM as A307 bolts. The two basic types of *high-strength bolts* have ASTM designations of A325 and A490. There are also twist-off bolt types that are equivalent to A325 and A490: F1852 is equivalent to A325, and F2280 is equivalent to A490. Figure 65.1 shows typical bolted connections.

A *concentric connection* is one for which the applied load passes through the centroid of the fastener group. If the load is not directed through the fastener group centroid, the connection is said to be an *eccentric connection*.

At low loading, the distribution of forces among the fasteners is very nonuniform, since friction carries some of the load. However, at higher stresses (i.e., those near yielding), the load is carried equally by all fasteners in the group. Stress concentration factors are not normally applied to connections with multiple redundancy.

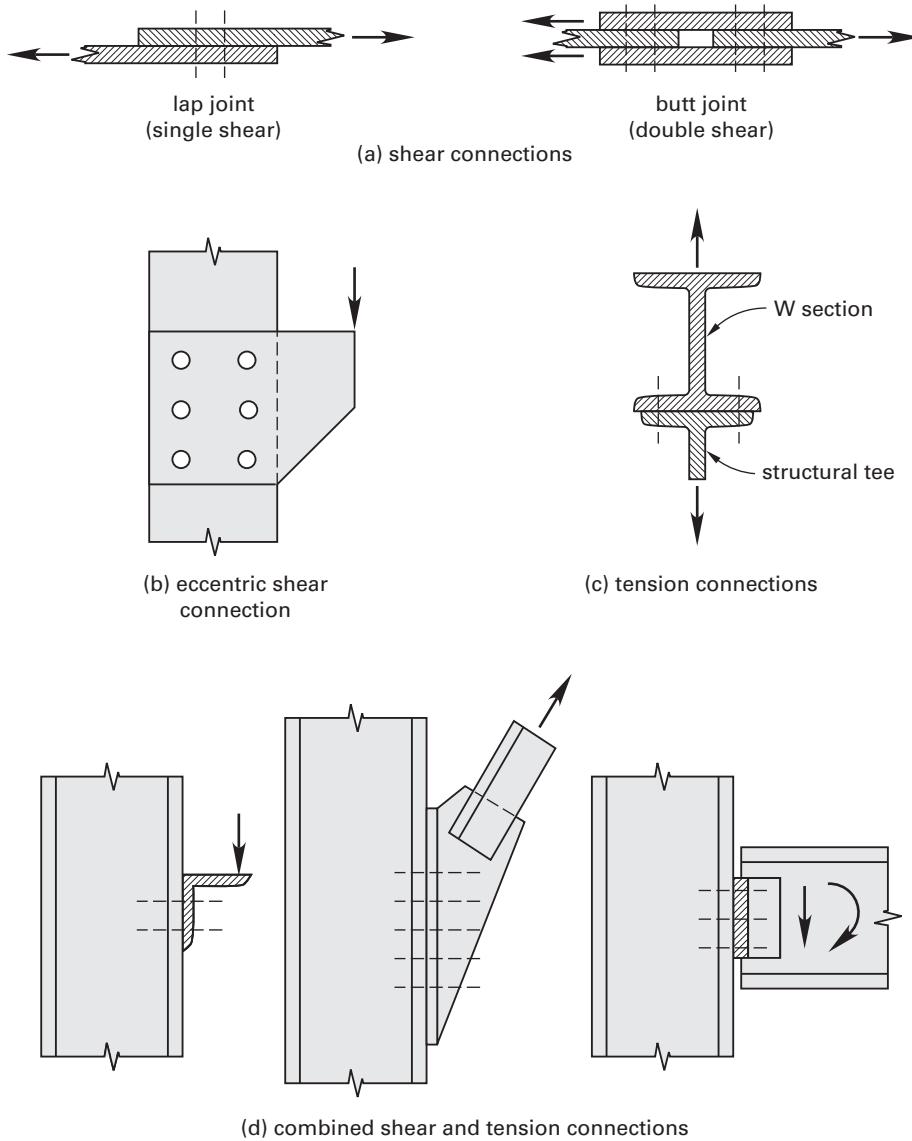

In many connection designs, materials with different strengths will be used. The item manufactured from the material with the minimum strength is known as the *critical part*, and the critical part controls the design.

Connections using bolts and rivets are analyzed and designed similarly. Such connections can place fasteners in direct shear, torsional shear, tension, or any combination of shear and tension. In accordance with *AISC Specification* Sec. B3.1, theoretical design by elastic, inelastic, or plastic analysis is permitted.

The analysis presented in this chapter for connection design and analysis assumes static loading. Provisions for fatigue loading are contained in the *AISC Specification* App. 3.

## 2. HOLE SPACING AND EDGE DISTANCES

The minimum distance between centers of standard, oversized, or slotted holes is  $2\frac{2}{3}$  times the nominal fastener diameter; a distance of  $3d$  is preferred [*AISC Specification* Sec. J3.3]. The longitudinal spacing between

**Figure 65.1** Typical Bolted Connections

Structural

bolts along the line of action of the force is specified in Sec. J3.5 of the *AISC Specification* and is a function of painted surfaces and material.

The minimum distance from the hole center to the edge of a member is approximately 1.75 times the nominal diameter for sheared edges, and approximately 1.25 times the nominal diameter for rolled or gas-cut edges, both rounded to the nearest  $\frac{1}{8}$  in [*AISC Specification* Sec. J3.4]. (For exact values, refer to Table J3.4 in *AISC Specification*.)

For parts in contact, the maximum edge distance from the center of a fastener to the edge in contact is 12 times the plate thickness or 6 in, whichever is less [*AISC Specification* Sec. J3.5].

### 3. BEARING AND SLIP-CRITICAL CONNECTIONS

A distinction is made between bearing and slip-critical connections. A *bearing connection* (which includes the categories of snug-tightened and pretensioned connections) relies on the shearing resistance of the fasteners to resist loading. In effect, it is assumed that the fasteners are loose enough to allow the plates to slide slightly, bringing the fastener shanks into contact with the holes. The area surrounding the hole goes into bearing, hence the name. Connections using rivets, welded studs, and A307 bolts are always considered to be bearing connections. However, high-strength bolts can also be used in bearing connections.

If the fasteners are constructed from high-strength steel, a high preload can be placed on the bolts. This preload will clamp the plates together, and friction alone will keep the plates from sliding. Such connections are known as *slip-critical connections*. The fastener shanks never come into contact with the plate holes. Bolts constructed from A325 and A490 steels are suitable for slip-critical connections.

Bolt type and connection type designations may be combined (e.g., A325SC, A325N, and A325X). A325 refers to the bolt type, while the SC, N, and X refer to the connection type and geometry. SC is used for a slip-critical connection. N is used to indicate that bolt threads are located in the shear plane, while X indicates no bolt threads are in the shear plane. Shear strength is reduced if threads are located within the shear plane.

In a slip-critical connection, the two clamped surface areas in contact are known as *faying surfaces*. (The verb *fay* means to join tightly.) *Coated faying surfaces* include surfaces that have been primed, primed and painted, and protected against corrosion, but not galvanized. *Galvanized faying surfaces* are specifically referred to by name. The condition of the faying surfaces affects the frictional shear force that can develop. The friction coefficient,  $\mu$ , is referred to as the *slip coefficient* and is the ratio of the total frictional shear load to the normal clamping force.

Faying surfaces are categorized as Class A and Class B. (A previous designation, Class C for roughened galvanized surfaces is obsolete, and such surfaces have been merged into Class A.) *Class A surfaces* include unpainted clean mill scale surfaces, blast-cleaned (wire brushed or sand-blasted) surfaces with Class A coatings (including phosphate conversion and zinc silicate paint), and galvanized surfaces that have been roughed by hand wire brushing. Power wire brushing is not permitted. *Class B surfaces* include unpainted blast-cleaned steel surfaces and blast-cleaned surfaces with Class B coatings. If qualified by testing, many commercial primers meet the requirements for Class B coatings. However, most epoxy top coats do not, and faying surfaces must be taped off when fabrication shops apply epoxy top coats. Corrosion on uncoated blast-cleaned steel surfaces due to normal atmospheric exposure up to a year or more between the time of fabrication and subsequent erection is not detrimental and may actually increase the slip resistance of the joint.

#### 4. AVAILABLE LOADS FOR FASTENERS

The *AISC Manual* contains tables of available loads for common connector types and materials. The design strength of a fastener can also be determined by multiplying its area by a nominal stress. Except for rods with upset ends, the area to be used is calculated simply from the fastener's nominal (unthreaded and undriven) dimension.

Table 65.1 lists nominal stresses for common connector types for tension and shear. (Available bearing stress is

**Table 65.1** Nominal Fastener Stresses for Static Loading

type of connector	$F_{nt}$ (ksi)	$F_{nv}$ in bearing connections	
		(ksi)	(ksi)
A307 common bolts	45	27	
A325 high-strength bolts			
no threads in shear plane	90	68	
A490 high-strength bolts			
no threads in shear plane	113	84	
		113	
			68
threads in shear plane			

Source: Based on *AISC Specification* Table J3.2.

covered in Sec. 65.5.) Reductions are required for use with oversized holes and connector patterns longer than 50 in.

For fasteners made from approved steels, including A449, A572, and A588 alloys, the nominal tensile stress is  $F_{nt} = 0.75F_u$ , whether or not threads are in the shear plane. For bearing connections using the same approved steels, the nominal shear stress is  $F_{nv} = 0.450F_u$  if threads are present in the shear plane and  $F_{nv} = 0.563F_u$  if threads are excluded from the shear plane [*AISC Specification* Table J3.2].

If fasteners are exposed to both tension and shear, *AISC Specification* Sec. J3.7 for bearing-type and Sec. J3.9 for slip-critical connections should be used to determine the maximum tensile stress.

For A325 and A490 bolts used in slip-critical connections with tension, the available shear stresses given in Table 65.1 must be determined in accordance with *AISC Specification* Sec. J3.8.

The design *slip resistance*,  $\phi R_n$ , and the allowable slip resistance,  $R_n/\Omega$ , are determined from Eq. 65.1 [*AISC Specification* Eq. J3-4].

$$R_n = \mu D_u h_f T_b n_s \quad 65.1$$

The LRFD and ASD resistance and safety factors vary from 0.7 to 1.0 and 1.5 to 2.14, respectively, depending on hole size. The *mean slip coefficient*,  $\mu$ , is 0.30 for a Class A surface and 0.50 for a Class B surface. The ratio of mean installed bolt pretension to a specified minimum bolt pretension,  $D_u$ , is 1.13. The *filler factor*,  $h_f$ , ranges from 0.85 to 1.0.  $n_s$  is the number of slip planes, and the minimum fastener tension,  $T_b$ , is per Table 65.2.

Table 65.2 gives the minimum pretension for specific bolt sizes and types. For bolts of other sizes, or for bolts manufactured from other steels, the minimum pretension is given by Eq. 65.2, where  $A_{b,th}$  is the tensile stress area of the bolt.

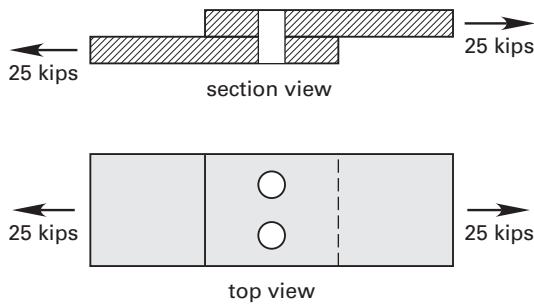

$$T_{b,min} = 0.70 A_{b,th} F_u \quad [\text{rounded}] \quad 65.2$$

**Table 65.2** Minimum Bolt Pretension (kips)\*

bolt size (in)	A325 bolts	A490 bolts
$\frac{1}{2}$	12	15
$\frac{5}{8}$	19	24
$\frac{3}{4}$	28	35
$\frac{7}{8}$	39	49
1	51	64
$1\frac{1}{8}$	56	80
$1\frac{1}{4}$	71	102
$1\frac{3}{8}$	85	121
$1\frac{1}{2}$	103	148

\*A325 and A490 bolts are required to be tightened to 70% of their minimum tensile strength.

Source: Based on *AISC Specification* Table J3.1.

### Solution

The area of the  $\frac{3}{4}$  in bolt is

$$A_b = A_v = \frac{\pi d^2}{4} = \frac{\pi(0.75 \text{ in})^2}{4} = 0.442 \text{ in}^2$$

### LRFD Method

Find the required strength.

$$T_u = (1.6)(25 \text{ kips}) = 40 \text{ kips}$$

$$V_u = (1.6)(25 \text{ kips}) = 40 \text{ kips}$$

Calculate  $f_{rv}$ . From Table 65.1,  $F_{nv} = 54 \text{ kips/in}^2$ .

$$f_{rv} = \frac{V_u}{A_v} = \frac{40 \text{ kips}}{0.442 \text{ in}^2} = 90.5 \text{ kips/in}^2 \quad [\text{required}]$$

$$\phi F_{nv} = (0.75) \left( 54 \frac{\text{kips}}{\text{in}^2} \right) = 40.5 \text{ kips/in}^2 \quad [\text{available}]$$

The number of required bolts is

$$\frac{90.5 \frac{\text{kips}}{\text{in}^2}}{40.5 \frac{\text{kips}}{\text{in}^2}} = 2.23$$

Use four bolts for the symmetry of the pattern.

Check for combined tension and shear using *AISC Specification* Eq. J3-3a, where  $\phi = 0.75$ .

$$\begin{aligned} F'_{nt} &= 1.3F_{nt} - \left( \frac{F_{nt}}{\phi F_{nv}} \right) f_{rv} \leq F_{nt} \\ &= (1.3) \left( 90 \frac{\text{kips}}{\text{in}^2} \right) \\ &\quad - \left( \frac{90 \frac{\text{kips}}{\text{in}^2}}{(0.75)(54 \frac{\text{kips}}{\text{in}^2})} \right) \left( \frac{90.5 \frac{\text{kips}}{\text{in}^2}}{4 \text{ bolts}} \right) \\ &= 66.7 \text{ kips/in}^2 < 90 \text{ kips/in}^2 \end{aligned}$$

$$\begin{aligned} R_n &= F'_{nt} A_b = \left( 66.7 \frac{\text{kips}}{\text{in}^2} \right) (0.442 \text{ in}^2) \\ &= 29.5 \text{ kips} \quad [\text{AISC Specification Eq. J3-1}] \end{aligned}$$

## 6. CONCENTRIC SHEAR CONNECTIONS

In a concentric shear connection, fasteners are subject to direct shear only. The number of fasteners required in the connection is determined by considering the fasteners in shear, the plate in bearing, and the effective net area of the plate in tension.

### Example 65.1

Two  $\frac{1}{4}$  in  $\times$  8 in A36 steel plates are joined with a lap joint using  $\frac{3}{4}$  in A325-N bolts. Design a bearing connection with threads in the shear plane to carry a concentric live load of 25 kips.

The design tensile strength is  $\phi R_n$ .

$$\phi R_n = (0.75)(29.5 \text{ kips}) = 22.1 \text{ kips}$$

Multiply the design tensile strength by the number of required bolts.

$$\left(22.1 \frac{\text{kips}}{\text{bolt}}\right)(4 \text{ bolts}) = 88.4 \text{ kips} > 40 \text{ kips}$$

88.4 kips is greater than the required tension strength, so it is OK.

#### ASD Method

Find the required strength.

$$T = 25 \text{ kips}$$

$$V = 25 \text{ kips}$$

Calculate  $f_{rv}$ .

$$f_{rv} = \frac{V}{A_v} = \frac{25 \text{ kips}}{0.442 \text{ in}^2} = 56.6 \text{ kips/in}^2 \quad [\text{required}]$$

$$\frac{F_{nv}}{\Omega} = \frac{54 \frac{\text{kips}}{\text{in}^2}}{2} = 27 \text{ kips/in}^2 \quad [\text{available}]$$

The number of required bolts is

$$\frac{56.6 \frac{\text{kips}}{\text{in}^2}}{27 \frac{\text{kips}}{\text{in}^2}} = 2.1$$

Use four bolts for the symmetry of the pattern.

Check for the combined tension and shear using AISC Specification Eq. J3-3b, where  $\Omega = 2.00$ .

$$\begin{aligned} F'_{nt} &= 1.3F_{nt} - \left(\frac{\Omega F_{nt}}{F_{nv}}\right)f_{rv} \leq F_{nt} \\ &= (1.3)\left(90 \frac{\text{kips}}{\text{in}^2}\right) \\ &\quad - \left(\frac{(2.00)\left(90 \frac{\text{kips}}{\text{in}^2}\right)}{54 \frac{\text{kips}}{\text{in}^2}}\right)\left(\frac{56.6 \frac{\text{kips}}{\text{in}^2}}{4 \text{ bolts}}\right) \\ &= 69.8 \text{ kips/in}^2 < 90 \text{ kips/in}^2 \end{aligned}$$

From Eq. 65.3,

$$\begin{aligned} R_n &= F'_{nt}A_b = \left(69.8 \frac{\text{kips}}{\text{in}^2}\right)(0.442 \text{ in}^2) \\ &= 30.8 \text{ kips} \quad [\text{AISC Specification Eq. J3-1}] \end{aligned}$$

The allowable tensile strength is

$$\frac{R_n}{\Omega} = \frac{30.8 \text{ kips}}{2.00} = 15.4 \text{ kips}$$

Multiply the allowable tensile strength by the number of required bolts.

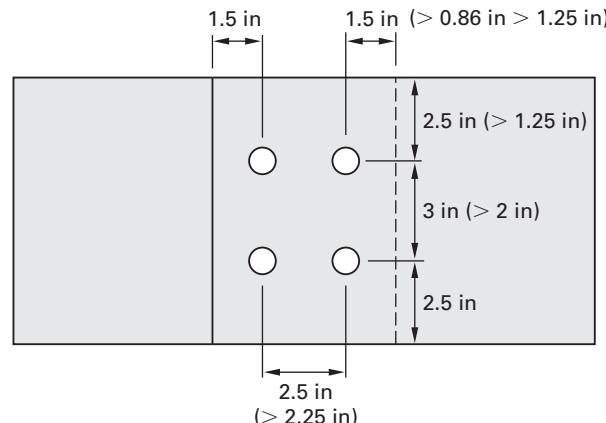

$$\left(15.4 \frac{\text{kips}}{\text{bolt}}\right)(4 \text{ bolts}) = 61.6 \text{ kips} > 25 \text{ kips}$$

61.6 kips is greater than the required tension strength, so it is OK.

To determine bolt-hole locations, AISC Specification Sec. J3.3 specifies that the minimum distance between holes must not be less than  $2/3$  times the nominal diameter, but a distance of  $3d$  is preferred.

Assuming sheared edges for a  $3/4$  bolt diameter, AISC Specification Table J3.4 specifies the minimum edge spacing to be  $1\frac{1}{4}$  in.

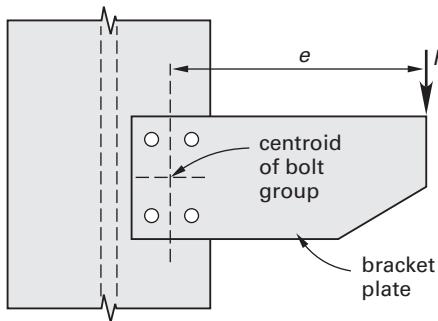

Based on these requirements, a trial layout is made.

## 7. ECCENTRIC SHEAR CONNECTIONS

An eccentric shear connection is illustrated in Fig. 65.2. The connection's tendency to rotate around the centroid of the fastener group is the torsion (or torque) on the connection, equal to the product  $Pe$ . This torsion is resisted by the shear stress in the fasteners. Friction is not assumed to contribute to the rotational resistance of the connection.

Two methods are available (and, both may be used) for designing and analyzing eccentric connections: the traditional elastic method and AISC's instantaneous center of rotation method. AISC's instantaneous center of rotation method is covered in Sec. 65.8. The traditional elastic approach has been covered in Chap. 45. The elastic method, although it provides a simplified solution, generally underestimates the capacity of an eccentric shear connection. In some cases, the actual capacity may be as much as twice the capacity calculated from the elastic model.

**Figure 65.2** Eccentric Shear Connection

The design of the *bracket* or *bracket plate* itself (see Fig. 65.2) is covered in *AISC Manual* Part 15. Bracket plates are essentially designed as cantilever beams, taking into consideration flexural yielding, rupture, and local buckling.

## 8. ULTIMATE STRENGTH OF ECCENTRIC SHEAR CONNECTIONS

Design and analysis using one of several available ultimate strength procedures is preferred over the use of elastic methods. In practice, these procedures involve more table look-up than theory. The design strength of a fastener group using AISC's *instantaneous center of rotation method* is calculated from the product of tabulated coefficients found in Table 7-6 through Table 7-13 in Part 7 of the *AISC Manual*. For example, in Eq. 65.4,  $R_n$  is the least nominal strength of one bolt determined from the limit states of bolt shear strength, bearing strength, and slip resistance. Coefficient  $C$  is found from Table 7-6 through Table 7-13 and is a function of bolt geometry and eccentricity.

$$P = CR_n \quad 65.4$$

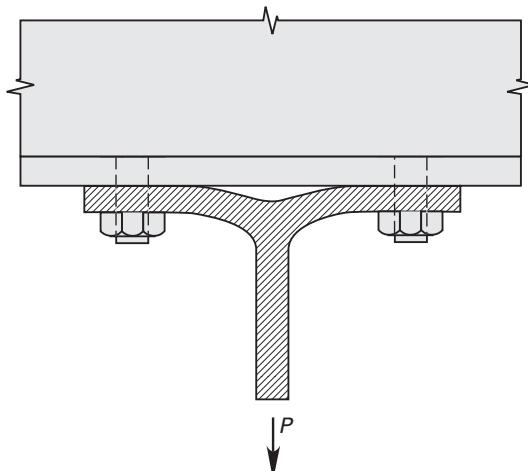

## 9. TENSION CONNECTIONS

Figure 65.3 illustrates a basic *tension connection*. As the name implies, fasteners in this hanger-type connection are subjected to tensile stresses. The nominal strength of bolts in tension is equal to the bolt area,  $A_b$ , multiplied by the nominal tension stress,  $F_{nt}$ . Nominal tension stresses in bolts are listed in Table J3.2 in the *AISC Specification*.

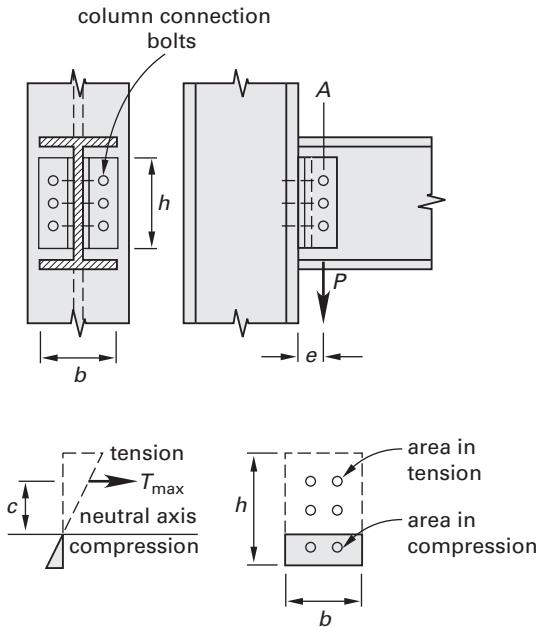

$$P = A_b F_{nt} \quad 65.5$$

## 10. COMBINED SHEAR AND TENSION CONNECTIONS

The tendency of the flanges to act as cantilever beams when a load is applied to them is called *prying action*. This must be considered in the design of tension connections. The effect of prying action is to increase the tension in the bolts.

**Figure 65.3** Fasteners in Tension Connection

Consider the simple framing connection that is shown in Fig. 65.4. If the vertical shear is assumed to act along line A, the bolts in the column connection will be put into tension by prying action. The most highly stressed (in tension) will be the topmost fasteners.

**Figure 65.4** Combined Shear and Tension Connection.

The moment on the connection is easily calculated, and the uppermost line of connectors is most likely to experience the greatest effect from prying. However, the performance of bolted connections with prying action is too complex to be evaluated without knowing certain factors and assuming others. The type of connectors, the type of connection (friction or bearing), and the amount of pretension all affect the methodology used. In friction-type connection with pretensioned bolts, the prying will

separate the pieces, elongating the bolts and reducing the stress in the bolts. Another complexity is the yielding that occurs to reduce the applied moment.

Part 7 of the *AISC Manual* outlines two methods for designing connections with combined shear and tension depending on assumptions regarding the neutral axis of the bolt group. The more direct and more conservative method is to assume the neutral axis at the center of gravity of the bolt group. The bolts in the tension region are subject to tension, shear, and prying action if any exists. Bolts in the compressive region are subject to shear alone. The required shear strength per bolt is merely the required shear force divided by the number of bolts. The required tension strength is the eccentric moment divided by the number of bolts in the tension region and the moment arm. Prying action must also be considered.

## 11. FRAMING CONNECTIONS

All connections are assumed to have some rigidity and are divided into two categories—FR, or *fully restrained* rigid connections (previously referred to as Type 1, rigid connections), and PR, or *partially restrained* semi-rigid connections (previously referred to as Type 3, semi-rigid connections). *Rigid connections* are assumed to be sufficiently rigid to maintain the angle of rotation between two connected parts like a beam and a column. *Semi-rigid connections* are assumed to lack the rigidity to maintain the rotation between two connected parts.

A simple connection (previously referred to as a Type 2, simple framing connection) is a PR connection without any rigidity. It is generally assumed that an FR connection will be able to develop at least 90% of a moment developed by a perfectly rigid connection. Other PR connections fall somewhere between the simple connection and the FR connection. PR connections are covered in *AISC Manual* Part 11.

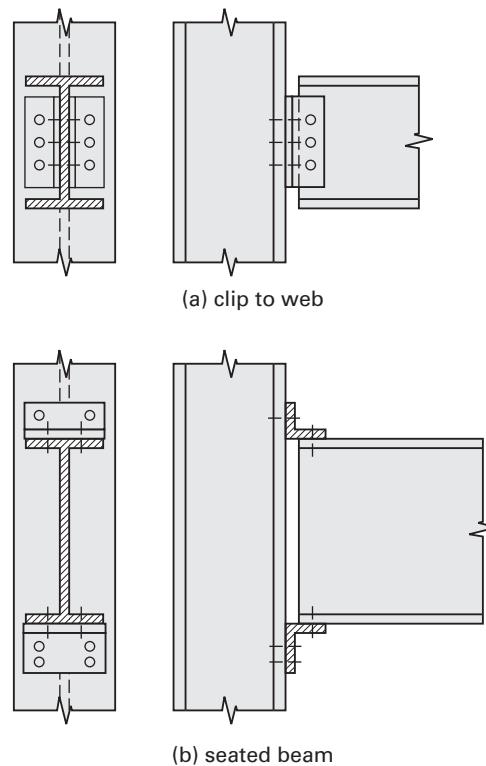

## 12. SIMPLE FRAMING CONNECTIONS

Simple framing connections are designed to be as flexible as possible. Design is predetermined by use of the standard tables of framed beam connections in the *AISC Manual*. Construction methods include use of beam seats and clips to beam webs. (See Fig. 65.5.)

Connections to beams and columns can be made by bolting and/or welding, and such fastening methods can be used on either the beams or the columns. Welded connections, stiffened connections, and the use of top seats do not necessarily imply a moment-resisting connection.

Direct shear determines the number of bolts required in the column connection. It is common to neglect the effect of eccentricity in determining shear stresses in riveted and bolted beam connections to webs. It is also common to neglect the effect of eccentricity in determining shear stresses in riveted and bolted column

**Figure 65.5** Bolted Simple Framing Connections

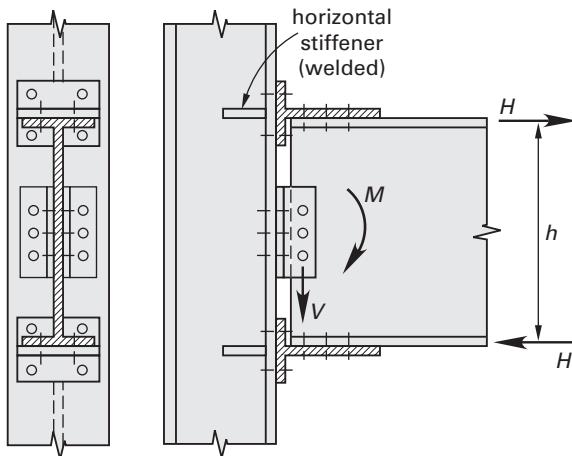

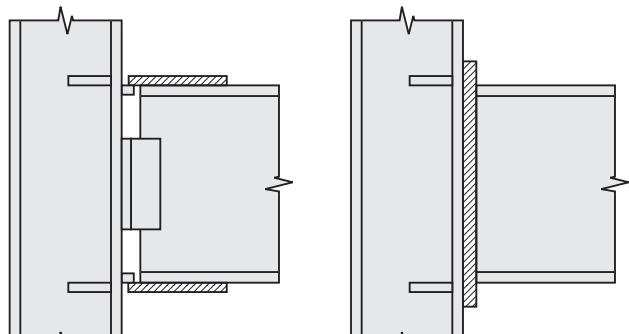

connections. However, the eccentricity can be considered, which will add tension stress to the shear stress on column fasteners.

Angle thickness must be checked for allowable bearing stress. Angles should be checked for direct shear, as well. Since the connection is designed to rotate, the angle (for seated beams) should be checked for bending stress as its free lip bends.

## 13. MOMENT-RESISTING FRAMING CONNECTIONS

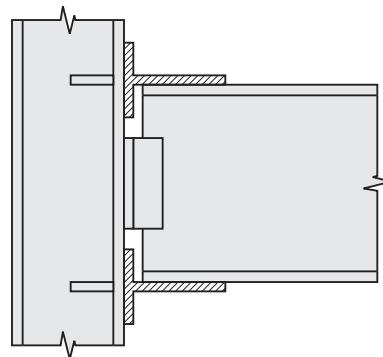

*FR moment-resisting connections* are covered in *AISC Manual* Part 12. They transmit their vertical (shearing) load through the same types of connections as simple connections, typically through connections at the beam web. However, the flanges of the beam are also rigidly connected to the column. These top and bottom flange connections are in tension and compression respectively, and they serve to transmit the moment. (See Fig. 65.6.)

Since moment transfer is through the flanges by tension and compression connections, the design of such connections involves ensuring adequate strength in tension and compression. Design of the shear transfer mechanism (i.e., the web connections) is essentially the same as for simple connections. Also, in order to prevent localized failure of the column flanges, horizontal stiffeners (between the column flanges) may be needed.

**Figure 65.6** Bolted Moment-Resisting Framing Connections**Figure 65.8** Welded Moment-Resisting Connections\*

(a) top plate construction

(b) end plate construction

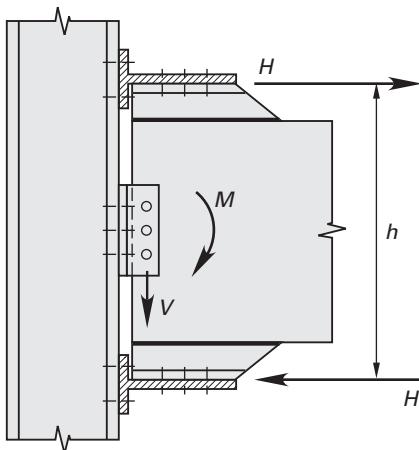

(c) split beam tee construction

The moment-resisting ability of a simple connection can be increased to essentially any desired value by increasing the distance between the tension and compression connections. Figure 65.7 illustrates how this could be accomplished by using an intermediate plate between the beam flanges and the column. The horizontal tensile and compressive forces,  $H$ , can be calculated from Eq. 65.6.

$$H = \pm \frac{M}{h} \quad 65.6$$

Special attention to moment-resisting connections is critical (and required) in regions of seismicity. Designs must specifically compensate for brittle fracture. (See Fig. 65.8.) This is a specialized area of structural engineering requiring knowledge of seismic design concepts.

## 1. INTRODUCTION

Welding is a joining process in which the surfaces of two pieces of structural steel (the *base metal*) are heated to a fluid state, usually with the addition of other molten steel (called *weld metal* or *filler metal*) from the *electrodes*. The properties of the base metal and those of the deposited weld metal should be similar, but the weld metal should be stronger than the metals it connects.

The American Welding Society's *Structural Welding Code—Steel* (AWS D1.1) is the governing standard for structural welding, and it is incorporated by reference, with a few differences, into *AISC Manual Part 8*.

Two processes are typically used for structural welding. The *shielded metal arc welding* (SMAW) process is used both in the shop and in the field. Electrodes available for SMAW welding are designated as E60XX, E70XX, E80XX, E90XX, E100XX, and E110XX. The letter E denotes an electrode. The first two digits indicate the electrode's ultimate tensile strength, *F<sub>u</sub>*, in ksi; the tensile strength of the weld metal ranges from 60 ksi to 110 ksi. The XX designations indicate how the electrodes are used.

The *submerged arc welding* (SAW) process is primarily used in the shop. The electrodes for the SAW process are specified somewhat differently. Each designation is a combination of flux (that shields the weld) and electrode classifications. For example, in the designation F7X-E7XX, F indicates a granular flux, the first digit following F represents the tensile strength requirement of the resulting weld (e.g., 7 means 70 ksi), E represents an electrode, the first digit following the E represents the minimum tensile strength of the weld metal (e.g., 7 means 70 ksi), and the XX represents numbers related to the use. The most commonly used electrode for

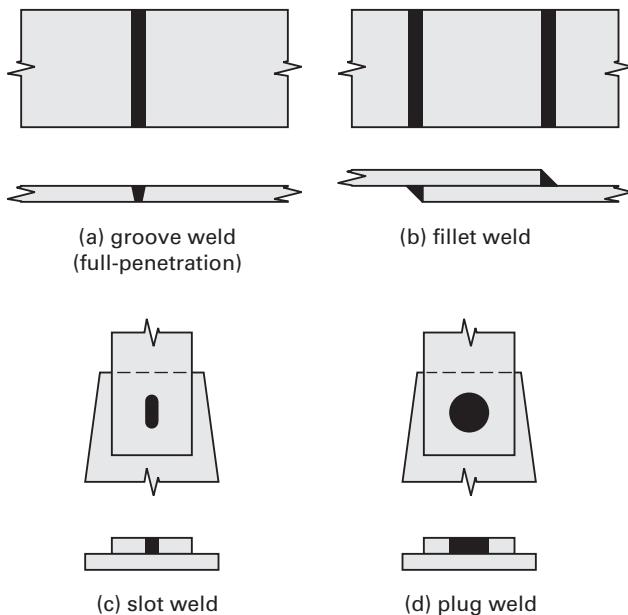

structural work is E70 because it is compatible with all grades of steel having yield stresses,  $F_y$ , up to 60 ksi.

In addition to SMAW and SAW, other welding processes that are occasionally used are *gas metal arc welding* (GMAW, also known as *metal inert gas welding* (MIG) and *metal active gas welding* (MAG)); *flux-cored arc welding* (FCAW, often an automated process); *electrogas welding* (EGW, a continuous, vertical position, high-deposition process that uses retaining shoes to confine the molten metal); and *electroslag welding* (ESW, useful with extremely thick-walled materials, which melts the base and filler metals by passing current through the molten conductive slag).

## 2. TYPES OF WELDS AND JOINTS

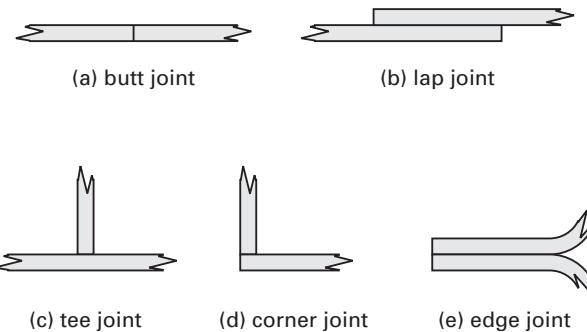

Figure 66.1 shows four common types of welds: fillet, groove, plug, and slot. Each type of weld has certain advantages that determine the extent of its use. The *fillet weld* is the most commonly used type in structural connections due to its overall economy and its ease of fabrication. The *groove weld* is primarily used to connect structural members aligned in the same plane. It is more costly, as it often requires extensive edge preparation and precise fabrication. The weld extends all the way from one side to the opposite side of the abutted pieces in a *full-penetration groove weld* (*complete-penetration groove weld* or *CJP weld*). In a *partial-penetration groove weld* (*PJP weld*), a portion of the butt connection remains unwelded, and the name applies even if a second partial-penetration groove weld is applied to the second side. The use of *slot welds* and *plug welds* is rather limited—they are used principally in combination with fillet welds, where the size of the connection limits the length available for fillet welds.

**Figure 66.1** Types of Welds

There are five basic types of joints: butt, lap, tee, corner, and edge, as shown in Fig. 66.2. The type of joint depends on factors such as type of loading, shape and size of members connected, joint area available, and relative costs of various types of welds. The *lap joint* is the most common type because of ease of fitting (i.e., there is no need for great precision in fabrication) and ease of joining (i.e., there is no need for special preparation of edges being joined). Standard weld symbols are shown in Fig. 66.3.

**Figure 66.2** Types of Welded Joints

## 3. FILLET WELDS

An enlarged view of a fillet weld is shown in Fig. 66.4. The applied load is assumed to be carried by the weld throat, which has an effective dimension of  $t_e$ .

The effective weld throat thickness,  $t_e$ , depends on the type of welding used. For hand-held, shielded metal arc welding (SMAW) processes,

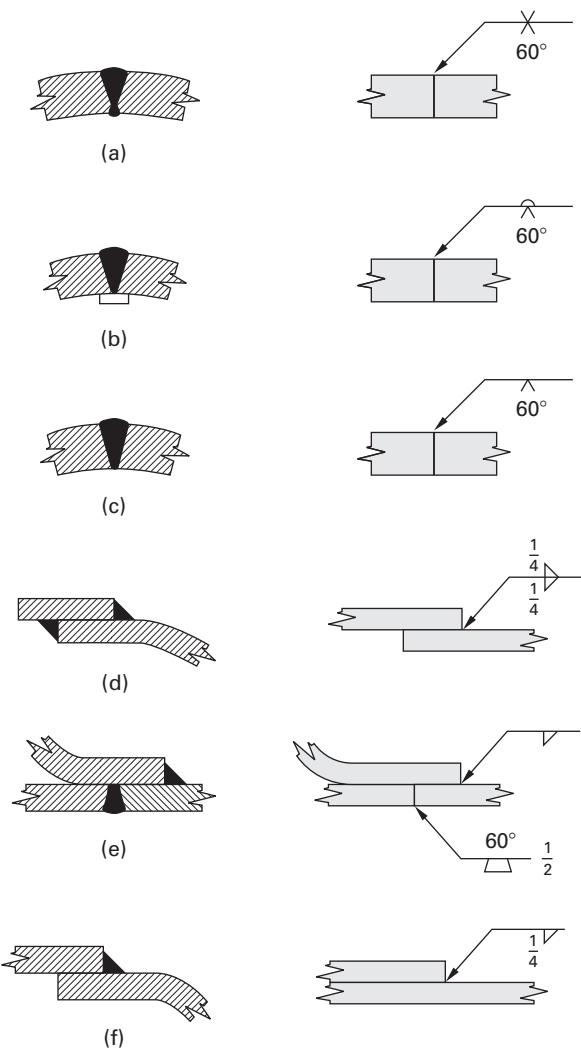

$$t_e = 0.707w \quad 66.1$$

The effective throat of a fillet weld may be larger than that given by Eq. 66.1 if consistent penetration beyond the root of the weld is provided. Appropriate tests are required to justify an increase in the effective throat [AISC Specification Sec. J2.2a].

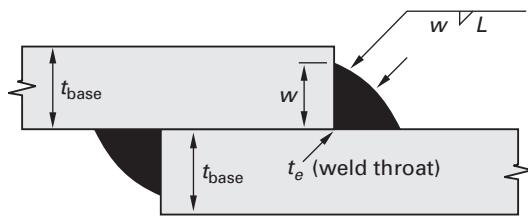

Weld sizes,  $w$ , of  $3/16$  in,  $1/4$  in, and  $5/16$  in are desirable because they can be made in a single pass. ( $5/16$  in is an appropriate limit for SMAW, especially when using hand-held rods. If SAW is used, up to  $1/2$  in welds can be made in one pass.) However, fillet welds from  $3/16$  in to  $1/2$  in can be made in  $1/16$  in increments. For welds larger than  $1/2$  in, every  $1/8$  in weld size can be made.

In almost all instances, loads carried by welds result in shear stresses in the weld material, regardless of the weld group orientation. The available shear strength on the weld throat is found from AISC Specification Table J2.5.

$$F_v = 0.60 F_{u,rod} \quad 66.2$$

**Figure 66.3** Standard Weld Symbols\*

\*Designations: (a) double-weld butt joint, (b) single-weld butt joint with integral backing strip, (c) single-weld butt joint without backing strip, (d) double-full fillet lap joint, (e) single-full fillet lap joint with plug welds, and (f) single-full fillet lap joint without plug welds.

**Figure 66.4** Fillet Weld

The shear stress in a concentrically loaded fillet weld group is

$$f_v = \frac{P}{A_w} = \frac{P}{l_w t_e} \quad 66.3$$

Shear and tensile strengths of the weld may not be greater than the nominal strength per unit area of the base metal times the cross-sectional area of the base metal, or the nominal strength of the weld metal per unit area times the area of the weld [AISC Specification Sec. J2.4]. For tensile or compressive loads, the allowable strength parallel to the weld axis is the same as for the base metal.

To simplify the analysis and design of certain types of welded connections, it is convenient to define the shear resistance per unit length of weld as Eq. 66.4. (When the base material thickness is small, the weld strength may be limited by the shear strength of the base metal. This should also be checked.)

$$R_w = 0.30 t_e F_{u,rod} \quad 66.4$$

Several special restrictions apply to fillet welds [AISC Specification Sec. J2.2b].

- Minimum weld size depends on the thickness of the thinner of the two parts joined, except that the weld size need not exceed the thickness of the thinner part. (See Table 66.1.) (When weld size is increased to satisfy these minimums, the capacity is not increased. Weld strength is based on the theoretical weld size calculated.)
- For materials less than  $\frac{1}{4}$  in thick, the maximum weld size along edges of connecting parts is equal to the material thickness. For materials thicker than  $\frac{1}{4}$  in, the maximum size must be  $\frac{1}{16}$  in less than the material thickness.
- The minimum-length weld for full strength analysis is four times the weld size. (If this criterion is not met, the weld size is reduced to one-fourth of the weld length.)
- If the strength required of a welded connection is less than would be obtained from a full-length weld of the smallest size, then an intermittent weld can be used. The minimum length of an intermittent weld is four times the weld size or  $1\frac{1}{2}$  in, whichever is greater.
- The minimum amount of lap length for lap joints (as illustrated in Fig. 66.2) is five times the thinner plate's thickness, but not less than 1 in.

**Table 66.1** Minimum Fillet Weld Size

thickness of thinner part joined (in)	minimum weld size* w (in)
to $\frac{1}{4}$ inclusive	$\frac{1}{8}$
over $\frac{1}{4}$ to $\frac{1}{2}$ inclusive	$\frac{3}{16}$
over $\frac{1}{2}$ to $\frac{3}{4}$ inclusive	$\frac{1}{4}$
over $\frac{3}{4}$	$\frac{5}{16}$

(Multiply in by 25.4 to obtain mm.)

\*Leg dimension of fillet weld. Single pass welds must be used.

Source: From AISC Specification Table J2.4.

#### 4. CONCENTRIC TENSION CONNECTIONS

*AISC Specification* Sec. J2.4 and Table J2.5 describe how the available strength of a weld group is determined. The method can be simplified for a single longitudinally loaded fillet weld whose length,  $l$ , is less than  $100w$ . Taking into consideration the LRFD resistance factor,  $\phi = 0.75$ , and the ASD safety factor,  $\Omega = 2.00$ , for fracture, the available nominal strength of a longitudinally loaded fillet weld is

$$\phi R_n = 1.392Dl \quad [\text{LRFD; E70 electrode}] \quad 66.5$$

$$\frac{R_n}{\Omega} = 0.928Dl \quad [\text{ASD; E70 electrode}] \quad 66.6$$

For fillet welds that are loaded in any manner other than longitudinally, the weld strength is increased due to a greater shear area due to the load angle, and the *ductility* (referred to as *load-deformation compatibility*) is decreased. The decrease in ductility is inconsequential for single line welds. The maximum strength increase, 50%, occurs when the loading is transverse the weld length. *AISC Specification* Table J2.5 describes the strength increase for various application angles. For a weld group with welds at various angles to a concentric load, the total available strength (without needing to consider ductility loss) can be taken as the sum of the available weld strengths assuming longitudinal loading (i.e., no increases) for all welds. Alternatively, *AISC Manual* Table 8-1, which accounts for loss of ductility, may be used.

##### Example 66.1

Two  $1/2$  in  $\times$  8 in A36 steel plates are lap-welded using E70 electrodes with a shielded metal arc process. Size the weld to carry a concentric tensile loading of 50 kips.

*Solution*

Good design will weld both joining ends to the base plate. The total weld length will be

$$l_w = (2)(8 \text{ in}) = 16 \text{ in}$$

Using Table 66.1, the minimum weld thickness for a  $1/2$  in plate is  $3/16$  in. Try  $w = 3/16$  in. The length meets the minimum-length specification of four times the weld size.

*LRFD Method*

The required strength is

$$R_n = P_u = (1.6)(50 \text{ kips}) = 80 \text{ kips}$$

The required strength per inch is

$$\frac{80 \text{ kips}}{16 \text{ in}} = 5 \text{ kips/in}$$

The available strength, as given in *AISC Manual* Part 8, where  $D$  is the weld size in sixteenths of an inch and  $l$  is the length, is

$$\frac{\phi R_n}{l} = 1.392D = (1.392)(3) = 4.176 \text{ kips/in}$$

$$< 5 \text{ kips/in} \quad [\text{NG}]$$

Since the available strength is less than the required strength, try a  $1/4$  in weld.

$$\frac{\phi R_n}{l} = 1.392D = (1.392)(4) = 5.568 \text{ kips/in}$$

$$> 5 \text{ kips/in} \quad [\text{OK}]$$

Since  $\phi R_n > R_n = P_a$ , use a  $1/4$  in weld.

*ASD Method*

The required strength is

$$P_a = 50 \text{ kips}$$

The required strength per inch is

$$\frac{50 \text{ kips}}{16 \text{ in}} = 3.125 \text{ kips/in}$$

The available strength, as given in *AISC Manual* Part 8, where  $D$  is the weld size in sixteenths of an inch and  $l$  is the length, is

$$\frac{R_n}{\Omega l} = 0.928D = (0.928)(3) = 2.784 \text{ kips/in}$$

$$< 3.125 \text{ kips/in} \quad [\text{NG}]$$

Since the available strength is less than the required strength, try a  $1/4$  in weld.

$$\frac{R_n}{\Omega l} = 0.928D = (0.928)(4) = 3.712 \text{ kips/in}$$

$$> 3.125 \text{ kips/in} \quad [\text{OK}]$$

Since  $R_n/\Omega > R_n = P_a$ , use a  $1/4$  in weld.

The maximum weld size allowed is  $1/2$  in  $- 1/16$  in  $= 7/16$  in. The  $1/4$  in weld can be used.

#### 5. BALANCED TENSION WELDS

When tension is applied along an unsymmetrical member, the tensile force will act along a line passing through the centroid of the member. In that instance, it may be desirable or necessary to design a *balanced weld group* in order to have the force also pass through the centroid of the weld group. (*AISC Specification* Sec. J1.7 exempts single and double angles from the need to balance welds when loading is static. All other static loading configurations, and angles subjected to fatigue loading, must have balanced welds.)

The procedure for designing the unequal weld lengths assumes that the end weld (if present) acts at full shear stress with a resultant passing through its mid-height (e.g.,  $d/2$  in Fig. 66.5). The forces in the other welds are assumed to act along the edges of the angle. Moments are taken about a point on the line of action of either longitudinal weld, resulting in Eq. 66.7.

$$P_3 = T\left(1 - \frac{y}{d}\right) - \frac{P_2}{2} \quad 66.7$$

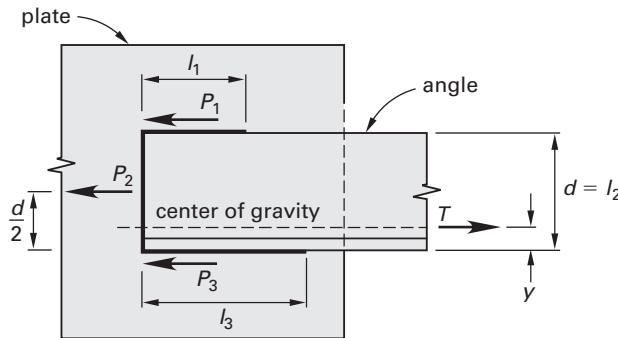

$$P_2 = R_w l_2 = R_w d \quad 66.8$$

$$P_1 = T - P_2 - P_3 \quad 66.9$$

$$l_1 = \frac{P_1}{R_w} \quad 66.10$$

$$l_3 = \frac{P_3}{R_w} \quad 66.11$$

**Figure 66.5** Balanced Weld Group

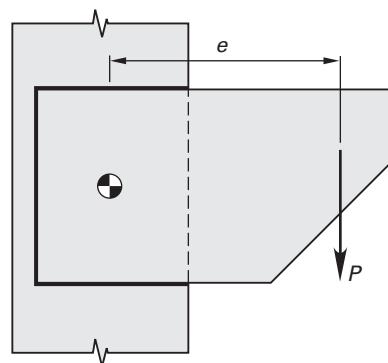

## 6. ECCENTRICALLY LOADED WELDED CONNECTIONS

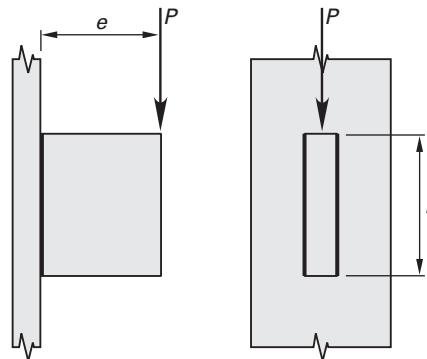

There are two possible loading conditions that will result in an eccentrically loaded weld group: (a) loading in the plane of the weld group (as shown in Fig. 66.6) causing combined shear and torsion, and (b) loading out of the plane of the weld group causing combined shear and bending (as shown in Fig. 66.7). These two cases are also distinguished by the orientation of the line of eccentricity. The loading in Fig. 66.6 is *eccentricity in the plane of the faying surfaces*, while the loading in Fig. 66.7 is *eccentricity normal to the plane of the faying surfaces*.

The complexity of the stress distribution in shear/torsion connections makes accurate analysis and design based on pure mechanics principles impossible. Therefore, simplifications are made and the assumed shear stress in the most critical location is calculated. This type of problem can be dealt with in two ways, as described in *AISC Manual* Part 8: the elastic method and the instantaneous center of rotation method. Both methods are permitted.

**Figure 66.6** Welded Connection in Combined Shear and Torsion (eccentricity in plane of faying surfaces)

**Figure 66.7** Welded Connection in Combined Shear and Bending (eccentricity normal to plane of faying surfaces)

## 7. ELASTIC METHOD FOR ECCENTRIC SHEAR/TORSION CONNECTIONS

The elastic method (for eccentricity in the plane of the faying surfaces) starts by finding the centroid of the weld group. The centroid can be located by weighting the weld areas (calculated from the weld throat size and length) by their distances from an assumed axis, or the welds can be treated as lines and their lengths used in place of their areas. Appendix 45.A is useful in this latter case. (In an analysis of a weld group, the throat size will be known and welds can be treated as areas. In design, the throat size will be unknown, and it is common to treat the welds as lines. Alternatively, a variable weld size can be used and carried along in a design problem. However, the results will be essentially identical.)

Once the centroid is located, the polar area moment of inertia,  $I_p$ , is calculated.<sup>1</sup> *AISC Manual* Fig. 8-6 provides detailed information for this parameter. This is usually accomplished by calculating and adding the moments of inertia with respect to the horizontal and vertical axes.

<sup>1</sup>The symbol  $J$  is used in other chapters of this book to represent the polar area moment of inertia.  $I_p$  is the symbol used in *AISC Manual* Part 8.

For the purpose of calculating the moment of inertia, the welds may also be treated as either areas or lines.

$$I_p = I_x + I_y \quad 66.12$$

The distance,  $c$ , from the weld group centroid to the critical location in the weld group is next determined, usually by inspection. This distance is used to calculate the torsional shear stress,  $r$ .<sup>2</sup>

$$r_m = \frac{Mc}{I_p} = \frac{Pec}{I_p} \quad 66.13$$

The direct shear stress is easily calculated from the total weld area (or length, if the throat size is not known).

$$r_p = \frac{P}{A} \quad 66.14$$

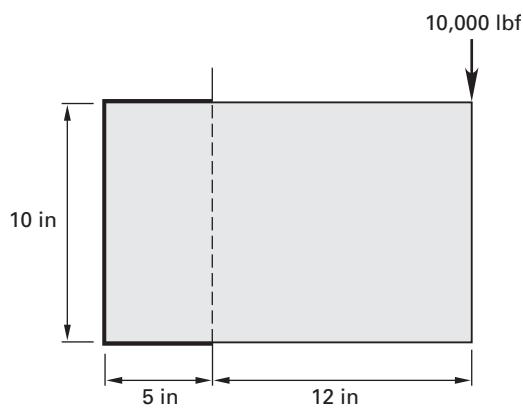

Vector addition is used to combine the torsional and direct shear stresses (i.e., the resultant shear stress).

$$r_a = \sqrt{(r_{m,y} + r_p)^2 + (r_{m,x})^2} \quad 66.15$$

Although the elastic method is simple, it does not result in a consistent factor of safety and may result in an excessively conservative design of connections.

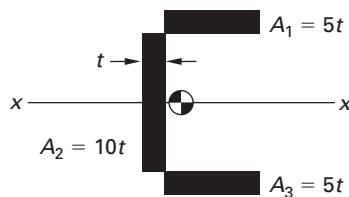

### Example 66.2

A 50 ksi plate bracket is attached using shielded metal arc welding with E70 electrodes to the face of a 50 ksi column as shown. Buckling and bending of the plate and column can be neglected. Using ASD, what size fillet weld is required?

### Solution

*step 1:* Assume the weld has an effective throat thickness,  $t$ .

*step 2:* Find the centroid of the weld group. By inspection,  $y_c = 0$ . For the three welds,

$$A_1 = 5t$$

$$\bar{x}_1 = 2.5 \text{ in}$$

$$A_2 = 10t$$

$$\bar{x}_2 = 0$$

$$A_3 = 5t$$

$$\bar{x}_3 = 2.5 \text{ in}$$

$$\bar{x}_c = \frac{(5t)(2.5 \text{ in}) + (10t)(0) + (5t)(2.5 \text{ in})}{5t + 10t + 5t} \\ = 1.25 \text{ in}$$

*step 3:* Determine the centroidal moment of inertia of the weld group about the  $x$ -axis. Use the parallel axis theorem for areas 1 and 3.

$$I_x = \frac{t(10 \text{ in})^3}{12} + (2) \left( \frac{(5 \text{ in})^3}{12} + (5 \text{ in})t(5 \text{ in})^2 \right) \\ = 333.33t + 0.833t^3$$

Since  $t$  will be small (probably less than 0.5 in), the  $t^3$  term can be neglected. So,  $I_x = 333.33t$ .

*step 4:* Determine the centroidal moment of inertia of the weld group about the  $y$ -axis.

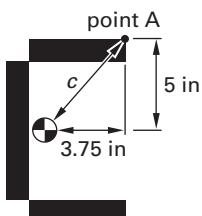

$$I_y = \frac{(10 \text{ in})^3}{12} + (10 \text{ in})t(1.25 \text{ in})^2 \\ + (2) \left( \frac{t(5 \text{ in})^3}{12} + (5 \text{ in})t(1.25 \text{ in})^2 \right) \\ = 52.08t + 0.833t^3 \approx 52.08t$$

*step 5:* The polar moment of inertia is

$$I_p = I_x + I_y = 333.33t + 52.08t = 385.42t$$

<sup>2</sup>The symbols  $r$  and  $f_v$  (or,  $\tau$ ) are used in other chapters of this book to represent the radial distance to a point of extreme stress and shear stress, respectively. The symbols  $c$  and  $r$  are used in *AISC Manual Part 8*, which defines the units of  $r$  as lbf/in (shear per inch of weld) rather than lbf/in<sup>2</sup> (shear stress). The actual units of  $r$  depend on the unit of  $I$ , which may be either in<sup>3</sup> (welds considered to be dimensionless lines) or in<sup>4</sup> (welds considered to be lines of thickness,  $t$ ).

*step 6:* By inspection, the maximum shear stress will occur at point A.

$$c = \sqrt{(3.75 \text{ in})^2 + (5 \text{ in})^2} = 6.25 \text{ in}$$

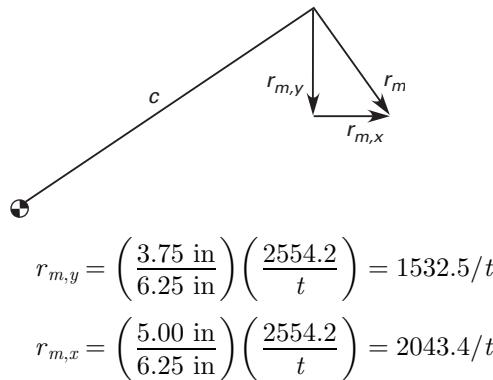

*step 7:* The applied moment is

$$\begin{aligned} M &= Pe = (10,000 \text{ lbf})(12 \text{ in} + 3.75 \text{ in}) \\ &= 157,500 \text{ in-lbf} \end{aligned}$$

*step 8:* The torsional shear stress is given by Eq. 66.13.

$$\begin{aligned} r_m &= \frac{Mc}{I_p} = \frac{(157,000 \text{ in-lbf})(6.25 \text{ in})}{385.42t} \\ &= 2554.2/t \end{aligned}$$

This shear stress is directed at right angles to the line  $c$ . The  $x$ - and  $y$ -components of the stress can be determined from geometry.

*step 9:* The direct shear stress from Eq. 66.14 is

$$\begin{aligned} r_{p,y} &= \frac{P}{A} = \frac{10,000 \text{ lbf}}{t(5 \text{ in} + 10 \text{ in} + 5 \text{ in})} \\ &= 500/t \end{aligned}$$

*step 10:* Using Eq. 66.15, the resultant shear stress at point A is

$$\begin{aligned} r_a &= \sqrt{\left( \frac{1532.5 + 500}{t} \right)^2 + \left( \frac{2043.4}{t} \right)^2} \\ &= 2882.1/t \end{aligned}$$

*step 11:* For a 50 ksi base metal with a 70 ksi rod, the weld strength controls the available strength (because not all of the 70 ksi strength is "available"). The design strength is given by Eq. 66.2 divided by the strength reduction factor, which is equal to 2.0.

$$\begin{aligned} \frac{F_w}{\Omega} &= \frac{0.6F_u}{2.0} = \frac{(0.6)(70 \frac{\text{kips}}{\text{in}^2})}{2.0} \\ &= 21 \text{ ksi} \end{aligned}$$

*step 12:* Equate the allowable stress to the shear stress at point A.

$$\begin{aligned} \frac{2882.1}{t} &= \left( 21 \frac{\text{kips}}{\text{in}^2} \right) \left( 1000 \frac{\text{lbf}}{\text{kip}} \right) \\ t &= 0.137 \text{ in} \end{aligned}$$

Use a  $3/16$  in (0.1875 in) weld.

### Example 66.3

Use App. 45.A to calculate the polar moment of inertia of the weld group in Ex. 66.2.

*Solution*

From App. 45.A, with  $b = 5$  in and  $d = 10$  in,

$$\begin{aligned} I_p &= \left( \frac{\frac{(8)(5 \text{ in})^3 + (6)(5 \text{ in})(10 \text{ in})^2 + (10 \text{ in})^3}{12 \text{ in}} - \frac{(5 \text{ in})^4}{(2)(5 \text{ in}) + 10 \text{ in}}}{t} \right) \\ &= 385.42t \end{aligned}$$

(This is the same result as was calculated in Ex. 66.2.)

## 8. AISC INSTANTANEOUS CENTER OF ROTATION METHOD FOR ECCENTRIC SHEAR/TORSION CONNECTIONS

An eccentrically loaded weld group has a tendency to rotate about a point called the *instantaneous center of rotation* (IC). The location of this point depends on the eccentricity, the geometry of the weld group, and the deformation of weld elements. The ultimate shear strength of a weld group is obtained by linking the load-deformation relationship of individual weld elements to the correct location of the instantaneous center. The AISC instantaneous center of rotation method calculates the capacity of an eccentrically loaded welded connection as Eq. 66.16.

$$R_n = CC_1Dl$$

66.16

$C$  and  $C_1$  are coefficients from the Eccentrically Loaded Weld Groups, Table 8-3 through Table 8-11, in the *AISC Manual*. These coefficients depend on the load configuration and electrode type.  $D$  is the number of multiples of  $\frac{1}{16}$  in in the weld size.  $l$  is the weld length.

#### Example 66.4

Use the *AISC Manual* to calculate the capacity of the weld group designed in Ex. 66.2.

*Solution*

Referring to *AISC Manual* Table 8-8,

$$l = 10 \text{ in}$$

$$kl = 5 \text{ in}$$

$$al = 12 \text{ in} + 3.75 \text{ in} = 15.75 \text{ in}$$

For a  $\frac{1}{4}$  in weld and E70 electrodes, the following coefficients are needed.

$$k = \frac{5 \text{ in}}{10 \text{ in}} = 0.5$$

$$a = \frac{15.75 \text{ in}}{10 \text{ in}} = 1.575$$

$$C = 1.10 \quad [\text{interpolated}]$$

$$C_1 = 1 \quad \left[ \begin{array}{l} \text{for E70 electrodes from} \\ \text{AISC Manual Table 8-3} \end{array} \right]$$

$$D = \frac{\frac{1}{4} \text{ in}}{\frac{1}{16} \text{ in}} = 4$$

From Eq. 66.16, the capacity of the connection is

$$R_n = CC_1Dl = (1.10)(1)(4)(10) = 44 \text{ kips}$$

#### 9. ELASTIC METHOD FOR OUT OF PLANE LOADING

Unlike bolted connections where bolts may be in tension, shear, or a combination of tension and shear, welds resist applied loads entirely in shear. Figure 66.7 illustrates a welded connection with eccentricity normal to the plane of the faying surfaces where the welds are stressed by both direct shear and moment-induced shear. Even though the maximum shear and maximum bending moment do not actually occur at the same place, assumptions are made that combine the stresses. As with eccentricity in the plane of the faying surfaces, either the elastic method or the instantaneous center of rotation method using *AISC Manual* Table 8-4 may be used, and the same comments related to these methods are relevant: The elastic method understates the capacity, and the instantaneous center of rotation method is essentially a table look-up procedure.

The nominal shear stress is

$$f_v = \frac{P_n}{A_w} = \frac{P_n}{2Lt_e} \quad 66.17$$

The nominal bending stress is easily calculated if the section modulus,  $S$ , of the weld group is obtained from App. 45.A.

$$f_b = \frac{Mc}{I} = \frac{M}{S} = \frac{P_n e}{S} \quad 66.18$$

The resultant stress is

$$f = \sqrt{f_v^2 + f_b^2} \quad 66.19$$

The resultant stress must be less than the allowable stress, as calculated from Eq. 66.2.

#### 10. WELDED CONNECTIONS IN BUILDING FRAMES

Part 10 of the *AISC Manual* contains tables listing capacities of various welded (E70XX electrodes) shear connections: framed beam connections, seated beam connections, stiffened seated beam connections, and end plate shear connections. The *AISC Manual* also contains several procedures for designing moment connections (both FR and PR). These procedures specifically assume top plate or end plate construction (as in Fig. 65.8) in order to transmit moments. Construction with split beam tees and the accompanying *prying action* are not addressed. See Chap. 65 for more information.

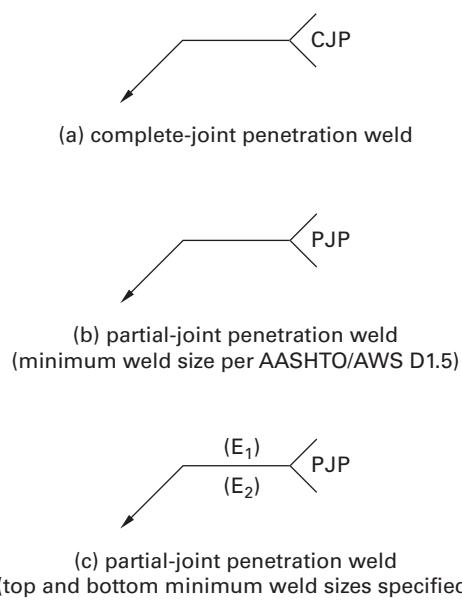

Welded beam-column connections intended to transfer moment in seismically active areas require special consideration to ensure that the connection behaves in a ductile manner.

#### 11. AASHTO LRFD PROVISIONS FOR WELDED CONNECTIONS

Welding on bridge steels is covered in the AASHTO/AWS *Bridge Welding Code* D1.5 (AASHTO/AWS D1.5) welding specifications. Since bridge welds are subject to fatigue and fracture, AASHTO/AWS D1.5 is more restrictive than the more general *Structural Welding Code* (AWS D1.1). AASHTO's *LRFD Bridge Design Specifications* (AASHTO *LRFD*) specifies weld strength limitations for different types of welds (e.g., complete-penetration groove, partial-penetration groove, and fillet), the types of stress that welds experience (e.g., tensile, compressive, and shear), and the weld direction (e.g., parallel or normal to the loading direction). (See Fig. 66.8.)

For complete-penetration groove weld connections subjected to tension or compression normal to the effective area or parallel to the axis of the weld, the factored resistance is taken as the factored resistance of the base

**Figure 66.8** Symbols for Groove Welds Used in Bridge Construction

metal. When these connections are subjected to shear, the factored resistance is the lesser of 60% of the factored resistance of the weld metal or 60% of the factored resistance of the base metal in tension.

For partial-penetration groove weld connections subjected to tension or compression parallel to the axis of the weld or compression normal to the effective area, the factored resistance is taken as the factored resistance of the base metal. When these connections are subjected to tension normal to the effective area, the factored resistance is the lesser of 60% of the factored resistance of the weld metal or the factored resistance of the base metal. When these connections are subjected to shear, the factored resistance is taken as the lesser of 60% of the factored resistance of the base metal or the factored resistance of the weld metal. If unspecified, Table 66.2 specifies the minimum effective weld size. The effective weld size of a PJP weld is the depth of bevel with or without a deduction of 3 mm ( $\frac{1}{8}$  in) [AASHTO/AWS D1.5].<sup>3</sup>

**Table 66.2** Minimum Effective Weld Sizes of Fillet and PJC Welds Used in Bridges\*

base metal thickness of thicker part joined	minimum effective weld size
$\leq 20$ mm ( $\frac{3}{4}$ in)	6 mm ( $\frac{1}{4}$ in)
$> 20$ mm ( $\frac{3}{4}$ in)	8 mm ( $\frac{5}{16}$ in)

\*Weld sizes larger than the thickness of the thinner part are not required.

Source: AASHTO/AWS D1.5 Table 2.1 and Table 2.2

For fillet weld connections subjected to tension or compression parallel to the axis of the weld, the factored resistance is the factored resistance of the base metal. When these connections are subjected to shear, the factored resistance is taken as 60% of the factored resistance of the weld metal.

<sup>3</sup>AASHTO/AWS D1.5 Sec. 2.3.1 defines how the effective weld size is measured. The effective weld size of a CJP weld is the thickness of the thinner part joined. For a PJP weld, when made by SMAW or SAW, or when made in the vertical or overhead welding positions by GMAW or FCAW, and when the groove root angle is less than 60° but not less than 45°, the effective weld size is the depth of the bevel less 3 mm ( $\frac{1}{8}$  in). The effective weld size of a PJP weld is the depth of bevel, without reduction, for grooves (1) with a root groove angle of 60° or greater when made by SMAW, SAW, GMAW, FCAW, EGW, or ESW, or (2) with a root groove angle not less than 45° when made in flat or horizontal positions by GMAW or FCAW.

## 1. INTRODUCTION

Masonry units used in the United States include concrete, clay (brick as well as structural clay tile), glass block, and stone. Concrete and clay masonry are used for the majority of structural masonry construction.

The relevant structural properties of clay and concrete masonry are similar, although test methods and requirements can vary significantly between the two materials. Requirements listed in this chapter are those of ACI 530/ASCE 5/TMS 402, *Building Code Requirements for Masonry Structures*, referred to as *MSJC* (Masonry Standards Joint Committee), and ACI 530.1/ASCE 6/TMS 602, *Specification for Masonry Structures*, referred to as the *MSJC Specification*, as referenced in and modified by the *International Building Code* (IBC).

## 2. UNIT SIZES AND SHAPES OF CONCRETE MASONRY

Concrete masonry units (CMUs) are manufactured in different sizes, shapes, colors, and textures to achieve a number of finishes and functions. The most common shapes are shown in Fig. 67.1. Typical concrete masonry unit nominal face dimensions are 8 in  $\times$  16 in (203 mm  $\times$  406 mm), with nominal thicknesses of 4 in, 6 in, 8 in, 10 in, and 12 in (102 mm, 152 mm, 203 mm, 254 mm, and 305 mm).

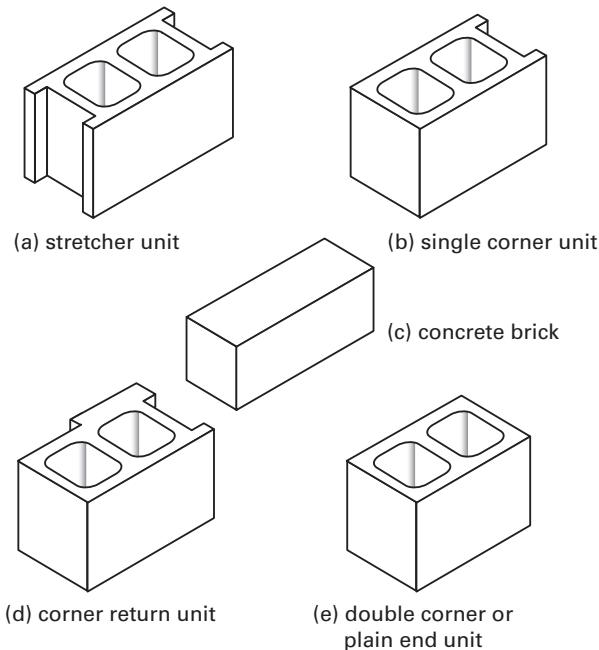

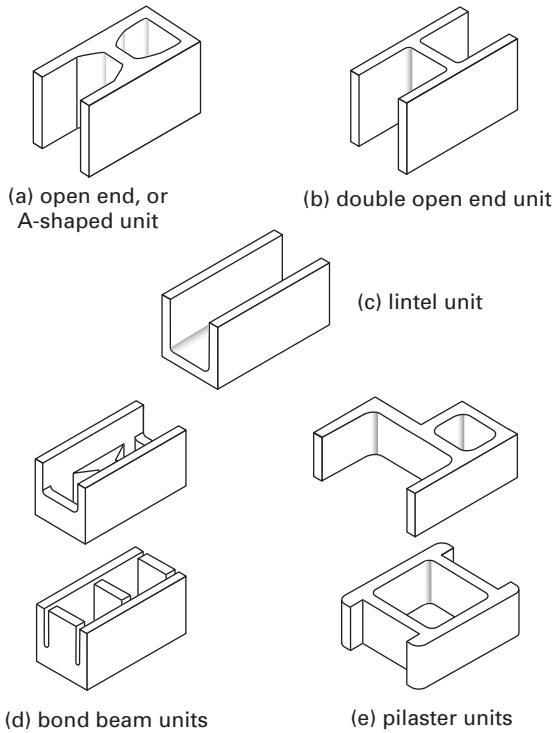

The shapes shown in Fig. 67.2 have been developed specifically for reinforced construction. Open-ended units can be placed around reinforcing bars.

In addition to the units shown, special unit shapes have been developed to maximize certain performance characteristics such as insulation, sound absorption, and resistance to water penetration.

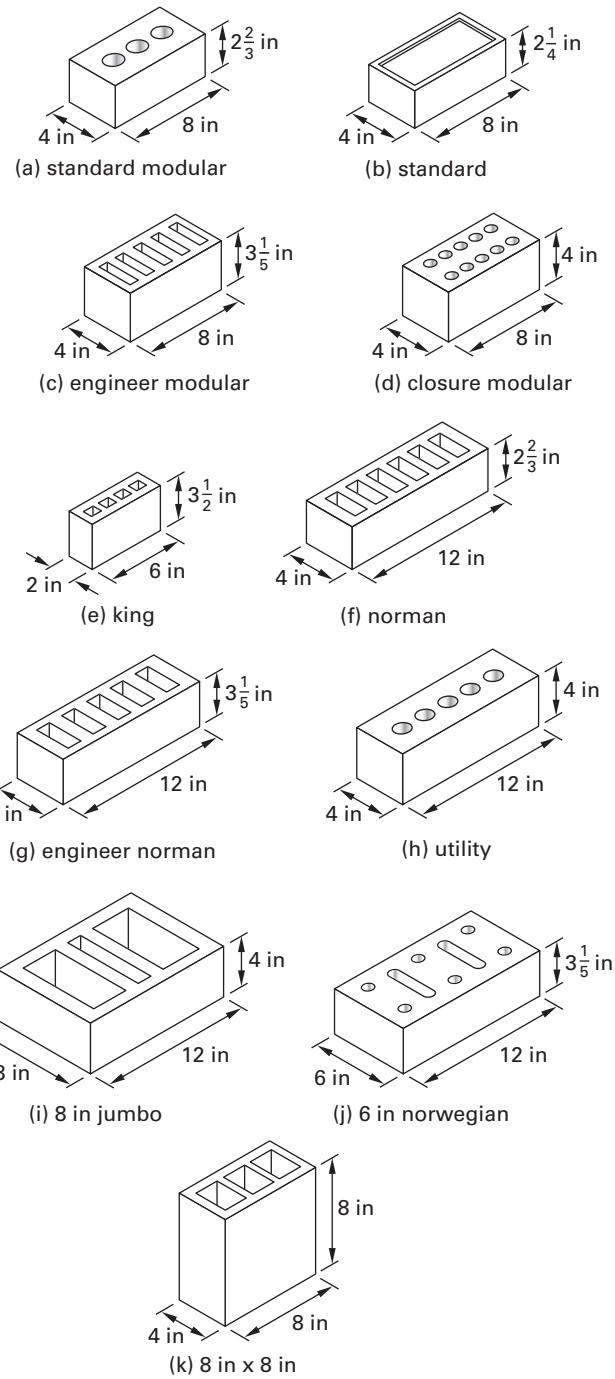

## 3. UNIT SIZES AND SHAPES OF CLAY MASONRY

Brick (i.e., clay masonry) is manufactured by either extrusion or molding; both processes make it easy to produce unique features. (Very large shapes can be difficult to manufacture because of problems with proper drying

<sup>1</sup>For the PE exam, only ASD methods may be used (except for strength design (SD) Sec. 3.3.5, which may be used for walls with out-of-plane loads). However, SD methods are provided in this chapter for your additional reference.

**Figure 67.1** Typical Concrete Masonry Units**Figure 67.2** Concrete Masonry Units Accommodating Reinforcement

and firing.) Clay brick is available in many sizes, most of which are based on a 4 in × 4 in (102 mm × 102 mm) module. Typical clay brick sizes are shown in Fig. 67.3. Actual dimensions are typically  $\frac{3}{8}$  in (9.5 mm) less than the nominal dimensions. For example, the thickness of a 4 in face shell brick would be  $3\frac{5}{8}$  in.

**Figure 67.3** Typical Brick Sizes (nominal dimensions\*)

\*Actual dimensions are typically  $\frac{3}{8}$  in (9.5 mm) less than nominal dimensions.

Brick types used in structural applications include building brick, face brick, and hollow brick. *Building brick* is typically used as a backing material or in other applications where appearance is not an issue. *Face brick* is used in both structural and nonstructural masonry where an appealing appearance is a requirement. *Hollow brick* is identical to face brick but has a larger core area, which allows hollow brick to be reinforced.

## 4. DIMENSIONS

Masonry unit dimensions are listed in the following order: width × height × length. Nominal dimensions are used for planning bond patterns and modular layout with respect to door and window openings. Actual dimensions of masonry units are typically  $\frac{3}{8}$  in (9.5 mm) less than nominal dimensions, so that the 4 in or 8 in (102 mm or 203 mm) module size is maintained with  $\frac{3}{8}$  in (9.5 mm) mortar joints. (See Table 67.1.)

## 5. BOND PATTERNS

Allowable design stresses, lateral support criteria, and minimum thickness requirements for masonry are based primarily on structural testing and research on wall panels laid in running bond. *Running bond* is defined as construction where the head joints in successive courses are horizontally offset at least one-quarter the unit length [MSJC Sec. 1.6]. The typical offset is half the unit length. When a different bond pattern is used, its influence on the compressive and flexural strength of the wall must be

considered. Allowable flexural tensile stresses and masonry modulus of rupture [MSJC Sec. 2.2.3.2 and Sec. 3.1.8.2, respectively] assign different design values based on bond pattern. Figure 67.4 illustrates typical bond patterns. Other decorative patterns are in use.

## 6. COMPRESSIVE STRENGTH

Compressive strength of a masonry assembly varies with time, unit properties, mortar type, and grout, if used. Strength is typically tested at 28 days. The specified compressive strength of masonry,  $f'_m$ , is noted in the project documents and is used to establish allowable stresses for masonry elements.

Compliance with specified compressive strength is verified by either the unit strength method or the prism test method. The *unit strength method* uses the net area compressive strength of the units and the mortar type to establish the compressive strength of the masonry assembly. Criteria from the *MSJC Specification* are listed in Table 67.2 and Table 67.3.

**Table 67.1** Nominal and Actual Brick Dimensions<sup>a</sup>

	nominal size <sup>b,c</sup> (in)	specified size <sup>d,e,f</sup> (in)	vertical coursing

(Multiply lbf/in<sup>2</sup> by 0.006895 to obtain MPa.)

\*For units of less than 4 in (102 mm) height, use 85% of the values listed.

Source: *MSJC Specification* Sec. 1.4B(2)b. Based on the compressive strength of concrete masonry units and the type of mortar used in construction.

America. The required minimum average compressive strength of clay brick is 3000 lbf/in<sup>2</sup> (20.7 MPa) for brick grade SW.

The *prism test method* determines the compressive strength of masonry at 28 days or at the designated test age. Prisms are constructed from materials representative of those to be used in the construction. Typical concrete masonry prisms are two units high, where brick prisms are five units high. A set of three prisms is tested in compression until failure. The individual prism strengths are then corrected to account for the aspect ratio of the prism and averaged together. The corrected value represents the net area compressive strength of masonry,  $f'_m$ . Checking that proper proportions of certified materials were used in the test provides verification of the net area compressive strength. The *MSJC Specification* does not require field testing of masonry units, mortar, grout, or completed assemblies.

**Table 67.2** Compressive Strength of Clay Masonry

9900 (68.3)	—	3500 (24.1)
11,500 (79.29)	—	4000 (27.6)

(Multiply lbf/in<sup>2</sup> by 0.006895 to obtain MPa.)Source: *MSJC Specification* Sec. 1.4B(2)a. Based on the compressive strength of clay masonry units and the type of mortar used in construction.

Concrete masonry units are required by ASTM C90 to have an average net area compressive strength of 1900 lbf/in<sup>2</sup> (13.1 MPa). This corresponds to  $f'_m$  values of 1500 lbf/in<sup>2</sup> and 1350 lbf/in<sup>2</sup> (10.3 MPa and 9.3 MPa) for mortar types M or S and type N, respectively.  $f'_m$  values up to 4000 lbf/in<sup>2</sup> (27.6 MPa) are attainable using high-strength concrete masonry units.

Clay units typically have strengths ranging from 3000 lbf/in<sup>2</sup> (20.7 MPa) to over 20,000 lbf/in<sup>2</sup> (138 MPa), averaging between 6000 lbf/in<sup>2</sup> and 10,000 lbf/in<sup>2</sup> (41.3 MPa and 68.9 MPa) in North

## 7. DENSITY

Density, or unit weight, of a masonry unit is described in terms of dry weight per cubic foot. Larger densities result in increased wall and building weight, heat capacity, sound transmission loss, and thermal conductivity (resulting in lower *R*-values and decreased fire resistance).

## 8. MODULUS OF ELASTICITY

*MSJC* defines the modulus of elasticity (elastic modulus) in compression as the *chord modulus* (defined as the slope of a line intersecting the stress-strain curve at two points, neither of which is the origin of the curve) from a stress value of 5–33% of the compressive strength of masonry.

Moduli of elasticity are determined from testing or tables, or are estimated from *MSJC* Sec. 1.8.2.2.1.

$$E_m = 700f'_m \quad [\text{clay masonry}] \quad 67.1$$

$$E_m = 900f'_m \quad [\text{concrete masonry}] \quad 67.2$$

## 9. BOND STRENGTH

*Bond* describes both the amount of unit/mortar contact and the strength of adhesion. Bond varies with mortar properties (air and water content, water retention), unit surface characteristics (texture and suction), workmanship (pressure applied to joint during tooling, time between spreading mortar and placing units), and curing. In unreinforced masonry design, relative bond strengths are reflected in allowable flexural tension values.

## 10. ABSORPTION

Absorption describes the amount of water a masonry unit can hold when it is saturated. For concrete masonry, absorption is determined either in terms of weight of water per cubic foot of concrete, or as a percent by dry weight of concrete. For a given aggregate type and gradation, absorption is an indication of how well the concrete was compacted during manufacture. This, in turn, influences compressive strength, tensile strength, and durability.

The maximum permissible absorption per ASTM C90 for concrete masonry ranges from 13 lbm/ft<sup>3</sup> to 18 lbm/ft<sup>3</sup> (208 kg/m<sup>3</sup> to 288 kg/m<sup>3</sup>), depending on the concrete density.

For brick, there are two categories of absorption: water absorption and *initial rate of absorption* (IRA). *Water absorption* tests are used to calculate a *saturation coefficient* for brick, which is an indicator of durability.

The IRA indicates how much water a brick draws in during the first minute of contact with water. Typical IRA values range between 5 g/min and 40 g/min per 30 in<sup>2</sup> of brick bed area (0.2 kg/min and 2.05 kg/min per square meter of brick bed area). IRA affects mortar and grout bond. If the IRA is too high, the brick absorption can impair the strength and extent of the bond with mortar and grout. High-suction brick should be wetted prior to laying to reduce suction (although the brick should be surface dry when laid). Very low-suction brick should be covered and kept dry on the jobsite.

In the laboratory, IRA is measured using oven-dried brick, which results in a higher measured IRA than if a moist brick were tested. The field test for IRA, on the other hand, is performed without drying the units. The laboratory test will indicate the order of magnitude of

the IRA, where the field test indicates if additional wetting is necessary to lay the units.

## 11. DURABILITY

Clay brick *durability* may be predicted from either (a) the compressive strength, absorption, and saturation coefficient or (b) the compressive strength and ability to pass 50 freeze-thaw cycles.

Brick durability is reflected in *weathering grades* (severe, moderate, or negligible weathering), defined in ASTM standards. These standards also indicate weather conditions in the United States and define where each grade is required. Brick that meets the severe weathering (SW) grade is commonly available.

## 12. MORTAR

*Mortar* structurally bonds units together, seals joints against air and moisture penetration, accommodates small wall movements, and bonds to joint reinforcement, ties, and anchors.

Mortar types are defined in ASTM C270. Four mortar types—M, S, N, and O—are included and vary by the proportions of ingredients. Types M, S, and N are the most commonly used.

Type N mortar is a medium-strength mortar suitable for exposed masonry above grade. It is typically recommended for exterior walls subject to severe exposure, for chimneys, and for parapet walls.

Type S mortar has a relatively high compressive strength and will typically develop the highest flexural bond strength (all other variables being equal). Type M mortar has high compressive strength and excellent durability. Both type M and type S mortar are recommended for below-grade construction and reinforced masonry.

Type O mortar is a relatively low compressive strength mortar suitable for limited exterior use and interior use. It should not be used in freezing or moist environments.

Mortar type is one factor used to determine  $f'_m$ , if the unit strength method is used. Mortar type is also used to determine allowable compressive strengths for empirically designed masonry and allowable flexural tension for unreinforced masonry.

*MSJC* restricts the use of some mortars for particular applications. In seismic design categories D, E, and F, for example, type N mortar and masonry cement mortar are prohibited in lateral force-resisting systems [*MSJC* Sec. 1.17.4.4]. Mortar type M or S must be used for empirical design of foundation walls [*MSJC* Sec. 5.6.3.1]. Glass block requires use of type S or N mortar [*MSJC* Sec. 7.6].

### 13. MORTAR COMPRESSIVE STRENGTH

Laboratory tests are for preconstruction evaluation of mortars and use low water content mortars. Results establish the general strength characteristics of the mortar mix. Field tests, on the other hand, establish quality control of mortar production and use mortars with high water contents, typical of those used in the work. Field test results are not required to meet the minimum compressive strength values contained in the property specification of ASTM C270.

Field test results should not be compared to lab test results, since the higher water content adversely affects the compressive strength of mortar, but also enhances the bond strength.

### 14. GROUT

*Grout* is a fluid cementitious mixture used to fill masonry cores or cavities to increase structural performance. Grout is most commonly used in reinforced construction to bond steel reinforcement to the masonry. The collar joint of a double wythe masonry wall is sometimes grouted to allow composite action.

*Grout modulus of elasticity* is calculated as  $500f'_g$  [MSJC Sec. 1.8.2.4].

### 15. GROUT SLUMP

*Grout slump* is determined using the same procedure that is used to measure concrete slump. Grout slump should be between 8 in and 11 in (203 mm and 279 mm) to facilitate complete filling of the grout space and proper performance [MSJC Specification Sec. 2.6B2]. When relatively quick water loss is expected due to high temperatures and/or highly absorptive masonry units, a higher slump should be maintained. The high initial water content of grout compensates for water absorption by the masonry units after placement. Grout gains high strength despite the high initial water-to-cement ratios.

### 16. GROUT COMPRESSIVE STRENGTH

When grout compressive strength testing is required, ASTM Test Method C1019 is used. Grout specimens are formed in a mold made up of masonry units with the same absorption and moisture content characteristics as those being used on the job. The masonry units remove excess water from the grout to more closely replicate grout strength in the wall. Concrete test methods should not be used for grout, as grout cubes or cylinders formed in nonabsorptive molds will produce unreliable results.

After curing, the grout specimens are capped and tested. Although a lower aggregate-to-cement ratio generally

produces higher grout strengths, there is no direct relationship between the two.

Grout compressive strength is required to equal the specified compressive strength of masonry, but cannot be less than 2000 lbf/in<sup>2</sup> (13.8 MPa) [MSJC Specification Sec. 1.4B(2)(b)(3)b].

### 17. STEEL REINFORCING BARS

Reinforcement increases masonry strength and ductility, providing increased resistance to applied loads and (in the case of horizontal reinforcement) to shrinkage cracking. The two principal types of reinforcement used in masonry are reinforcing bars and cold-drawn wire products.

*Reinforcing bars* are placed vertically and/or horizontally in the masonry and are grouted into position.

MSJC Specification Sec. 3.4B covers reinforcement installation requirements to ensure elements are placed as assumed in the design. MSJC Sec. 1.15.4 provides for a minimum masonry and grout cover around reinforcing bars to reduce corrosion and ensure sufficient clearance for grout and mortar to surround reinforcement and accessories, so that stresses can be properly transferred. Bar positioners are often used to hold reinforcement in place during grouting.

Reinforcing bars for masonry are the same type as those used in concrete construction. For ASD, bars should not exceed an eighth of the nominal wall thickness or a quarter of the smallest of the cell, course, or collar joint in which it is placed [IBC Sec. 2107.5]. Bars larger than no. 9 are not permitted when using strength design [MSJC Sec. 3.3.3.1] and should generally be avoided otherwise. When using bars sized no. 9 or greater with ASD, mechanical splices are required [IBC Sec. 2107.4]. Core size and masonry cover requirements may further restrict the maximum bar size that can be used. For bar reinforcement in tension, the allowable stress is  $F_s = 24,000 \text{ lbf/in}^2$  (165 MPa) for grade-60 steel [MSJC Sec. 2.3.2.1].

### 18. DEVELOPMENT LENGTH

*Development length (anchorage or embedment length)* ensures that forces can be transferred. Reinforcing bars can be anchored by embedment length, hooks, or mechanical devices. Reinforcing bars anchored by embedment length rely on interlock of the bar deformations with grout and on the masonry cover being sufficient to prevent splitting from the reinforcing bar to the free surface.

MSJC has harmonized the development length,  $l_d$ , provisions for allowable stress design, ASD (MSJC Chap. 2), and strength design, SD (MSJC Chap. 3). The required development length for wires in tension is given by

Eq. 67.3, but it cannot be less than 6 in (152 mm) for wire [MSJC Sec. 2.1.9.2].

$$l_d = 0.22d_b F_s \quad [\text{SI}] \quad 67.3(a)$$

$$l_d = 0.0015d_b F_s \quad [\text{U.S.}] \quad 67.3(b)$$

When *epoxy-coated wire* is used, the development length determined by Eq. 67.3 must be increased by 50% [MSJC Sec. 2.1.9.2].

The required development length of reinforcing bars is determined using Eq. 67.4 [MSJC Sec. 2.1.9.3 and Sec. 3.3.3.3].

$$l_d = \frac{1.57d_b^2 f_y \gamma}{K \sqrt{f'_m}} \quad [\text{SI}] \quad 67.4(a)$$

$$l_d = \frac{0.13d_b^2 f_y \gamma}{K \sqrt{f'_m}} \quad [\text{U.S.}] \quad 67.4(b)$$

The distance  $K$  is the smallest of the rebar cover, clear spacing between adjacent reinforcement splices and bars, and  $5d_b$ . ( $K = 5d_b$  effectively specifies the minimum concrete cover required to have fully developed splices.)  $\gamma$  is 1.0 for nos. 3–5 bars (M#10–16), 1.3 for nos. 6–7 bars (M#19–22), and 1.5 for nos. 8–9 bars (M#25–29). (In ASD,  $\gamma$  is 1.5 for nos. 8–11 bars (M#25–36).)

The required embedment may not be less than 12 in (305 mm). When epoxy-coated reinforcing bars are used, the development length determined by Eq. 67.4 must be increased by 50%. For SD, the embedment need not be greater than  $72d_b$  [IBC Sec. 2108.2]. For SD, reinforcement splices must have a minimum lap equal to the development length determined by Eq. 67.4.

For ASD, the *minimum splice length* for reinforcing bars is determined using Eq. 67.5 [IBC Eq. 21-1].  $f_s$  is the calculated stress in reinforcement due to design loads.

$$l_d = 0.29d_b f_s \quad [\text{SI}] \quad 67.5(a)$$

$$l_d = 0.002d_b f_s \quad [\text{U.S.}] \quad 67.5(b)$$

The splice length should be at least 12 in (305 mm) and no less than  $48d_b$  per MSJC or  $40d_b$  per IBC. If  $f_s$  is greater than  $0.8F_s$ , the minimum lap length determined from Eq. 67.5 must be increased by at least 50% [IBC Sec. 2107.3]. Splice length need not exceed  $72d_b$ .

Mechanical or welded splices must be capable of developing 125% of the reinforcement yield strength,  $f_y$ . For mechanical splices, requirements are placed on the weld, rebar type, and rebar placement [IBC Sec. 2107.4 and Sec. 2108.3].

The equivalent embedment length for standard hooks,  $l_e$ , in tension is slightly different in the ASD and SD chapters. For ASD,  $l_e = 11.25d_b$  [MSJC Sec. 2.1.9.5.1], while for SD  $l_e = 13d_b$  [MSJC Sec. 3.3.3.2].

## 19. HORIZONTAL JOINT REINFORCEMENT

Joint reinforcement is a welded wire assembly consisting of two or more longitudinal wires connected with cross wires. It is placed in horizontal mortar bed joints, most commonly to control wall cracking associated with thermal or moisture shrinkage or expansion. Secondary functions include (a) metal tie system for bonding adjacent masonry wythes and (b) structural steel reinforcement.

For wire joint reinforcement that is in tension, the allowable stress is  $F_s = 30,000 \text{ lbf/in}^2$  (207 MPa) [MSJC Sec. 2.3.2.1].

*Horizontal joint reinforcement* is required for seismic design, and it is generally desirable for crack control. Such reinforcement should be included with every course for foundation walls; for above-grade walls, horizontal reinforcement is placed every two or three courses. Wire for joint reinforcement is galvanized (i.e., zinc plated) and is available in several lengths and diameters. For standard  $3/8$  in mortar joints, 9-gauge wire is used. Extra heavy duty wire is used less frequently. Special, thinner 11-gauge wire is used with glass block masonry and where  $1/4$  in mortar joints are specified. Wire mesh, flat, corrugated, and twisted sheet metal, and other prefabricated ties and appliances can also be used. The steel industry uses *W&M* (*Washburn and Moen, American Steel, U.S. Steel, and USSWG*) *wire gauge* numbers which are different than those used to describe electrical conductors. Table 67.4 lists actual diameters of joint reinforcement wire. (The “W” designation gives the area of the wire in hundredths of a square inch.)

**Table 67.4** Wire for Masonry Reinforcement

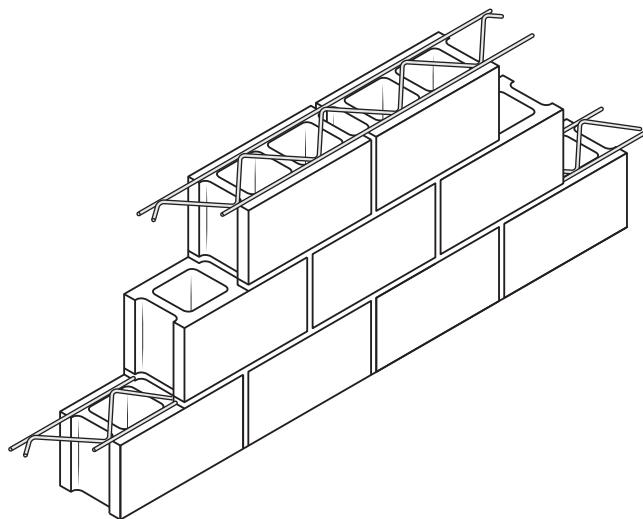

wire designation (gauge or size, in)	diameter (in)	area (in <sup>2</sup> )
extra heavy duty (W2.8)	0.1875 ( $3/16$ )	0.0276
8 (W2.1, heavy duty)	0.1620	0.0206
9 (W1.7, standard duty)	0.1483	0.0173
10 (W1.4)	0.1350	0.0143
11 (W1.1)	0.1205	0.0114
12 (W0.9)	0.1055	0.00874

(Multiply in by 25.4 to obtain mm.)

In the common *two-wire joint reinforcement* arrangement, both face joints of a layer receive joint reinforcement. Where one bar ends and another begins, lap (overlap) length must be 54 wire diameters for grouted cells and grouted collar joints. In a mortared bed joint, the lap length must be 75 bar diameters. The lap length is 54 wire diameters plus twice the bed joint spacing when the wire is placed in adjacent (not the same) bed joints (i.e., starting below and continuing above a masonry unit). In single-wythe walls, perpendicular (“ladder” or “cross”) ties in the end face joints (webs)

or diagonal (“truss style”) ties may be used. (See Fig. 67.5.) Ladder ties interfere less with grouting operations, but truss ties contribute more steel and are stronger. Cross wires (i.e., ties, rungs of the ladder) are typically 12 gauge.

**Figure 67.5** Truss Style Two-Wire Horizontal Joint Reinforcement

## Nomenclature

<i>a</i>	depth of an equivalent compression zone at nominal strength	in	mm				
<i>A</i>	area	in <sup>2</sup>	mm <sup>2</sup>				
<i>A<sub>n</sub></i>	net cross-sectional area of masonry	in <sup>2</sup>	mm <sup>2</sup>				
<i>A<sub>s</sub></i>	cross-sectional area of steel	in <sup>2</sup> /ft	mm <sup>2</sup> /m				
<i>A<sub>st</sub></i>	total area of laterally tied longitudinal reinforced steel in reinforced masonry	in <sup>2</sup>	mm <sup>2</sup>				
<i>A<sub>v</sub></i>	cross-sectional area of shear reinforcement	in <sup>2</sup>	mm <sup>2</sup>				
<i>b</i>	effective width	in	mm				
<i>b<sub>w</sub></i>	for partially grouted walls, width of grouted area (i.e., width of grout cell plus width of the two adjacent webs)	in	mm				
<i>c</i>	distance from neutral axis to extreme fiber in bending	in	mm				
<i>C</i>	compressive force	lbf	N				
<i>d</i>	depth to tension reinforcement	in	mm				
<i>d</i>	effective depth	in	mm				
<i>e</i>	eccentricity	in	mm				
<i>e<sub>u</sub></i>	eccentricity of <i>P<sub>uf</sub></i>	in	mm				
<i>E<sub>m</sub></i>	modulus of elasticity of masonry in compression	lbf/in <sup>2</sup>	MPa				
<i>E<sub>s</sub></i>	modulus of elasticity of steel	lbf/in <sup>2</sup>	MPa				
<i>f<sub>a</sub></i>	compressive stress in masonry due to axial load alone	lbf/in <sup>2</sup>	MPa				
<i>f<sub>b</sub></i>	stress in masonry due to flexure alone	lbf/in <sup>2</sup>	MPa				
<i>f'<sub>g</sub></i>	specified compressive strength of grout	lbf/in <sup>2</sup>	MPa				
<i>f'<sub>m</sub></i>	specified compressive strength of masonry	lbf/in <sup>2</sup>	MPa				
<i>f<sub>r</sub></i>	modulus of rupture for masonry	lbf/in <sup>2</sup>	MPa				
<i>f<sub>s</sub></i>	stress in reinforcement	lbf/in <sup>2</sup>	MPa				
<i>f<sub>v</sub></i>	shear stress in masonry	lbf/in <sup>2</sup>	MPa				
<i>f<sub>y</sub></i>	yield strength of steel for reinforcement and anchors	lbf/in <sup>2</sup>	MPa				
<i>F<sub>a</sub></i>	allowable compressive stress due to axial load alone	lbf/in <sup>2</sup>	MPa				
<i>F<sub>b</sub></i>	allowable stress due to flexure only	lbf/in <sup>2</sup>	MPa				
<i>F<sub>s</sub></i>	allowable reinforcement tensile stress	lbf/in <sup>2</sup>	MPa				
<i>F<sub>v</sub></i>	allowable shear stress in masonry	lbf/in <sup>2</sup>	MPa				
<i>h</i>	effective height	in	mm				
<i>I</i>	moment of inertia	in <sup>4</sup>	mm <sup>4</sup>				
<i>I<sub>cr</sub></i>	moment of inertia of the cracked cross section of the member	in <sup>4</sup>	mm <sup>4</sup>				
<i>I<sub>g</sub></i>	moment of inertia of the gross cross section of the member	in <sup>4</sup>	mm <sup>4</sup>				
<i>I<sub>n</sub></i>	moment of inertia of the net cross section of the member	in <sup>4</sup>	mm <sup>4</sup>				
<i>j</i>	ratio of distance between centroid of flexural compressive forces and centroid of tensile forces to depth	—	—				
<i>k</i>	ratio of the distance between compression face of wall and neutral axis to the effective depth	—	—				
<i>l</i>	clear span between supports	in	mm				
<i>M</i>	moment	in-lbf	N·m				
<i>M<sub>cr</sub></i>	nominal masonry cracking moment	in-lbf	N·m				
<i>M<sub>m</sub></i>	resisting moment assuming masonry governs	in-lbf	N·m				

<sup>1</sup>For the PE exam, only ASD methods may be used (except for strength design (SD) Sec. 3.3.5, which may be used for walls with out-of-plane loads). However, SD methods are provided in this chapter for your additional reference.

$M_n$	nominal moment strength	in-lbf	N·m	$d$	ductile
$M_R$	resisting moment of wall (the lesser of $M_m$ and $M_s$ )	in-lbf	N·m	$fs$	face shell
$M_s$	resisting moment assuming steel governs	in-lbf	N·m	$g$	gross or grout
$M_{ser}$	service moment at midheight of member, including $P\Delta$ effects	in-lbf	N·m	$m$	masonry
$M_u$	factored moment	in-lbf	N·m	$n$	net or nominal
$n$	modular ratio ( $E_1/E_2$ or $f_1/f_2$ )	—	—	$r$	rupture
$N_u$	factored compressive force acting normal to shear surface	lbf	N	$R$	resisting
$N_v$	compressive force acting normal to shear surface	lbf	N	$s$	steel, stress, or service
$P$	axial load	lbf	N	$ser$	service
$P_a$	allowable compressive force in reinforced masonry due to axial load	lbf	N	$t$	total
$P_e$	Euler buckling load	lbf	N	$tr$	transformed
$P_n$	nominal axial strength	lbf	N	$u$	ultimate
$P_u$	factored axial load	lbf	N	$v$	shear
$P_{uf}$	factored load from tributary floor or roof areas	lbf	N		
$Q$	statical moment	in <sup>3</sup>	mm <sup>3</sup>		
$r$	radius of gyration	in	mm		
$R$	seismic response modification factor	—	—		
$s$	spacing of reinforcement	in	mm		
$S$	section modulus	in <sup>3</sup>	mm <sup>3</sup>		
$t$	wall thickness	in	mm		
$t_{fs}$	face shell thickness of masonry unit	in	mm		
$T$	tensile force	lbf	N		
$v$	shear stress	lbf/in <sup>2</sup>	MPa		
$V$	design shear force	lbf	N		
$V_n$	nominal shear strength	lbf	N		
$V_{nm}$	nominal shear strength provided by masonry	lbf	N		
$V_{ns}$	nominal shear strength provided by shear reinforcement	lbf	N		
$V_R$	resisting shear of wall	lbf	N		
$V_u$	factored shear force	lbf	N		
$w$	uniformly distributed load	lbf/ft <sup>2</sup>	MPa		
$x_c$	distance from centroid of element to neutral axis of section	in	mm		

**Symbols**

$\delta$	deflection	in	mm
$\delta_s$	horizontal deflection at midheight due to service loads	in	mm
$\Delta$	lateral deflection	in	mm
$\rho$	ratio of tensile steel area to compressive area, $bd$	—	—
$\rho_t$	ratio of steel area to gross area of masonry, $bt$	—	—
$\phi$	strength reduction factor	—	—

**Subscripts**

$a$	allowable or axial
$b$	flexure (bending)
bal	balanced
br	brick
$c$	centroidal
CMU	concrete masonry unit
cr	cracked or cracking

**1. METHODS OF DESIGN**

*Building Code Requirements for Masonry Structures (MSJC)* defines a wall as a vertical element with a horizontal length-to-thickness ratio greater than three that is used to enclose space [MSJC Sec. 1.6]. This differentiates walls from columns, which are subject to additional design limitations. Masonry walls can serve as veneer facings subject to out-of-plane flexure; load-bearing walls subject to axial compression, flexure, or both; and shear walls. While walls are typically designed to span vertically (between floors) or horizontally (between intersecting walls or pilasters), they can also be designed for two-way bending to limit deflection and increase stability.

Masonry structures are designed using one of several methods, including empirical procedures, allowable stress design (ASD), and strength design (SD). Allowable stress design (ASD) is the most widely used of the three methods, although strength design (SD) is gaining popularity.

**2. EMPIRICAL WALL DESIGN**

Empirical design is a procedure of proportioning and sizing masonry elements. The criteria are based on historical experience rather than analytical methods. This method is conservative for most masonry construction. It is an expedient method for typical load-bearing structures, exterior curtain walls, and interior partitions.

Prescriptive criteria in *MSJC* Chap. 5 govern vertical and lateral load resistance of walls. Certain limitations apply to empirical designs, helping to ensure the construction and design loads are consistent with the experience used to establish the empirical criteria. *MSJC* prohibits its use in *seismic design categories* (SDC) D, E, and F; in any seismic-resisting system in SDC B or C; and for lateral force-resisting elements when the basic wind speed exceeds 110 mph (145 km/hr), or the building height exceeds 35 ft (10.67 m). Additional restrictions are included for nonlateral force-resisting elements based on combinations of building height and basic wind speed. *MSJC* Chap. 5 includes requirements for wall lateral support, allowable stresses, anchorage for lateral support, and shear wall spacing.

### 3. ALLOWABLE STRESS WALL DESIGN

The allowable stress design (ASD) method compares expected or calculated design stresses due to expected loads to allowable design stresses. Loads are unfactored; that is, the service loads are such that they may be expected to occur during the structure's life. When calculated design stresses are less than allowable stresses, the design is acceptable.

Allowable stresses are determined by reducing expected material strengths by appropriate factors of safety. Historically, a one-third increase was allowed for ASD load combinations that include wind or seismic loads. This increase is no longer permitted by *MSJC*, as a one-third stress increase is not a structurally sound way to handle load combination effects [*MSJC* Sec. 2.1.1]. Masonry allowable stresses may vary with unit type, mortar type, compressive strength, and other factors. Stronger masonry will have higher allowable stresses.

The following assumptions form the basis of ASD for masonry. (a) Stress is linearly proportional to strain for stresses that are within the allowable stress (elastic) range. (b) Masonry materials combine to form a homogeneous, isotropic material. Therefore, sections that are plane before bending will remain plane after bending. (c) Reinforcement, when used, is perfectly bonded to masonry.

ASD of *unreinforced masonry* is covered in *MSJC* Sec. 2.2. When unreinforced, masonry is designed to resist tensile and compressive loads; the tensile strength of any steel in the wall is neglected. Tension due to axial loads, such as wind uplift, is not permitted in unreinforced masonry. Compressive stress from dead loads can be used to offset axial tension, although if axial tension develops, the wall must be reinforced to resist the tension. However, flexural tension due to bending may be resisted by the unreinforced masonry.

*MSJC* Sec. 2.3 gives requirements for reinforced masonry that is subjected to axial compression and tension, flexure, and shear. The tensile strength of masonry units, mortar, and grout is neglected, as is the compressive resistance of steel reinforcement, unless confined by lateral ties to prevent buckling in accordance with provisions in *MSJC*. (These confinement provisions are virtually impossible to meet for walls.) Axial tension and flexural tension are resisted entirely by steel reinforcement.

### 4. STRENGTH DESIGN

The strength design (SD) method compares factored loads to the design strength of the material. Expected loads are multiplied by load factors to provide a factor of safety. The ultimate strength of the wall section is reduced by a strength reduction factor,  $\phi$ , that accounts for variations in material properties and workmanship. Although this same method is typically used to design reinforced concrete elements, different design parameters apply to masonry. *MSJC* Chap. 3 covers SD of masonry.

In SD, a compressive masonry stress of  $0.80f'_m$  is assumed to be rectangular and uniformly distributed over an equivalent compression zone, bounded by the compression face of the masonry, with a depth,  $a$ , of  $0.80c$ . The maximum usable strain at the extreme compression fiber of the masonry is limited to 0.0035 for clay masonry and 0.0025 for concrete masonry [*MSJC* Sec. 3.3.2].

*MSJC* defines the strength reduction factors,  $\phi$ , as 0.90 for reinforced masonry subjected to flexure or axial loads, 0.60 for unreinforced masonry subjected to flexure or axial loads, and 0.80 for shear design of masonry [*MSJC* Sec. 3.1.4].

The maximum amount of reinforcement permitted in a masonry wall is limited by code to ensure that ductility is achieved. The specific limitation is based on the ductility demand as indicated by the *seismic response modification factor*,  $R$ , which is used in design, as well as in the type of force (in plane or out of plane). Reinforcement is limited so that the steel will reach a prescribed strain level before the masonry crushes. The maximum reinforcing limits are based on less restrictive assumptions. Depending on the design conditions, the steel must reach 0, 1.5, 3, or 4 times its yield strain [*MSJC* Sec. 3.3.3.5].

### 5. PROPERTIES OF BUILT-UP SECTIONS

In addition to masonry unit dimensions, properties used in *MSJC* for design and analysis are net cross-sectional area,  $A_n$ , moment of inertia,  $I$ , section modulus,  $S$ , radius of gyration,  $r$ , and first moment of the area (statical moment),  $Q$ . Additional properties ( $j$ ,  $k$ , and  $d$ ) depend on amount and location of reinforcing, and the modular ratio,  $n$ , depends on the materials used.

The effective width,  $b$ , of cracked masonry experiencing axial and flexural compression is the least of the center-to-center vertical bar spacing (i.e., essentially the distance between grouted cores),  $s$ , six times the wall thickness,  $6t$ , and 72 in (1829 mm) [*MSJC* Sec. 2.3.3.3.1]. The effective width for the purpose of shear is the width of the solid grouted core and confining masonry.

Per *MSJC*, net sectional properties (e.g.,  $A_n$ ) should be used when determining stresses (and, by extension, strains) due to applied loads. For ungrouted, hollow units laid with face-shell bedding, the minimum net cross-sectional area is the mortar bedded area. For grouted units, the grouted area is included [*MSJC* Sec. 1.9.1]. Average (which is the same as average net) sectional properties (e.g.,  $I$  and  $r$ ) should be used when determining stiffness and deflection due to applied loads [*MSJC* Sec. 1.9.2 and Sec. 1.9.3]. Use of the average properties is appropriate because the distribution of material within ungrouted and partially grouted units is nonuniform.

Wall design is greatly assisted by using tabulations of wall properties. Appendix 68.A is for walls with concrete

masonry units spanning horizontally. For running bond walls, for example, this is equivalent to vertical loading, parallel to the wall face, and hence bending about the  $x$ -axis. Appendix 68.B is for concrete masonry units spanning vertically, which is equivalent to loading perpendicular to the wall face and bending about the  $y$ -axis. Appendix 68.C and App. 68.D contain similar data for ungrouted and grouted brick walls spanning horizontally.

Masonry units are typically mortared on the front and back face shells only (i.e., *face shell mortar bedding*). Webs are not typically mortared unless they are adjacent to a grouted core, in which case, the webs are mortared to confine the grout that will be subsequent poured into the cores (i.e., *full mortar bedding*). Tabulated section properties in the appendices reflect these practices.

## 6. ASD WALL DESIGN: FLEXURE—UNREINFORCED

Examples of walls subjected to out-of-plane flexure are exterior non-load-bearing walls subjected to wind or seismic loads, along with retaining walls. The self-weight of the wall can be neglected where the wall design will be governed by tension, such as for a one-story wall. In this case, the wall weight will offset tension in the wall, so the assumption is conservative.

In ASD, the actual wall stress is calculated as  $f_b = M/S$  and compared to the allowable stress,  $F_b$ , obtained from Table 68.1. Out-of-plane flexure produces tension stress in the mortar normal to the bed joints.

**Table 68.1** Allowable Flexural Tensile Stress,  $F_b$ , for Clay and Concrete Masonry in psi (MPa)

masonry type	mortar types			
	portland cement/lime or mortar cement	masonry cement or air entrained portland cement/lime		
	M or S	N	M or S	N
<b>normal to bed joints</b>				
solid units	40 (0.28)	30 (0.21)	24 (0.17)	15 (0.10)
hollow units*				
ungrounded	25 (0.17)	19 (0.13)	15 (0.10)	9 (0.06)
fully grouted	65 (0.45)	63 (0.43)	61 (0.42)	58 (0.40)
<b>parallel to bed joints in running bond</b>				
solid units	80 (0.55)	60 (0.41)	48 (0.33)	30 (0.21)
hollow units				
ungrounded and partially grouted	50 (0.35)	38 (0.26)	30 (0.21)	19 (0.13)
fully grouted	80 (0.55)	60 (0.41)	48 (0.33)	30 (0.21)
<b>parallel to bed joints in stack bond</b>				
continuous grout section parallel to bed joints	100 (0.69)	100 (0.69)	100 (0.69)	100 (0.69)
other	0 (0)	0 (0)	0 (0)	0 (0)

(Multiply lb/in<sup>2</sup> by 0.006895 to obtain MPa.)

\*For partially grouted masonry, allowable stresses shall be determined on the basis of linear interpolation between hollow units that are fully grouted or ungrouted and hollow units based on the amount of grouting.

Source: MSJC Table 2.2.3.2

### Example 68.1

Evaluate the tensile stresses in a one-story masonry wall for a wind load of 20 lbf/ft<sup>2</sup>. The wall is 12 ft high and simply supported at the top and bottom. 12 in hollow concrete masonry and portland cement-lime type S mortar are used.

*Solution*

From Table 68.1,  $F_b = 25$  lbf/in<sup>2</sup>, which can be increased by one-third for wind loads. Therefore,

$$F_b = \left(1 + \frac{1}{3}\right) \left(25.0 \frac{\text{lbf}}{\text{in}^2}\right) = 33.3 \frac{\text{lbf}}{\text{in}^2}$$

From App. 68.B,  $S = 159.9$  in<sup>3</sup>/ft.

Determine the maximum moment.

$$M = \frac{wl^2}{8} = \frac{\left(20 \frac{\text{lbf}}{\text{ft}^2}\right)(12 \text{ ft})^2 \left(12 \frac{\text{in}}{\text{ft}}\right)}{8} \\ = 4320 \text{ in-lbf/ft}$$

Calculate the stress and compare to the allowable stress.

$$f_b = \frac{M}{S} = \frac{4320 \frac{\text{in-lbf}}{\text{ft}}}{159.9 \frac{\text{in}^3}{\text{ft}}} \\ = 27.0 \frac{\text{lbf}}{\text{in}^2} < 33.3 \frac{\text{lbf}}{\text{in}^2} \quad [\text{OK}]$$

The wall will be overstressed if the one-third increase in allowable stress is not used. However, if the compressive stress due to the masonry dead load is included in the analysis, the net flexural tension stress is less than 25 lbf/in<sup>2</sup>.

## 7. SD WALL DESIGN: FLEXURE—UNREINFORCED

SD of unreinforced walls subjected to flexure is similar to ASD. All contributions from reinforcement are ignored, and principles of engineering mechanics are applied. The nominal compressive strength of the masonry is taken as  $0.80f'_m$ , and the nominal flexural tension strength is taken as the modulus of rupture,  $f_r$ . Values for  $f_r$  are given in Table 68.2 [MSJC Table 3.1.8.2.1]. The maximum factored tension and compression forces must not exceed the calculated respective strengths as decreased by the strength reduction factor of 0.60 for flexure and axial loads in unreinforced masonry.

## 8. ASD WALL DESIGN: FLEXURE—REINFORCED

The structural model for ASD of fully grouted flexural members is shown in Fig. 68.1. The allowable tensile stress,  $F_s$ , for grades 40 and 50 steel is 20,000 lbf/in<sup>2</sup> (137.9 MPa). For grade 60 (the most common type of steel), it is 32,000 lbf/in<sup>2</sup> (220.7 MPa). For wire joint reinforcement, it is 30,000 lbf/in<sup>2</sup> (206.9 MPa) [MSJC Sec. 2.3.2.1].

From MSJC Sec. 2.3.3.2.2, the allowable bending stress for masonry flexural members in compression is

$$F_b = \frac{1}{3}f'_m \quad 68.1$$

From MSJC Sec. 2.3.5.2.2, the allowable shear stress for masonry flexural members is given by Eq. 68.2, although shear due to out-of-plane bending seldom governs the design.

$$F_v = \sqrt{f'_m} \leq 50 \text{ psi} \quad 68.2$$

Fully grouted masonry walls respond in bending similar to reinforced concrete beams. Analysis of these walls is based on the straight-line theory for beams subjected to bending. The equations governing the analysis follow the traditional ASD equations for reinforced concrete.

$$\rho = \frac{A_s}{bd} \quad 68.3$$

$$k = \sqrt{2\rho n + (\rho n)^2} - \rho n \quad 68.4$$

$$j = 1 - \frac{k}{3} \quad 68.5$$

$$M_m = F_b bd^2 \left( \frac{jk}{2} \right) \quad 68.6$$

$$M_s = A_s F_s j d \quad 68.7$$

$$M_R = \text{the lesser of } M_m \text{ and } M_s \quad 68.8$$

$$V_R = F_v bd \quad 68.9$$

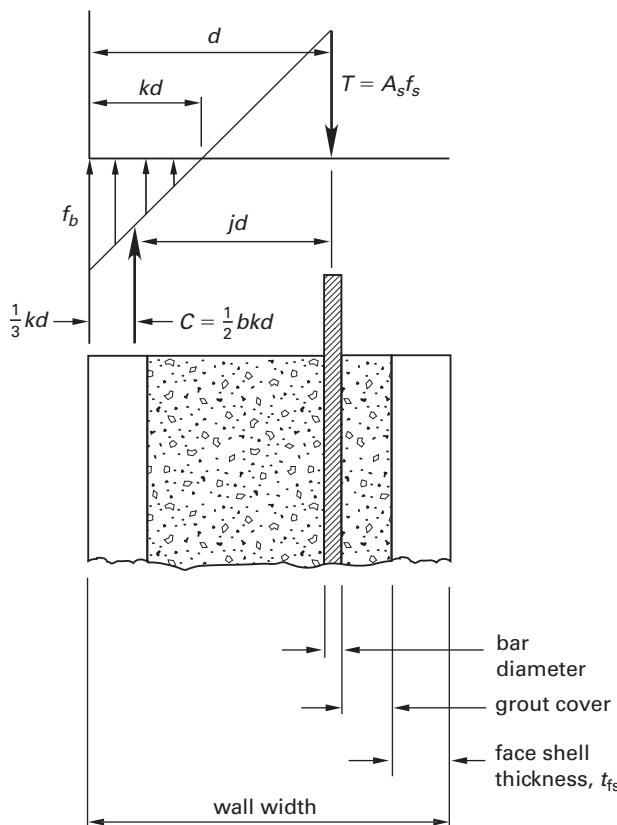

**Table 68.2** Modulus of Rupture for Clay and Concrete Masonry in psi (MPa)

direction of flexural tensile stress and masonry type	mortar types

(Multiply lbf/in<sup>2</sup> by 0.006895 to obtain MPa.)

\*For partially grouted masonry, modulus of rupture values shall be determined on the basis of linear interpolation between hollow units that are fully grouted and ungrouted based on amount (percentage) of grouting.

Source: MSJC Table 3.1.8.2.1

**Figure 68.1** Stress Distribution for Fully Grouted Masonry

**MSJC Sec. 1.9.6.1** limits the width of the compression area,  $b$ , used in stress calculations to the smallest of: the center-to-center bar spacing, six times the wall thickness, or 72 in (1829 mm) for running bond masonry.

Determining the balanced condition allows the designer to know whether reinforcement stress or masonry stress governs the design. A *balanced condition* occurs when both the steel and masonry reach their respective allowable stresses at the same time (i.e.,  $f_m = F_b$  and  $f_s = F_s$ ), although the balanced design is not necessarily the most cost-effective. If there is less reinforcement than that required for a balanced condition, moment capacity is governed by  $F_s$ . The balanced condition is determined by setting masonry compressive force,  $C$ , equal to reinforcement tensile force,  $T$ .

$$\rho_{\text{bal}} = \frac{nF_b}{2F_s \left( n + \frac{F_s}{F_b} \right)} \quad [\text{balanced}] \quad 68.10$$

When analyzing *partially grouted masonry* (i.e., where some core voids are filled and others are not), there are two cases to consider: (a) neutral axis falling within the face shell of the masonry, and (b) neutral axis falling within the core area. When the neutral axis falls within the face shell (i.e., when  $kd$  is less than the face shell

thickness), the bending analysis is identical to the analysis of the fully grouted masonry wall.

When the neutral axis falls within the core area of the masonry, the masonry wall responds to bending similar to a reinforced concrete T-beam. The grouted area and the face shell react to forces as a single unit, rather than as two separate beams. (T-beam performance seldom occurs in walls less than 10 in thick.) The analysis of partially grouted walls is summarized in Eq. 68.11 through Eq. 68.16. ( $b$  is the actual distance between corresponding points in a wall segment containing one grouted cell.)

$$k = \frac{-A_s n - t_{fs}(b - b_w)}{db_w} \quad 68.11$$

$$+ \sqrt{\frac{\left( A_s n + t_{fs}(b - b_w) \right)^2}{db_w} + \frac{t_{fs}^2 b_w (b - b_w) + 2db_w A_s n}{db_w}} \quad 68.11$$

$$j = \left( \frac{1}{kdb_w + t_{fs}(b - b_w) \left( 2 - \frac{t_{fs}}{kd} \right)} \right) \times \left( kb_w \left( d - \frac{kd}{3} \right) + \left( \frac{2t_{fs}(b - b_w)}{kd^2} \right) \times (kd - t_{fs}) \left( d - \frac{t_{fs}}{2} \right) + \left( \frac{t_{fs}}{2} \right) \left( d - \frac{t_{fs}}{3} \right) \right) \quad 68.12$$

$$M_m = \frac{1}{2} F_b k db_w \left( d - \frac{kd}{3} \right) + F_b t_{fs} (b - b_w) \times \left( \left( 1 - \frac{t_{fs}}{kd} \right) \left( d - \frac{t_{fs}}{2} \right) + \left( \frac{t_{fs}}{2kd} \right) \left( d - \frac{t_{fs}}{3} \right) \right) \quad 68.13$$

$$M_s = A_s F_s j d \quad 68.14$$

$$M_R = \text{the lesser of } M_m \text{ and } M_s \quad 68.15$$

$$V_R = F_v \left( b t_{fs} + b_w (d - t_{fs}) \right) \quad 68.16$$

### Example 68.2

Design a fully grouted cantilever concrete masonry retaining wall for a maximum design moment of 12,960 in-lbf/ft. The wall is 6 ft high. Use 8 in units with  $f'_m = 1500$  lbf/in<sup>2</sup>.

*Solution*

Work on a per unit width basis.

Place steel on the tension (soil) side of the wall. Choose  $d = 4.75$  in. Use fully grouted masonry.

For an initial steel estimate, assume  $j = 0.9$ .

$$\begin{aligned} E_m &= 900f'_m = (900)\left(1500 \frac{\text{lbf}}{\text{in}^2}\right) \\ &= 1,350,000 \text{ lbf/in}^2 \\ n &= \frac{E_s}{E_m} = \frac{29,000,000 \frac{\text{lbf}}{\text{in}^2}}{1,350,000 \frac{\text{lbf}}{\text{in}^2}} \\ &= 21.5 \end{aligned}$$

From Eq. 68.1,

$$\begin{aligned} F_b &= \frac{1}{3}f'_m = \left(\frac{1}{3}\right)\left(1500 \frac{\text{lbf}}{\text{in}^2}\right) \\ &= 500 \text{ lbf/in}^2 \end{aligned}$$

Obtain an initial estimate of the steel required. From Eq. 68.7,

$$\begin{aligned} A_s &= \frac{M}{F_s j d} = \frac{12,960 \frac{\text{in-lbf}}{\text{ft}}}{\left(24,000 \frac{\text{lbf}}{\text{in}^2}\right)(0.9)(4.75 \text{ in})} \\ &= 0.126 \text{ in}^2/\text{ft} \end{aligned}$$

From Table 68.3, try no. 6 bars at 32 in on center, giving  $A_s = 0.166 \text{ in}^2/\text{ft}$ . From Eq. 68.3,

$$\begin{aligned} \rho &= \frac{A_s}{bd} = \frac{0.166 \frac{\text{in}^2}{\text{ft}}}{\left(12 \frac{\text{in}}{\text{ft}}\right)(4.75 \text{ in})} \\ &= 0.00291 \end{aligned}$$

From Eq. 68.4,

$$\begin{aligned} k &= \sqrt{2\rho n + (\rho n)^2} - \rho n \\ &= \sqrt{(2)(0.00291)(21.5) + (0.00291)^2(21.5)^2} \\ &\quad - (0.00291)(21.5) \\ &= 0.297 \end{aligned}$$

From Eq. 68.5,

$$\begin{aligned} j &= 1 - \frac{k}{3} = 1 - \frac{0.297}{3} \\ &= 0.901 \end{aligned}$$

From Eq. 68.6,

$$\begin{aligned} M_m &= F_b bd^2 \left(\frac{jk}{2}\right) \\ &= \left(500 \frac{\text{lbf}}{\text{in}^2}\right) \left(12 \frac{\text{in}}{\text{ft}}\right) (4.75 \text{ in})^2 \left(\frac{(0.901)(0.296)}{2}\right) \\ &= 18,052 \text{ in-lbf/ft} \end{aligned}$$

**Table 68.3** Reinforcing Steel Areas,  $A_s$ , in  $\text{in}^2/\text{ft}$

bar spacing (in)	reinforcing bar size						
	no. 3	no. 4	no. 5	no. 6	no. 7	no. 8	no. 9
8	0.166	0.295	0.460	0.663	0.902	1.178	1.491
16	0.083	0.147	0.230	0.331	0.451	0.589	0.746
24	0.055	0.098	0.153	0.221	0.301	0.393	0.497
32	0.041	0.074	0.115	0.166	0.225	0.295	0.373
40	0.033	0.059	0.092	0.133	0.180	0.236	0.298
48	0.028	0.049	0.077	0.110	0.150	0.196	0.249
56	0.024	0.042	0.066	0.095	0.129	0.168	0.213
64	0.021	0.037	0.058	0.083	0.113	0.147	0.186
72	0.018	0.033	0.051	0.074	0.100	0.131	0.166

From Eq. 68.7,

$$\begin{aligned} M_s &= A_s F_s j d \\ &= \left(0.166 \frac{\text{in}^2}{\text{ft}}\right) \left(24,000 \frac{\text{lbf}}{\text{in}^2}\right) (0.901)(4.75 \text{ in}) \\ &= 17,051 \text{ in-lbf/ft} \end{aligned}$$

$$M_R = 17,051 \text{ in-lbf/ft} > 12,960 \text{ in-lbf/ft} \quad [\text{OK}]$$

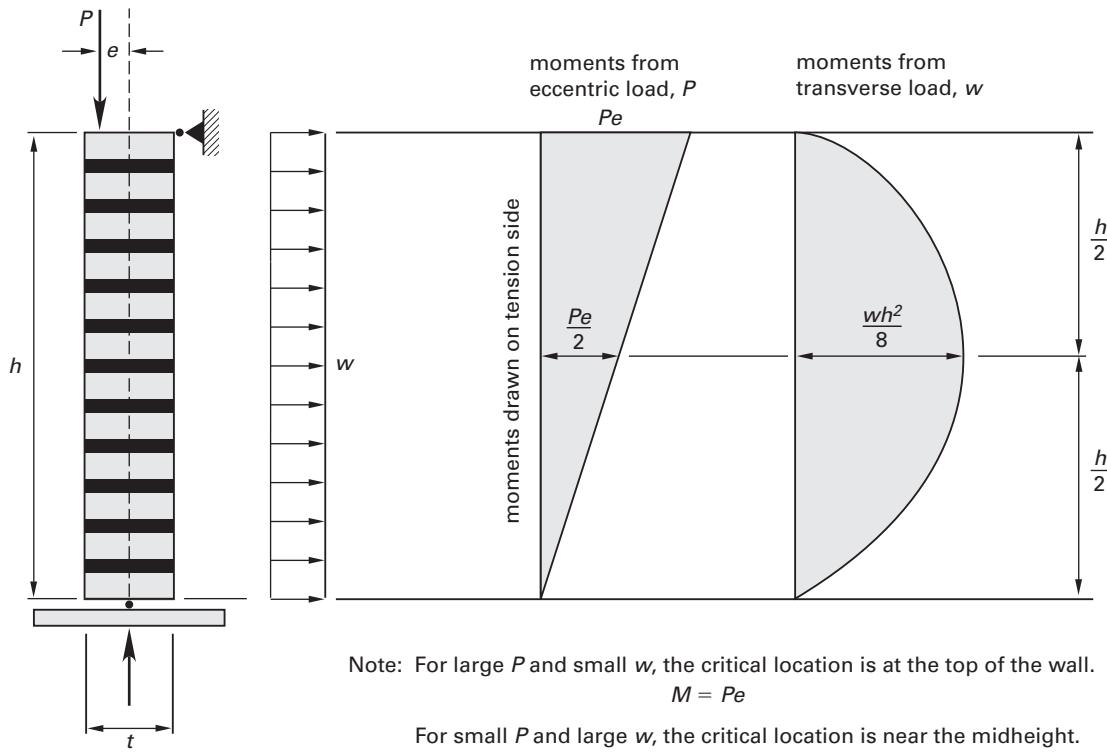

## 9. ASD WALL DESIGN: AXIAL COMPRESSION AND FLEXURE—UNREINFORCED

Many masonry walls are designed for both axial compression and flexure. Examples include: load-bearing exterior walls (subject to wind and/or seismic loads), tall non-load-bearing exterior walls (where the self-weight of the wall decreases wall capacity), and walls with an eccentric vertical load. Figure 68.2 shows the bending moment and transverse loading distributions assumed in the design of such walls.

Axial capacity decreases with increasing wall height. For very tall slender walls, elastic buckling is the limiting factor. For most masonry walls, however, the main effect of slenderness is the development of additional bending due to deflection (known as the  $P\Delta$  effect). *MSJC* uses  $h/r$  to evaluate the performance of hollow and partially grouted masonry.

Walls subject only to compressive loads may be in pure compression or may be subject to flexure. For unreinforced walls where the compressive load is within a distance  $S/A_n$  (i.e.,  $t/6$  for solid sections) from the centroid of the wall, there will be no net tensile stress due to load eccentricity.

The critical section for walls subject to eccentric load and out-of-plane loads (such as wind or seismic) may be either at the top of the wall or at midheight, depending on the magnitudes of the loads. Both locations should be checked. Unreinforced walls subjected to axial compression, flexure, or both must satisfy Eq. 68.17 through Eq. 68.22 [*MSJC* Sec. 2.2.3]. In Eq. 68.19,  $e$  should be the

**Figure 68.2** Unreinforced Walls Subject to Axial Compression and Flexure

actual or estimated eccentricity. It should not include virtual eccentricity due to lateral load.

$$\frac{f_a}{F_a} + \frac{f_b}{F_b} \leq 1 \quad 68.17$$

$$P \leq \frac{1}{4}P_e \quad 68.18$$

$$P_e = \left( \frac{\pi^2 E_m I_n}{h^2} \right) \left( 1 - 0.577 \left( \frac{e}{r} \right)^3 \right) \quad 68.19$$

$$F_a = \frac{1}{4}f'_m \left( 1 - \left( \frac{h}{140r} \right)^2 \right) \quad [\text{for } h/r \leq 99] \quad 68.20$$

$$F_a = \frac{1}{4}f'_m \left( \frac{70r}{h} \right)^2 \quad [\text{for } h/r > 99] \quad 68.21$$

$$F_b = \frac{1}{3}f'_m \quad 68.22$$

Equation 68.17 recognizes that compressive stresses due to both axial load and bending may occur simultaneously, and it assumes a straight-line interaction between axial and flexural compression stresses. This is often referred to as the *unity equation*. Equation 68.18 is intended to safeguard against buckling due to an eccentric axial load. This replaces arbitrary slenderness limits used in previous codes.

The effect of wall slenderness is included in Eq. 68.20 and Eq. 68.21. The allowable compressive stress is reduced by the final term in each equation based on its

$h/r$  ratio. The axial capacity of the wall is reduced by 50% when its slenderness reaches the transition value ( $h/r = 99$ ) from Eq. 68.20 to Eq. 68.21.

### Example 68.3

Determine the maximum allowable concentric axial load on an 8 in hollow unreinforced concrete masonry wall (with face shell mortar bedding) rising vertically 12 ft.  $f'_m = 2000$  psi.

*Solution*

From App. 68.A,

$$r = 2.84 \text{ in}$$

$$A_n = 30 \text{ in}^2/\text{ft}$$

$$I_n = 308.7 \text{ in}^4/\text{ft}$$

$$S = 81.0 \text{ in}^3/\text{ft}$$

$$\frac{h}{r} = \frac{(12 \text{ ft})(12 \frac{\text{in}}{\text{ft}})}{2.84 \text{ in}}$$

$$= 50.7 \quad [< 99]$$

From Eq. 68.20,

$$\begin{aligned} F_a &= \frac{1}{4}f'_m \left( 1 - \left( \frac{h}{140r} \right)^2 \right) \\ &= \left( \frac{1}{4} \right) \left( 2000 \frac{\text{lbf}}{\text{in}^2} \right) \left( 1 - \left( \frac{50.7}{140} \right)^2 \right) \\ &= 434 \frac{\text{lbf}}{\text{in}^2} \end{aligned}$$

For concentric loading,

$$\begin{aligned} P &= A_n F_a = \left( 30 \frac{\text{in}^2}{\text{ft}} \right) \left( 434 \frac{\text{lbf}}{\text{in}^2} \right) \\ &= 13,020 \frac{\text{lbf}}{\text{ft}} \end{aligned}$$

Check buckling.

$$\begin{aligned} E_m &= 900f'_m = (900) \left( 2000 \frac{\text{lbf}}{\text{in}^2} \right) \\ &= 1,800,000 \frac{\text{lbf}}{\text{in}^2} \\ e &= 0 \end{aligned}$$

From Eq. 68.19, with concentric ( $e = 0$ ) loading,

$$\begin{aligned} P_e &= \left( \frac{\pi^2 E_m I_n}{h^2} \right) \left( 1 - 0.577 \left( \frac{e}{r} \right) \right)^3 \\ &= \left( \frac{\pi^2 (1.8 \times 10^6 \frac{\text{lbf}}{\text{in}^2}) (308.7 \frac{\text{in}^4}{\text{ft}})}{(144 \text{ in})^2} \right) (1)^3 \\ &= 264,475 \frac{\text{lbf}}{\text{ft}} \end{aligned}$$

Check using Eq. 68.18.

$$\begin{aligned} P &\leq \frac{1}{4}P_e \\ &\leq \left( \frac{1}{4} \right) (264,475 \frac{\text{lbf}}{\text{ft}}) \end{aligned}$$

$$\boxed{13,020 \frac{\text{lbf}}{\text{ft}}} \leq 66,119 \frac{\text{lbf}}{\text{ft}} \quad [\text{OK}]$$

#### Example 68.4

Repeat Ex. 68.3 assuming an eccentricity of 1.5 in.

*Solution*

From Ex. 68.3,  $F_a = 434 \frac{\text{lbf}}{\text{in}^2}$ .

$$\begin{aligned} f_a &= \frac{P}{A_n} \\ f_b &= \frac{M}{S} = \frac{Pe}{S} \end{aligned}$$

From Eq. 68.22,

$$\begin{aligned} F_b &= \frac{1}{3}f'_m = \left( \frac{1}{3} \right) \left( 2000 \frac{\text{lbf}}{\text{in}^2} \right) \\ &= 667 \frac{\text{lbf}}{\text{in}^2} \end{aligned}$$

From Eq. 68.17,

$$\begin{aligned} \frac{P}{F_a} + \frac{Pe}{F_b} &= 1 \\ \frac{P}{30 \frac{\text{in}^2}{\text{ft}}} + \frac{P(1.5 \text{ in})}{81 \frac{\text{in}^3}{\text{ft}}} &= 1 \\ 434 \frac{\text{lbf}}{\text{in}^2} + \frac{667 \frac{\text{lbf}}{\text{in}^2}}{81 \frac{\text{in}^3}{\text{ft}}} &= 1 \\ P &= 9563 \frac{\text{lbf}}{\text{ft}} \end{aligned}$$

Check buckling using Eq. 68.18 and Eq. 68.19.

$$\begin{aligned} P_e &= \left( \frac{\pi^2 E_m I_n}{h^2} \right) \left( 1 - 0.577 \left( \frac{e}{r} \right) \right)^3 \\ &= \left( \frac{\pi^2 (1.8 \times 10^6 \frac{\text{lbf}}{\text{in}^2}) (308.7 \frac{\text{in}^4}{\text{ft}})}{(144 \text{ in})^2} \right) \\ &\quad \times \left( 1 - (0.577) \left( \frac{1.5 \text{ in}}{2.84 \text{ in}} \right) \right)^3 \\ &= 88,879 \frac{\text{lbf}}{\text{ft}} \\ P &\leq \frac{1}{4}P_e = \left( \frac{1}{4} \right) (88,879 \frac{\text{lbf}}{\text{ft}}) = 22,220 \frac{\text{lbf}}{\text{ft}} \quad [\text{OK}] \end{aligned}$$

Check tension.

$$\begin{aligned} -f_a + f_b &< F_t \\ -\frac{P}{A_n} + \frac{Pe}{S} &< F_t = 19 \frac{\text{lbf}}{\text{in}^2} \quad [\text{for type N mortar}] \\ -\frac{9563 \frac{\text{lbf}}{\text{ft}}}{30 \frac{\text{in}^2}{\text{ft}}} + \frac{\left( 9563 \frac{\text{lbf}}{\text{ft}} \right) (1.5 \text{ in})}{81 \frac{\text{in}^3}{\text{ft}}} &= -142 \frac{\text{lbf}}{\text{in}^2} \end{aligned}$$

The section is in compression, so there is no net tension.

#### 10. SD WALL DESIGN: AXIAL COMPRESSION AND FLEXURE—UNREINFORCED

SD of unreinforced masonry walls is performed in accordance with principles of engineering mechanics with the masonry compressive stresses limited to  $0.80f'_m$  and the tension stresses limited in accordance with values in Table 68.2 [MSJC Table 3.1.8.2.1]. The strength reduction factor for both flexure and axial loading is 0.60 for unreinforced masonry. The nominal axial capacity is modified on the basis of the wall slenderness and computed using MSJC Sec. 3.2.2.3 as

$$P_n = 0.80 \left( 0.80 A_n f'_m \left( 1 - \left( \frac{h}{140r} \right)^2 \right) \right) \quad [\text{when } h/r \leq 99] \quad 68.23$$

$$P_n = 0.80 \left( 0.80 A_n f'_m \left( \frac{70r}{h} \right)^2 \right) \quad [ \text{when } h/r > 99 ] \quad 68.24$$

From *MSJC* Sec. 3.1.3,

$$P_u \leq \phi P_n \quad 68.25$$

$P_u$  is calculated using the applicable load factors from the code. *MSJC* does not require checking the unity (interaction) equation for SD of unreinforced walls.

$P-\Delta$  effects must also be accounted for in SD of masonry walls. *MSJC* Sec. 3.2.2.4 states that the member must be designed for both the factored axial load,  $P_w$ , and the moment magnified for the effects of curvature,  $M_c$ .  $M_c$  must be calculated by second-order analysis or by using a first-order analysis along with the simplified equations provided in *MSJC* Sec. 3.2.2.4.2.

## 11. ASD WALL DESIGN: AXIAL COMPRESSION AND FLEXURE REINFORCED

Reinforced walls subjected to axial compression and/or flexure are designed according to the following requirements. From *MSJC* Sec. 2.3.3.2.2,

$$F_b = \frac{1}{3} f'_m \quad 68.26$$

The compressive force due to axial loading is limited by *MSJC* Sec. 2.3.3.2.1 to

$$P_a = (0.25 f'_m A_n + 0.65 A_s F_s) \left( 1 - \left( \frac{h}{140r} \right)^2 \right) \quad [ \text{when } h/r \leq 99 ] \quad 68.27$$

$$P_a = (0.25 f'_m A_n + 0.65 A_s F_s) \left( \frac{70r}{h} \right)^2 \quad [ \text{when } h/r > 99 ] \quad 68.28$$

Many approaches are used to design reinforced masonry walls for combined axial compression and flexure, typically using iterative procedures (usually by means of computer programs) or graphic methods (i.e., interaction diagrams).

Figure 68.3 and Fig. 68.4 show interaction diagrams. For cases where compression controls, use Fig. 68.3. Where tension controls, use Fig. 68.4. The controlling condition is determined by comparing  $k$  to  $k_b$ , where

$$k_b = \frac{F_b}{F_b + \frac{F_s}{n}} \quad 68.29$$

These diagrams are applicable to fully grouted masonry and to partially grouted masonry where the neutral axis falls within the face shell. Therefore, the designer must verify that  $kd < t_{fs}$  when using these diagrams.

### Example 68.5

Determine the amount of steel needed to adequately reinforce an 8 in fully grouted concrete masonry wall subjected to a compressive load of 1000 lbf/ft with an eccentricity at the midheight of the wall of 6 in. Use the following values.

$$f'_m = 1500 \text{ lbf/in}^2$$

$$F_b = 500 \text{ lbf/in}^2$$

$$n = 21.5$$

$$\frac{h}{r} = 68$$

$$A_n = 91.5 \text{ in}^2/\text{ft}$$

$$F_s = 24,000 \text{ lbf/in}^2$$

### Solution

Calculate the relevant parameters for the interaction diagrams.

$$\frac{P}{F_b b t} = \frac{1000 \frac{\text{lbf}}{\text{ft}}}{\left( 500 \frac{\text{lbf}}{\text{in}^2} \right) (12 \text{ in}) (7.625 \text{ in})} = 0.022$$

$$\frac{P_e}{F_b b t^2} = \frac{\left( 1000 \frac{\text{lbf}}{\text{ft}} \right) (6 \text{ in})}{\left( 500 \frac{\text{lbf}}{\text{in}^2} \right) (12 \text{ in}) (7.625 \text{ in})^2} = 0.017$$

From Eq. 68.29,

$$k_b = \frac{F_b}{F_b + \frac{F_s}{n}} = \frac{500 \frac{\text{lbf}}{\text{in}^2}}{500 \frac{\text{lbf}}{\text{in}^2} + \frac{24,000 \frac{\text{lbf}}{\text{in}^2}}{21.5}} = 0.309$$

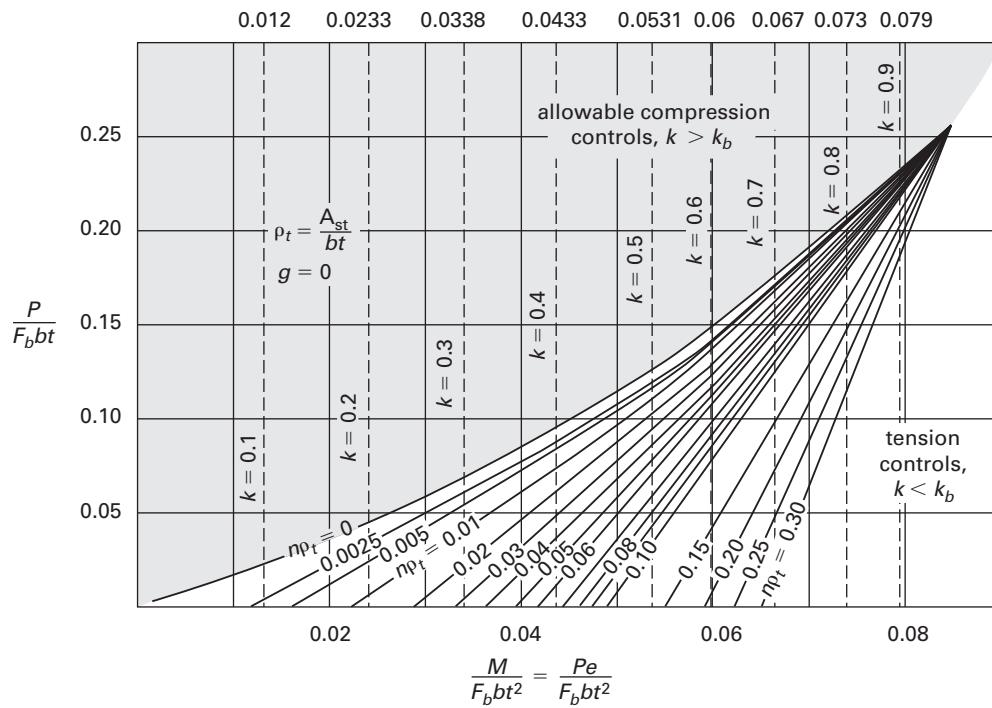

From Fig. 68.3,  $k = 0.14$ . Since  $k < k_b$ , tension governs and Fig. 68.4 should be used. From Fig. 68.4,  $n\rho_t = 0.014 = \rho_t F_s / F_b$ . For bonded materials experiencing the same strain,  $n = f_1/f_2$ .

$$\rho_t = \frac{0.014 F_b}{F_s} = \frac{(0.014) \left( 500 \frac{\text{lbf}}{\text{in}^2} \right)}{24,000 \frac{\text{lbf}}{\text{in}^2}} = 0.00029$$

$$A_s = \rho_t b t = (0.00029) (12 \text{ in}) (7.625 \text{ in}) = 0.027 \text{ in}^2/\text{ft}$$

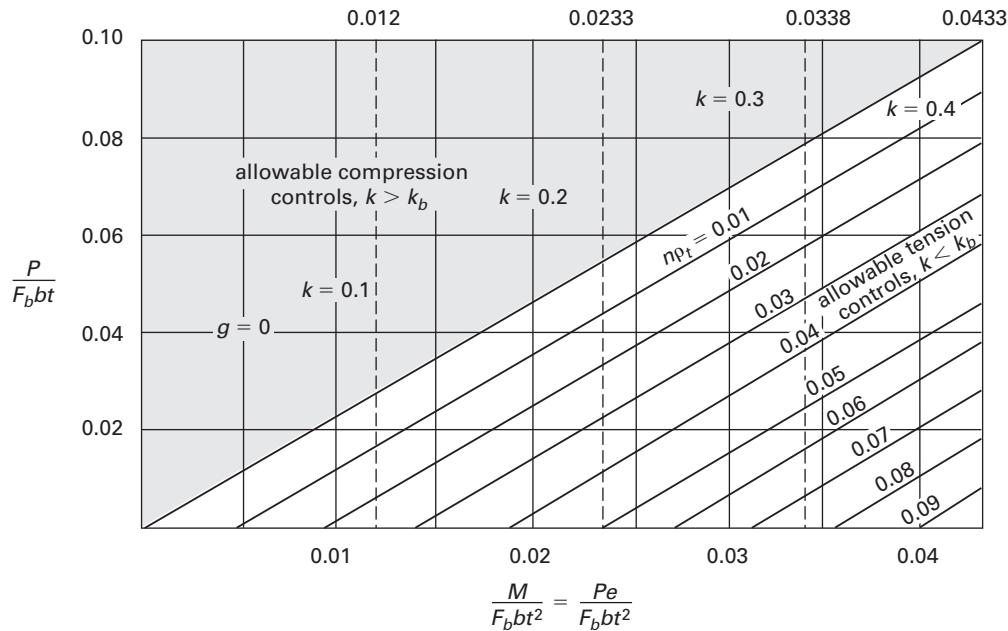

From Table 68.3, choose no. 3 bars at 48 in on center for a steel area of  $A_s = 0.028 \text{ in}^2/\text{ft}$ .

**Figure 68.4** Interaction Diagram for Reinforced Wall (tension controls)

Reprinted by permission of the American Concrete Institute from *Masonry Designer's Guide*, copyright © 1993.

Check the allowable compressive force. For  $h/r < 99$ , use Eq. 68.27.

$$P_a = (0.25f'_m A_n + 0.65A_{st}F_s) \left(1 - \left(\frac{h}{140r}\right)^2\right)$$

$$= \left( (0.25) \left( 1500 \frac{\text{lbf}}{\text{in}^2} \right) \left( 91.5 \frac{\text{in}^2}{\text{ft}} \right) + (0.65) \left( 0.028 \frac{\text{in}^2}{\text{ft}} \right) \left( 24,000 \frac{\text{lbf}}{\text{in}^2} \right) \right) \times \left( 1 - \left( \frac{68}{140} \right)^2 \right)$$

$$= 26,551 \text{ lbf/ft} > 1000 \text{ lbf/ft} \quad [\text{OK}]$$

## 12. SD WALL DESIGN: AXIAL COMPRESSION AND FLEXURE—REINFORCED

SD of reinforced walls for flexure and axial compression is similar to reinforced concrete design, although the values for many of the design parameters are different. The equivalent rectangular stress block has a depth of  $0.80c$ , and the maximum usable compressive masonry stress is assumed to be  $0.80f'_m$ . The maximum usable compression fiber strain is assumed to be 0.0035 for clay masonry and 0.0025 for concrete masonry [MSJC Sec. 3.3.2].

Flexure of walls is generally due to out-of-plane loads such as wind, soil, earthquake, or eccentric axial loads. MSJC Sec. 3.3.5 presents the design requirements. The effects of floor load eccentricity and wall deflection are included. The factored design moment and strength are computed from MSJC Sec. 3.3.5.3 based on a simple support at the top and bottom and steel located in the center of the wall.

$$M_u = \frac{w_u h^2}{8} + P_{uf} \frac{e_u}{2} + P_u \delta_u \quad 68.30$$

$$M_u \leq \phi M_n \quad 68.31$$

$$M_n = (A_s f_y + P_u) \left( d - \frac{a}{2} \right) \quad 68.32$$

$$a = \frac{A_s f_y + P_u}{0.80f'_m b} \quad 68.33$$

The design solution, however, must limit the reinforcement to ensure ductility as defined in MSJC Sec. 3.3.3.5. Walls designed using a seismic response modification factor,  $R > 1.5$ , must be capable of achieving a steel strain of 0, 1.5, 3, or 4 times yield prior to reaching the maximum permitted masonry compression strain, depending on the design conditions.

MSJC does not have any specific slenderness limitations for walls that have a relatively low axial stress ( $< 0.05f'_m$ ). Walls with a higher axial stress are limited to a slenderness ratio no greater than 30; however, a factored axial stress exceeding  $0.20f'_m$  is not permitted [MSJC Sec. 3.3.5.3]. Slenderness is addressed by placing limits on wall deflection. MSJC Sec. 3.3.5.4 requires that

the horizontal midheight deflection of walls due to service loads,  $\delta_s$ , must not exceed  $0.007h$ . The  $P-\Delta$  effect and effects of masonry cracking must be included. The cracking moment is calculated from the modulus of rupture (see Table 68.2) and the section modulus,

$$M_{cr} = Sf_r \quad 68.34$$

When the service loads moment does not exceed the cracking moment ( $M_{ser} < M_{cr}$ ), Eq. 68.35 [MSJC Eq. 3-30] applies.

$$\delta_s = \frac{5M_{ser}h^2}{48E_m I_g} \quad 68.35$$

When  $M_{cr} < M_{ser} < M_n$ , Eq. 68.36 [MSJC Eq. 3-31] applies.

$$\delta_s = \frac{5M_{cr}h^2}{48E_m I_g} + \frac{5(M_{ser} - M_{cr})h^2}{48E_m I_{cr}} \quad 68.36$$

## 13. ASD WALL DESIGN: SHEAR

Design of masonry walls for shear focuses primarily on shear walls, since flexural shear due to out-of-plane bending seldom governs the design. (In-plane shear often controls.) Shear walls must be oriented along both axes of the building, since seismic and wind lateral loads can occur in any direction.

Small openings in shear walls do not impact intended performance to a great degree. Shear walls with large openings can be thought of as smaller shear panels connected by panels subject to shear and flexure.

Loads distributed to shear walls depend on the relative rigidities of the floor diaphragms and shear walls. *Flexible diaphragms* transfer loads in proportion to the distance between the load and shear wall, whereas *rigid diaphragms* transfer loads in proportion to the relative stiffness of the walls. To design walls as rigid diaphragms, the proportions must meet the ratios given in Table 68.4.

**Table 68.4** Maximum Span-to-Width Ratios for Rigid Floor Diaphragms

floor construction	span-to-width
cast-in-place solid concrete slab	5:1
precast concrete interconnected	4:1
metal deck with concrete fill	3:1
metal deck with no fill	2:1
cast-in-place gypsum deck (roof)	3:1

Shear wall design depends on the wall axial load for two reasons. First, walls in compression have greater shear resistance. Second, compression offsets flexural tension from lateral loads, which may eliminate the need for flexural reinforcement due to shear.

If there is no net flexural tension, the shear wall is designed as an unreinforced wall [MSJC Sec. 2.3.5.1]. Shear reinforcement is required only if  $f'_v > F'_v$ . If there

is flexural tension in the wall, the wall must be reinforced to resist that tension. The design is checked to determine if that reinforcement is sufficient to resist shear as well.  $f_v$  is calculated in accordance with *MSJC* Sec. 2.3.5.2.1.

If  $f_v > F_v$ , shear reinforcement must be provided.  $F_v$  is recalculated according to *MSJC* Sec. 2.3.5.2.3, assuming that all of the design shear is resisted by the shear reinforcement steel. If  $f_v$  still exceeds  $F_v$ , a larger wall must be used to resist shear.

*MSJC* Sec. 1.17 gives restrictions and requirements for structures based on the applicable seismic design category (SDC). Unreinforced shear walls are not permitted in SDC C, D, E, or F [*MSJC* Sec. 1.17.4.3, Sec. 1.17.4.4, and Sec. 1.17.4.5]. Based on the SDC, the code may require the addition of minimum reinforcement at prescribed locations. These requirements help ensure ductility in the walls during extreme loadings.

#### 14. ASD WALL DESIGN: SHEAR WALLS WITH NO NET TENSION—UNREINFORCED

If the compressive stress,  $P/A_n$ , exceeds flexural stress,  $M/S$ , the wall has no net flexural tension. In this case,  $f_v$  and  $F_v$  are determined according to the following procedure [*MSJC* Sec. 2.2.5.1].

$$f_v = \frac{VQ}{I_n b} = \frac{3V}{2A_n} \quad [\text{rectangular sections}] \quad 68.37$$

Under *MSJC* Sec. 2.2.5.2, allowable in-plane shear stress,  $F_v$ , is the least of

$$(a) 1.5\sqrt{f'_m} \quad 68.38$$

$$(b) 120 \text{ lbf/in}^2 \quad (0.83 \text{ MPa}) \quad 68.39$$

$$(c) v + 0.45N_v/A_n \quad 68.40$$

In Eq. 68.40,  $v$  has values of  $37 \text{ lbf/in}^2$  ( $0.26 \text{ MPa}$ ) for masonry in running bond that is not grouted solid,  $37 \text{ lbf/in}^2$  ( $0.26 \text{ MPa}$ ) for masonry in other than running bond with open end units that are grouted solid, and  $60 \text{ lbf/in}^2$  ( $0.41 \text{ MPa}$ ) for masonry in running bond that is grouted solid. For masonry in other than running bond with other than open end units that are grouted solid, Eq. 68.40 is replaced by a single value of  $15 \text{ lbf/in}^2$  ( $0.10 \text{ MPa}$ ).

As for other stress conditions in ASD, the calculated stress,  $f_v$ , may not exceed the allowable  $F_v$ . If  $f_v > F_v$ , the wall must be reinforced or increased in size.

#### 15. SD WALL DESIGN: SHEAR WALLS—UNREINFORCED

Unreinforced shear walls are addressed in *MSJC* Sec. 3.2.4. For walls where the factored shear strength,  $V_u$ , does not exceed the design shear strength, no special shear reinforcing is required. The nominal shear

strength,  $V_n$ , is a function of the net cross section and is the least of the following values.

$$(a) 3.8A_n\sqrt{f'_m} \quad 68.41$$

$$(b) 300A_n \quad 68.42$$

$$(c) 56A_n + 0.45N_u \quad \begin{matrix} [\text{for running bond masonry}] \\ \text{not grouted solid} \end{matrix} \quad 68.43$$

$$(d) 90A_n + 0.45N_u \quad \begin{matrix} [\text{for running bond masonry}] \\ \text{grouted solid} \end{matrix} \quad 68.44$$

Values of  $V_n$  are reduced for patterns other than running bond. If  $V_u > \phi V_n$ , then the wall must be reinforced for shear or increased in size. The strength reduction factor,  $\phi$ , is 0.80 for masonry subjected to shear [*MSJC* Sec. 3.1.4.3].

#### 16. ASD WALL DESIGN: SHEAR WALLS WITH NET TENSION—REINFORCED

Walls subjected to flexural tension are reinforced to resist the tension. In this case, the calculated shear stress in the masonry is determined by Eq. 68.45 [*MSJC* Sec. 2.3.5.2].

$$f_v = \frac{V}{bd} \quad 68.45$$

Where reinforcement is not provided to resist all of the calculated shear,  $F_v$  is determined from *MSJC* Sec. 2.3.5.2.2. The quantity  $M/Vd$  is always taken as a positive value.

$$F_v = \frac{1}{3}\left(4 - \frac{M}{Vd}\right)\sqrt{f'_m} \\ < 80 - 45\left(\frac{M}{Vd}\right) \quad [\text{when } M/Vd < 1] \quad 68.46$$

$$F_v = \sqrt{f'_m} \\ < 35 \text{ lbf/in}^2 \quad (0.24 \text{ MPa}) \quad [\text{when } M/Vd \geq 1] \quad 68.47$$

If  $f_v < F_v$ , the section is satisfactory. If  $f_v > F_v$ , shear reinforcement is required, and  $F_v$  is recalculated with reinforcement provided to resist all of the calculated shear. *MSJC* Sec. 2.3.5.2.3 specifies the allowable shear stress as shown in Eq. 68.45.

$$F_v = \frac{1}{2}\left(4 - \frac{M}{Vd}\right)\sqrt{f'_m} \\ < 120 - 45\left(\frac{M}{Vd}\right) \quad [\text{when } M/Vd < 1] \quad 68.48$$

$$F_v = 1.5\sqrt{f'_m} \\ < 75 \text{ lbf/in}^2 \quad (0.52 \text{ MPa}) \quad [\text{when } M/Vd \geq 1] \quad 68.49$$

If  $f_v$  still exceeds  $F_v$ , the wall size must be increased.

When shear reinforcement is required to resist all of the calculated shear, *MSJC* contains the following

requirements. The minimum area of shear reinforcement placed parallel to the direction of applied shear force according to *MSJC* Sec. 2.3.5.3 is

$$A_v = \frac{V_s}{F_s d} \quad 68.50$$

Maximum spacing of shear reinforcement is the lesser of  $d/2$  or 48 in (1219 mm). Reinforcement must also be provided perpendicular to the shear reinforcement. This reinforcement must be uniformly distributed, have a maximum spacing of 8 ft (2.44 m), and have a minimum reinforcement area of at least  $\frac{1}{3}A_v$  [*MSJC* Sec. 2.3.5.3.1 and Sec. 2.3.5.3.2].

## 17. SD WALL DESIGN: SHEAR WALLS—REINFORCED

Walls subjected to in-plane loads (shear walls) are addressed in *MSJC* Sec. 3.3.4.1.2 and Sec. 3.3.6. Shear forces may be shared by the masonry and the shear reinforcement as indicated by the following equation.

$$V_n = V_{nm} + V_{ns} \quad [\text{MSJC Sec. 3.3.4.1.2}] \quad 68.51$$

$$\leq 6A_n\sqrt{f'_m} \quad [\text{when } M_u/V_ud_v < 0.25] \quad 68.52$$

$$\leq 4A_n\sqrt{f'_m} \quad [\text{when } M_u/V_ud_v > 1.0] \quad 68.53$$

When  $0.25 < M_u/V_ud_v < 1.0$ , the value of  $V_n$  may be interpolated.

The nominal shear strength provided by the masonry,  $V_{nm}$ , is computed from *MSJC* Sec. 3.3.4.1.2.1 as

$$V_{nm} = \left(4 - 1.75 \frac{M_u}{V_ud_v}\right) A_n \sqrt{f'_m} + 0.25P_u \quad 68.54$$

If  $M_u/V_ud_v$  is conservatively taken as its maximum value of 1.0 and the axial force is minimal, Eq. 68.54 becomes

$$V_{nm} = 2.25A_n\sqrt{f'_m} \quad 68.55$$

The nominal shear strength provided by shear reinforcement is calculated from *MSJC* Sec. 3.3.4.1.2.3 as

$$V_{ns} = 0.5 \left(\frac{A_v}{s}\right) f_y d_v \quad 68.56$$

*MSJC* limits the maximum reinforcement permitted in SD shear wall design, similar to the limits for SD wall design related to axial compression and flexure. However, *MSJC* Sec. 3.3.3.5 requires that shear walls that are part of structures designed for a seismic response modification factor,  $R$ , greater than 1.5 must be capable of achieving a steel strain of five times yield prior to reaching the maximum permitted masonry strain. This requirement is severe and may control the design.

The flexural and axial strength of shear walls is calculated using the criteria for nominal strength of beams, piers, and columns [*MSJC* Sec. 3.3.4.1.1]. The following equations are used to compute the nominal axial capacity.

$$P_n = 0.80 \left(0.80f'_m(A_n - A_s) + f_y A_s\right) \left(1 - \left(\frac{h}{140r}\right)^2\right) \quad [\text{when } h/r \leq 99] \quad 68.57$$

$$P_n = 0.80 \left(0.80f'_m(A_n - A_s) + f_y A_s\right) \left(\frac{70r}{h}\right)^2 \quad [\text{when } h/r > 99] \quad 68.58$$

The nominal axial strength,  $P_n$ , when reduced by the strength reduction factor, must not exceed the factored axial loads. The strength reduction factor,  $\phi$ , is 0.90 for masonry subjected to axial loads [*MSJC* Sec. 3.1.4.1].

$$P_u \leq \phi P_n$$

## 18. MULTI-WYTHE CONSTRUCTION

Multiple-wythe masonry walls are analyzed using the same procedures outlined in previous sections. In some cases, however, determination of wall thickness or other parameters may vary, depending on the type of wall and how it is loaded.

Multi-wythe walls can be designed for *composite action* (i.e., where the two wythes act as one unit to resist loads) or for *noncomposite action*. Masonry veneer is a nonstructural facing that transfers the out-of-plane load to the backing (structural wythe). *MSJC* Chap. 6 contains requirements for both anchored and adhered veneer. SD of multi-wythe construction is not addressed by the code.

## 19. MULTI-WYTHE CONSTRUCTION—COMPOSITE ACTION

Multi-wythe walls designed for composite action are tied together by either wall ties or masonry headers. (Wall ties are more common and provide more ductility than headers.) The ties or headers ensure adequate shear transfer across the collar joint. When wall ties are used, the space between the wythes (collar joint) must be filled with mortar or grout. To help ensure shear transfer, specific requirements govern the size and spacing of the headers and ties, and shear stresses are limited.

For composite action, stresses are calculated using section properties based on the minimum transformed net cross-sectional area of the composite member. Areas of dissimilar materials are transformed in accordance with relative elastic moduli ratios.

Shear stresses at the interfaces between wythes and collar joints or within headers are limited to the following: mortared collar joints, 5 lbf/in<sup>2</sup> (0.034 MPa);

grouted collar joints,  $10 \text{ lbf/in}^2$  ( $0.069 \text{ MPa}$ ); headers,  $\sqrt{\text{unit compressive strength of header}}$ , in  $\text{lbf/in}^2$  ( $\text{MPa}$ ), over net area of header [MSJC Sec. 2.1.5.2.2].

When bonded by headers, the headers must be uniformly distributed. The sum of their cross-sectional areas must be at least 4% of the wall surface area. Headers must be embedded at least 3 in (76 mm) into each wythe [MSJC Sec. 2.1.5.2.3].

Wythes bonded using wall ties are subject to the following restrictions [MSJC Sec. 2.1.5.2.4].

- Maximum spacing between ties is 36 in (914 mm) horizontally and 24 in (610 mm) vertically.
- With a W1.7 wire, one wall tie is needed for every  $2\frac{2}{3} \text{ ft}^2$  ( $0.25 \text{ m}^2$ ) of wall. With W2.8 wire, one wall tie is needed for every  $4\frac{1}{2} \text{ ft}^2$  ( $0.42 \text{ m}^2$ ) of wall.

Cross wires of joint reinforcement or rectangular wall ties may be used as wall ties. "Z" wall ties can be used only on walls constructed of solid masonry units.

### Example 68.6

Determine the maximum lateral wind load that can be sustained by a non-load-bearing multi-wythe composite wall constructed of 8 in concrete masonry units (CMUs), a 3 in grouted collar joint, and 4 in meridian face brick. Both wythes are constructed with type-S portland cement-lime mortar. The wall spans vertically 20 ft and can be assumed to be simply supported laterally at the top and bottom. Neglect the self-weight of the wall and utilize the one-third increase in allowable stress for wind loads. The following properties are to be used.

	CMU	brick	grout
$f'_m$ or $f'_g$ (in $\text{lbf/in}^2$ )	1500	2500	2000
$E_m$ (in $\text{lbf/in}^2$ )	1,350,000	1,750,000	1,000,000

### Solution

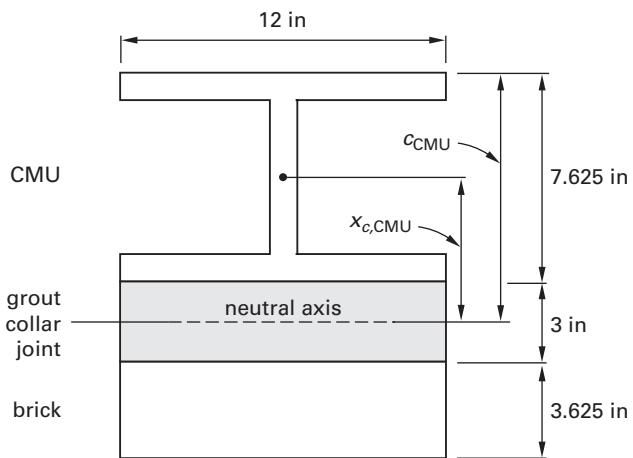

The modular ratios for the brick and grout are

$$n_{br} = \frac{E_{m,br}}{E_{m,CMU}} = \frac{1,750,000 \frac{\text{lbf}}{\text{in}^2}}{1,350,000 \frac{\text{lbf}}{\text{in}^2}} = 1.3$$

$$n_g = \frac{E_{m,g}}{E_{m,CMU}} = \frac{1,000,000 \frac{\text{lbf}}{\text{in}^2}}{1,350,000 \frac{\text{lbf}}{\text{in}^2}} = 0.74$$

The thickness of the CMU, grout, and 4 in face brick are  $7\frac{5}{8}$  in (7.625 in), 3 in, and  $3\frac{5}{8}$  in (3.625 in) respectively. From App. 68.A,  $A_{n,CMU} = 30 \text{ in}^2/\text{ft}$ , and  $A_{n,br} = 42 \text{ in}^2/\text{ft}$ . The area of the grout is

$$A_g = (3 \text{ in})(12 \text{ in}) = 36 \text{ in}^2$$

The modular ratios transform the brick and grout areas without changing their thicknesses. Determine the location of the centroid of the composite wall. Work with a 1 ft wall width, which corresponds to the width of the CMU. Measure the distance from the centroid of the CMU.

$$\begin{aligned} x_c &= \frac{\sum A_i x_{c,i}}{\sum A_i} \\ &= \frac{A_{CMU} x_{c,CMU} + n_g A_g x_{c,g} + n_{br} A_{br} x_{c,br}}{A_{CMU} + n_g A_g + n_{br} A_{br}} \\ &= \frac{(30 \text{ in}^2)(0 \text{ in}) + (0.74)(36 \text{ in}^2)\left(\frac{7.625 \text{ in}}{2} + \frac{3 \text{ in}}{2}\right)}{30 \text{ in}^2 + (0.74)(36 \text{ in}^2) + (1.3)(42 \text{ in}^2)} \\ &= 5.506 \text{ in} \end{aligned}$$

From App. 68.B,  $I_{CMU} = 308.7 \text{ in}^4/\text{ft}$ . From App. 68.C,  $I_{br} = 42.9 \text{ in}^4/\text{ft}$ . The centroidal moment of inertia of the grout is

$$I_g = \frac{wt^3}{12} = \frac{(12 \text{ in})(3 \text{ in})^3}{12} = 27 \text{ in}^4$$

Work with a 1 ft wall width, which corresponds to the width of the CMU. Use the parallel axis theorem. The transformed moment of inertia per foot of wall is

$$\begin{aligned} I_{tr} &= \sum (I_{c,i} + A_t d_i^2) \\ &= 308.7 \text{ in}^4 + (30 \text{ in}^2)(5.506 \text{ in})^2 \\ &\quad + 27 \text{ in}^4 + (0.74)(36 \text{ in}^2) \left( \frac{5.506 \text{ in} - \frac{7.625 \text{ in}}{2}}{\frac{3 \text{ in}}{2}} \right)^2 \\ &\quad + 42.9 \text{ in}^4 + (1.3)(42 \text{ in}^2) \left( \frac{5.506 \text{ in} - \frac{7.625 \text{ in}}{2}}{\frac{3 \text{ in} - \frac{3.625 \text{ in}}{2}}{2}} \right)^2 \\ &= 1820.2 \text{ in}^4 \end{aligned}$$

Determine the allowable flexural tension from Table 68.1.

$$F_{b,CMU} = \left(25 \frac{\text{lbf}}{\text{in}^2}\right)(1.33) = 33.3 \text{ lbf/in}^2$$

$$F_{b,br} = \left(40 \frac{\text{lbf}}{\text{in}^2}\right)(1.33) = 53.2 \text{ lbf/in}^2$$

Determine the maximum allowable moment for each wythe.

$$c_{CMU} = x_{c,CMU} + \frac{d_{CMU}}{2} = 5.506 \text{ in} + \frac{7.625 \text{ in}}{2} \\ = 9.32 \text{ in}$$

$$\text{CMU: } M = \frac{F_b I_{\text{tr}}}{c} \\ = \frac{\left(33.3 \frac{\text{lbf}}{\text{in}^2}\right)(1820.2 \text{ in}^4)}{9.32 \text{ in}} \\ = 6504 \text{ in-lbf}$$

$$c_{\text{brick}} = d_{\text{total}} - c_{\text{CMU}} \\ = 7.625 \text{ in} + 3 \text{ in} + 3.625 \text{ in} - 9.32 \text{ in} \\ = 4.93 \text{ in}$$

$$\text{brick: } M = \frac{F_b I_{\text{tr}}}{cn_{\text{br}}} \\ = \frac{\left(53.2 \frac{\text{lbf}}{\text{in}^2}\right)(1820.2 \text{ in}^4)}{(4.93 \text{ in})(1.3)} \\ = 15,109 \text{ in-lbf}$$

This design is limited by the allowable flexural tension stress in the CMU wythe:  $M_{\max} = 6504 \text{ in-lbf}$ .

Since the wall is simply supported laterally at its top and bottom,  $M_{\max} = wl^2/8$ .

$$w = \frac{8M_{\max}}{l^2} = \frac{(8)(6504 \frac{\text{in-lbf}}{\text{ft}})}{(20 \text{ ft})^2 \left(\frac{12 \text{ in}}{\text{ft}}\right)} \\ = 10.8 \text{ lbf/ft}^2$$

Check the shear at the collar joint. For simply supported walls,

$$V = \frac{wl}{2} = \frac{\left(10.8 \frac{\text{lbf}}{\text{ft}^2}\right)(20 \text{ ft})}{2} \\ = 108 \text{ lbf/ft}$$

The statical moment at the CMU/collar joint interface is

$$Q = (1.3)(42 \text{ in}^2)(3.12 \text{ in}) + (0.74)(36 \text{ in}^2)(0.19 \text{ in}) \\ = 175.4 \text{ in}^3$$

Use Eq. 68.37.

$$f_v = \frac{VQ}{I_{\text{tr}}b} = \frac{(108 \text{ lbf})(175.4 \text{ in}^3)}{(1820.2 \text{ in}^4)(0.74)(12 \text{ in})} \\ = 1.2 \text{ psi} < 10 \text{ psi} \quad [\text{OK}]$$

## 20. MULTI-WYTHE CONSTRUCTION—NONCOMPOSITE ACTION

For noncomposite design, each wythe is designed to individually resist the applied loads. Unless a more detailed analysis is performed, the following guidelines and restrictions apply [MSJC Sec. 2.1.5.3.1].

- Collar joints may not contain headers, grout, or mortar.
- Gravity loads from supported horizontal members are resisted by the wythe nearest to the center of the span of the supported member. Any resulting bending moment about the weak axis of the wall is distributed to each wythe in proportion to its relative stiffness.
- In-plane loads are carried only by the wythe subjected to the load.
- Out-of-plane loads are resisted by all wythes in proportion to their relative flexural stiffness.
- Stresses are determined using the net cross-sectional area of the member or part of member under consideration and, where applicable, using the transformed area concept described previously.
- Collar joint width is limited to 4.5 in (114 mm) unless a detailed wall tie analysis is performed.

Wythes can be connected using wall ties or adjustable ties. If wall ties are used, the spacings described previously under composite action are applicable. Adjustable ties are subject to the following restrictions [MSJC Sec. 2.1.5.3.2].

- One tie must be provided for each  $1.77 \text{ ft}^2$  ( $0.16 \text{ m}^2$ ) of wall area.
- The maximum horizontal and vertical spacing is 16 in (406 mm).
- Adjustable ties may not be used when the misalignment of bed joints from one wythe to the other exceeds  $1\frac{1}{4}$  in (32 mm).
- Maximum clearance between connecting parts of the tie is  $\frac{1}{6}$  in (1.6 mm).
- Pintle ties shall have at least two pintle legs of wire size W2.8 (i.e., be a *double pintle tie*).

## Nomenclature

$a$	depth of equivalent stress block	in	mm
$A$	area	in <sup>2</sup>	mm <sup>2</sup>
$A_n$	net cross-sectional area of masonry	in <sup>2</sup>	mm <sup>2</sup>
$A_s$	cross-sectional area of reinforcing steel	in <sup>2</sup>	mm <sup>2</sup>
$A_{st}$	area of laterally tied longitudinal steel in a column or pilaster	in <sup>2</sup>	mm <sup>2</sup>
$b$	column dimension	in	mm
$c$	distance from neutral axis to extreme fiber in bending	in	mm
$e$	eccentricity	in	mm
$e_k$	kern eccentricity	in	mm
$f'_m$	compressive strength of masonry	lbf/in <sup>2</sup>	MPa
$f_y$	specified steel yield strength	lbf/in <sup>2</sup>	MPa
$F_b$	allowable compressive stress due to flexure alone	lbf/in <sup>2</sup>	MPa
$F_s$	allowable stress in reinforcement	lbf/in <sup>2</sup>	MPa
$g$	ratio of distance between tension steel and compression steel to overall column depth	—	—
$h$	effective height	in	mm
$M$	maximum moment occurring simultaneously with design shear force $V$	in-lbf	N·m
$n$	modular ratio	—	—
$P$	axial load	lbf	N
$P_a$	allowable load	lbf	N
$P_{biaxial}$	maximum allowable design load for the specified biaxial load	lbf	N
$P_n$	nominal axial strength	lbf	N
$P_o$	maximum allowable design load for zero eccentricity	lbf	N
$P_u$	sum of factored axial loads	lbf	N
$P_x$	maximum allowable design load for the specified eccentricity in the $x$ -direction	lbf	N

<sup>1</sup>For the PE exam, only ASD methods may be used (except for strength design (SD) Sec. 3.3.5, which may be used for walls with out-of-plane loads). However, SD methods are provided in this chapter for your additional reference.

$P_y$	maximum allowable design load for the specified eccentricity in the $y$ -direction	lbf	N
$r$	radius of gyration	in	mm
$R$	seismic response modification factor	—	—
$S$	section modulus	in <sup>3</sup>	mm <sup>3</sup>
$t$	thickness of column	in	mm
$V$	shear force	lbf	N

## Symbols

$\Delta$	lateral deflection	in	mm
$\rho_t$	ratio of total steel area to gross area of masonry, $b_t$	—	—
$\phi$	strength reduction factor	—	—

## Subscripts

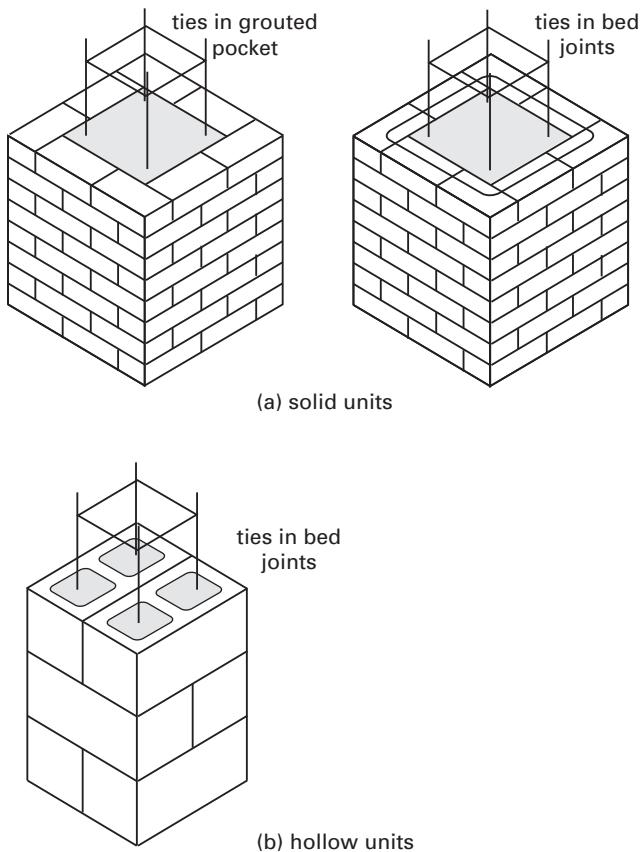

$a$	allowable
$b$	bending
$k$	kern
$m$	masonry
$n$	net or nominal
$o$	zero eccentricity
$s$	steel
$t$	tied
$u$	ultimate
$y$	yield

## 1. MASONRY COLUMNS

Columns are isolated structural elements subject to axial loads and often to flexure. To distinguish columns from short walls, *Building Code Requirements for Masonry Structures (MSJC)* defines a column as an isolated vertical member whose length-to-thickness ratio does not exceed 3 and whose height-to-thickness ratio is greater than 4 [MSJC Sec. 1.6].

*Pilasters* are sometimes confused with columns. Whereas columns are isolated elements, pilasters are integral parts of masonry walls. A pilaster is a thickened wall section that typically projects beyond one or both faces. It provides lateral stability to the masonry wall and may carry axial loads as well.

Concrete masonry columns are most often constructed of hollow masonry units, with grout and reinforcement in the masonry cores. Brick columns are typically constructed of solid units laid with an open center, as shown in Fig. 69.1. In both cases, units in successive courses should be laid in a running bond (i.e., overlapping) pattern to avoid a continuous vertical mortar joint up the side of the column.

**Figure 69.1** Column Reinforcement

Columns are designed for axial compression, flexure, and shear as needed. Design methods and assumptions are essentially the same as those presented for masonry walls. However, three significant differences may exist. (a) Due to the structural importance of columns, *MSJC* imposes additional criteria for minimum size, slenderness, and reinforcement. (b) Biaxial bending may be significant in columns. (c) Compression reinforcement may be necessary. Since all columns must be reinforced, unreinforced masonry column design is not permitted.

The method used to design the column depends on the magnitude of the axial load relative to the bending moment. There are three possibilities: (a) the column is in pure compression and the allowable axial load is governed by the allowable axial compressive force,  $P_a$ ; (b) the allowable moment and axial force are governed by the allowable flexural compressive stress,  $F_b$ ; and (c) the allowable moment and axial force are governed by the allowable tensile stress in the reinforcement,  $F_s$ .

*MSJC* Chap. 2 presents the requirements for allowable stress design (ASD), while Chap. 3 presents strength design (SD) requirements. Columns may not be designed using *MSJC* Chap. 5, which describes empirical design of masonry.

## 2. SLENDERNESS

Whereas slenderness effects are not a major consideration with most walls, they can be significant for columns. Load-carrying capacity can be reduced due to either buckling or to additional bending moments caused by deflection ( $P\Delta$  effects). In *MSJC*, slenderness effects are included in the calculation of permitted compressive stress for reinforced masonry. Columns are required by *MSJC* to have nominal side dimensions of at least 8 in (203 mm) [*MSJC* Sec. 2.1.6.1 and Sec. 3.3.4.4.2]. ASD limits the ratio of the effective height to its least dimension to 25 [*MSJC* Sec. 2.1.6.2]. SD limits the distance between supports to 30 times its least dimension [*MSJC* Sec. 3.3.4.4.2].

The effective height of a column varies with end conditions. *Effective height* is equal to the distance between points of inflection of the member's buckled configuration. Effective height reductions are made in accordance with conventional design principles. If the restraint conditions are unknown, the clear height between supports should be used (as is usually done).

## 3. REINFORCEMENT

*MSJC* requires a minimum amount of reinforcement to prevent brittle collapse of columns. The general design provisions for reinforced masonry described in this chapter are used to analyze masonry columns, as well.

The area of vertical column reinforcement must be between  $0.0025A_n$  and  $0.04A_n$ . A minimum of four reinforcement bars is required, which allows ties to provide a confined core of masonry [*MSJC* Sec. 1.14.1.2]. Vertical bars must have a clear distance between bars of at least  $1\frac{1}{2}$  times the nominal bar diameter, but not less than  $1\frac{1}{2}$  (38 mm) [*MSJC* Sec. 1.15.3.2].

Lateral ties in columns enclose the vertical bars and provide support to prevent buckling of column reinforcement acting in compression and resistance to diagonal tension for columns subjected to shear. Requirements are based on those for concrete columns and are summarized as follows [*MSJC* Sec. 1.14.1.3].

- Lateral ties must be at least  $\frac{1}{4}$  in (6.4 mm) in diameter, with maximum vertical spacing of 16 longitudinal bar diameters, 48 lateral tie bar or wire diameters, or the least cross-sectional dimension of the member.
- Every corner and alternate longitudinal bar must be supported by a tie corner. Tie corners may not have an included angle of more than  $135^\circ$ . No vertical bar can be more than 6 in (152 mm) away from such a laterally supported bar.
- Lateral ties may be placed in either a mortar joint or in grout, although placement in grout is preferable. Ties in contact with the vertical reinforcing bars are

more effective in preventing buckling and result in more ductile behavior. In seismic design categories (SDC) D, E, and F, *MSJC* requires ties to be embedded in grout, be spaced no more than 8 in (230 mm) on center, and be at least  $\frac{3}{8}$  in (9.5 mm) diameter.

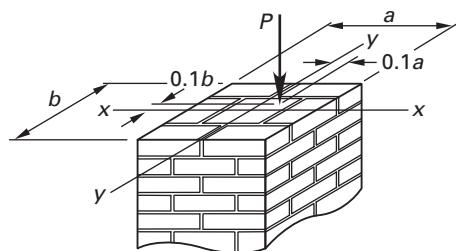

- Where longitudinal bars are located around the perimeter of a circle, a complete circular lateral tie is permitted. (The lap length for circular ties is 48 tie diameters.)
- Lateral ties must be located within one-half the lateral tie spacing at the top and bottom of the column.
- Where beams or brackets frame into a column from four directions, lateral ties may be terminated within 3 in (76 mm) below the lowest reinforcement.

Devices used to transfer lateral support to columns should be designed for the actual lateral force imposed to the columns [*MSJC* Sec. 1.7.4.3]. In SDC C, D, E, and F, *MSJC* mandates further prescriptive requirements, including ties around anchor bolts and size and spacing of column ties.

#### 4. MINIMUM COLUMN ECCENTRICITY

The eccentricity of column loads is an important consideration because of slenderness effects. Eccentricity can be due to eccentric axial loads, lateral loads, or a column that is out of plumb. For column design, *MSJC* Sec. 2.1.6.2 requires a minimum eccentricity equal to 0.1 times each side dimension. (See Fig. 69.2.) This requirement is intended to account for construction imperfections that may introduce eccentricities. If the actual eccentricity exceeds the code minimum, the actual eccentricity is used in the design. Stresses about each principal axis must be checked independently.

**Figure 69.2** Minimum Design Eccentricity

#### 5. ASD DESIGN FOR PURE COMPRESSION

When the eccentricity falls within the *kern* of the section (the middle third), the entire section will be in compression. Transformed longitudinal column steel can be included using a transformation factor of  $n$ , although

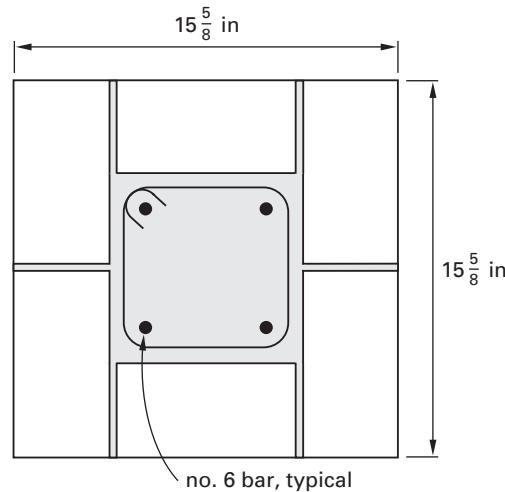

neglecting the steel is conservative. Equations for members in compression are used to determine capacity [*MSJC* Sec. 2.3.3.2.1].

$$P_a = (0.25f'_m A_n + 0.65A_{st}F_s) \left( 1 - \left( \frac{h}{140r} \right)^2 \right) \quad [\text{when } h/r \leq 99] \quad 69.1$$

$$P_a = (0.25f'_m A_n + 0.65A_{st}F_s) \left( \frac{70r}{h} \right)^2 \quad [\text{when } h/r > 99] \quad 69.2$$

#### Example 69.1

Determine the maximum column height for the clay brick column shown. The column carries a concentric axial load of 100,000 lbf. Use  $f'_m = 2500$  lbf/in<sup>2</sup>,  $A_n = 244$  in<sup>2</sup>,  $S = 636$  in<sup>3</sup>, and  $r = 4.51$  in.

#### Solution

*MSJC* allows a maximum height of

$$(25)(15.625 \text{ in}) = 390.6 \text{ in}$$

Check the load capacity. The minimum required eccentricity is

$$e = (0.1)(15.625 \text{ in}) = 1.56 \text{ in}$$

$$e_k = \frac{t}{6} = \frac{15.625 \text{ in}}{6} = 2.6 \text{ in}$$

Since  $e < e_k$ , the section is in pure compression.

Neglecting the steel and assuming  $h/r < 99$ , Eq. 69.1 becomes

$$P_a = 0.25f'_m A_n \left( 1 - \left( \frac{h}{140r} \right)^2 \right)$$

$$100,000 \text{ lbf} = (0.25) \left( 2500 \frac{\text{lbf}}{\text{in}^2} \right) (244 \text{ in}^2)$$

$$\times \left( 1 - \left( \frac{h}{(140)(4.51 \text{ in})} \right)^2 \right)$$

$$h = 370 \text{ in} < 390.6 \text{ in}$$

Check the  $h/r$  ratio.

$$h/r = \frac{370 \text{ in}}{4.51 \text{ in}} = 82 < 99 \quad [\text{OK}]$$

The maximum column height is 370 in.

## 6. SD DESIGN FOR PURE COMPRESSION

SD for pure compression is similar to ASD, with the nominal axial strength reduced based on the effects of slenderness. Using *MSJC* Sec. 3, the following equations are used to compute the nominal axial capacity [*MSJC* Sec. 3.3.4.1.1].

$$P_n = 0.80 \left( 0.80f'_m(A_n - A_s) + f_y A_s \right) \left( 1 - \left( \frac{h}{140r} \right)^2 \right)$$

[when  $h/r \leq 99$ ] 69.3

$$P_n = 0.80 \left( 0.80f'_m(A_n - A_s) + f_y A_s \right) \left( \frac{70r}{h} \right)^2$$

[when  $h/r > 99$ ] 69.4

The factored axial loads must not exceed the nominal axial strength,  $P_n$ , reduced by the strength reduction factor.

$$P_u \leq \phi P_n \quad 69.5$$

$\phi = 0.90$  for reinforced masonry subjected to flexure, axial load, or combinations thereof [*MSJC* Sec. 3.1.4.1].

## 7. ASD DESIGN FOR COMPRESSION AND BENDING

For large eccentricities, the section is subject to axial compression and flexure, and the interaction of vertical load and bending moment must be checked as for reinforced masonry walls, typically using interaction diagrams or computer solutions.

The interaction diagrams shown in App. 69.A through App. 69.F were developed for rectangular columns with steel symmetrically placed and adequately tied. Three cases are presented representing three values of the steel spacing ratio,  $g$ . Appendix 69.A through App. 69.C assume the allowable masonry compressive stress controls

the design. Appendix 69.D through App. 69.F assume allowable steel tensile stress governs. If it is unknown whether masonry or steel stress governs, the required value of  $\rho_t$  should be calculated from both interaction diagrams, and the larger steel area should be used.

### Example 69.2

For the column in Ex. 69.1, assume a compressive load occurs at an eccentricity of 4.7 in. Determine the maximum load if the effective column height is 18 ft. The modular ratio,  $n$ , is 12. Use interaction curves for  $g = 0.6$ .

*Solution*

Use Eq. 69.1 as in Ex. 69.1.

$$P_a = 0.25f'_m A_n \left( 1 - \left( \frac{h}{140r} \right)^2 \right)$$

$$= (0.25) \left( 2500 \frac{\text{lbf}}{\text{in}^2} \right) (244 \text{ in}^2)$$

$$\times \left( 1 - \left( \frac{(18 \text{ ft})(12 \frac{\text{in}}{\text{ft}})}{(140)(4.51 \text{ in})} \right)^2 \right)$$

$$= 134,653 \text{ lbf}$$

$$\frac{e}{t} = \frac{4.7 \text{ in}}{15.625 \text{ in}} = 0.30$$

As longitudinal reinforcement, the column has four vertical no. 6 bars with diameters of 0.75 in. The reinforcing steel area is

$$A_s = 4 \left( \frac{\pi d^2}{4} \right) = (4) \left( \frac{\pi (0.75 \text{ in})^2}{4} \right) = 1.767 \text{ in}^2$$

$$n\rho_t = \frac{nA_s}{bt} = \frac{(12)(1.767 \text{ in}^2)}{(15.625 \text{ in})(15.625 \text{ in})} = 0.087$$

From App. 69.B,  $P/F_{bt} = 0.31$ . The allowable bending stress is limited to one-third of the compressive strength.

$$P = 0.31F_{bt}t$$

$$= (0.31) \left( \frac{1}{3} \right) \left( 2500 \frac{\text{lbf}}{\text{in}^2} \right) (15.625 \text{ in})(15.625 \text{ in})$$

$$= 63,070 \text{ lbf} < P_a \quad [\text{OK}]$$

## 8. SD DESIGN FOR COMPRESSION AND BENDING

Columns subjected to axial compression and flexure are affected by the interaction of forces for both tension and compression stresses. SD of reinforced masonry columns is similar to reinforced concrete design, although the values for many of the design parameters are different. The design assumptions are given in *MSJC* Sec. 3.3.2. The equivalent rectangular stress block has a depth,  $a = 0.80c$ , and the maximum usable compressive masonry stress is assumed to be  $0.80f'_m$ . The maximum usable

compression fiber strain is assumed to be 0.0035 for clay masonry and 0.0025 for concrete masonry. Generally, an interaction diagram or computer solution is utilized to evaluate the capacity of a masonry column section. The stress and strain relationships are entered into a spreadsheet to quickly generate a custom interaction diagram for a specific column configuration.

The nominal axial capacity of a column is reduced based on its slenderness. Equation 69.3 and Eq. 69.4 are also applicable for columns subjected to axial compression and flexure. In addition to the minimum reinforcement criteria,  $A_s \geq 0.0025A_n$ , *MSJC* Chap. 3 places a limit on the maximum amount of reinforcement that is permitted [*MSJC* Sec. 3.3.3.5]. This limit ensures that the tension steel has strained sufficiently to achieve ductile behavior. For columns in structures designed with a seismic response modification factor,  $R > 1.5$ , or columns where  $M_u/V_ud \geq 1$ , the reinforcing steel must reach a strain of 1.5 times yield before the masonry reaches its maximum compressive strain.

## 9. BIAXIAL BENDING

Biaxial bending is due to the eccentricity of the vertical load about both principal axes of the column. Corner columns are particularly subject to biaxial bending. In this case, the neutral axis is not parallel to either principal axis. This requires an iterative process to determine the depth and angle of the neutral axis that satisfies the equilibrium of the axial force and bending moments about both principal axes.

The following interaction relationship may be used to determine an approximate allowable axial load under biaxial bending of columns. This equation applies to columns with significant axial load (i.e.,  $P > 0.1P_o$ ).

$$\frac{1}{P_{\text{biaxial}}} = \frac{1}{P_x} + \frac{1}{P_y} - \frac{1}{P_o} \quad 69.6$$

### Example 69.3

Assume the compressive load on the column in Ex. 69.2 has an additional eccentricity of 7.8 in along the  $y$ -axis. Determine the maximum compressive load.

*Solution*

From Ex. 69.2,  $P_x$  is 63,070 lbf, and  $P_o$  is 134,650 lbf.

Considering eccentricity about the  $y$ -axis,

$$\frac{e}{t} = \frac{7.8 \text{ in}}{15.625 \text{ in}} = 0.5$$

From Ex. 69.2,

$$n\rho_t = 0.087$$

From App. 69.B,  $P/F_{bt} = 0.19$ .

$$\begin{aligned} P_y &= (0.19)\left(\frac{1}{3}\right)\left(2500 \frac{\text{lbf}}{\text{in}^2}\right)(15.625 \text{ in})(15.625 \text{ in}) \\ &= 38,656 \text{ lbf} \end{aligned}$$

Use Eq. 69.6.

$$\begin{aligned} \frac{1}{P_{\text{biaxial}}} &= \frac{1}{P_x} + \frac{1}{P_y} - \frac{1}{P_o} \\ &= \frac{1}{63,070 \text{ lbf}} + \frac{1}{38,656 \text{ lbf}} - \frac{1}{134,653 \text{ lbf}} \\ P_{\text{biaxial}} &= 29,156 \text{ lbf} \end{aligned}$$

### 1. CENTER OF GRAVITY

A solid body will have both a center of gravity and a centroid, but the locations of these two points will not necessarily coincide. The earth's attractive force, called *weight*, can be assumed to act through the *center of gravity* (also known as the *center of mass*). Only when the body is homogeneous will the *centroid of the volume* coincide with the center of gravity.<sup>1</sup>

For simple objects and regular polyhedrons, the location of the center of gravity can be determined by inspection. It will always be located on an axis of symmetry. The location of the center of gravity can also be

determined mathematically if the object can be described mathematically.

$$x_c = \frac{\int x dm}{m} \quad 70.1$$

$$y_c = \frac{\int y dm}{m} \quad 70.2$$

$$z_c = \frac{\int z dm}{m} \quad 70.3$$

If the object can be divided into several smaller constituent objects, the location of the composite center of gravity can be calculated from the centers of gravity of each of the constituent objects.

$$x_c = \frac{\sum m_i x_{ci}}{\sum m_i} \quad 70.4$$

$$y_c = \frac{\sum m_i y_{ci}}{\sum m_i} \quad 70.5$$

$$z_c = \frac{\sum m_i z_{ci}}{\sum m_i} \quad 70.6$$

### 2. MASS AND WEIGHT

The *mass*, *m*, of a homogeneous solid object is calculated from its mass density and volume. Mass is independent of the strength of the gravitational field.

$$m = \rho V \quad 70.7$$

The *weight*, *w*, of an object depends on the strength of the gravitational field, *g*.

$$w = mg \quad [\text{SI}] \quad 70.8(a)$$

$$w = \frac{mg}{g_c} \quad [\text{U.S.}] \quad 70.8(b)$$

<sup>1</sup>The study of nonhomogeneous bodies is beyond the scope of this book. Homogeneity is assumed for all solid objects.

### 3. INERTIA

Inertia (the *inertial force* or *inertia vector*),  $ma$ , is the resistance the object offers to attempt to accelerate it (i.e., change its velocity) in a linear direction. Although the mass,  $m$ , is a scalar quantity, the acceleration,  $\mathbf{a}$ , is a vector.

### 4. MASS MOMENT OF INERTIA

The *mass moment of inertia* measures a solid object's resistance to changes in rotational speed about a specific axis.  $I_x$ ,  $I_y$ , and  $I_z$  are the mass moments of inertia with respect to the  $x$ -,  $y$ -, and  $z$ -axes. They are not components of a resultant value.<sup>2</sup>

The *centroidal mass moment of inertia*,  $I_c$ , is obtained when the origin of the axes coincides with the object's center of gravity. Although it can be found mathematically from Eq. 70.9 through Eq. 70.11, it is easier to use App. 70.A for simple objects.

$$I_x = \int (y^2 + z^2) dm \quad 70.9$$

$$I_y = \int (x^2 + z^2) dm \quad 70.10$$

$$I_z = \int (x^2 + y^2) dm \quad 70.11$$

### 5. PARALLEL AXIS THEOREM

Once the centroidal mass moment of inertia is known, the *parallel axis theorem* is used to find the mass moment of inertia about any parallel axis.

$$I_{\text{any parallel axis}} = I_c + md^2 \quad 70.12$$

For a composite object, the parallel axis theorem must be applied for each of the constituent objects.

$$I = I_{c,1} + m_1 d_1^2 + I_{c,2} + m_2 d_2^2 + \dots \quad 70.13$$

<sup>2</sup>At first, it may be confusing to use the same symbol,  $I$ , for area and mass moments of inertia. However, the problem types are distinctly dissimilar, and both moments of inertia are seldom used simultaneously.

### 6. RADIUS OF GYRATION

The *radius of gyration*,  $k$ , of a solid object represents the distance from the rotational axis at which the object's entire mass could be located without changing the mass moment of inertia.<sup>3</sup>

$$k = \sqrt{\frac{I}{m}} \quad 70.14$$

$$I = k^2 m \quad 70.15$$

### 7. PRINCIPAL AXES

An object's mass moment of inertia depends on the orientation of axes chosen. The *principal axes* are the axes for which the *products of inertia* are zero. Equipment rotating about a principal axis will draw minimum power during speed changes.

Finding the principal axes through calculation is too difficult and time consuming to be used with most rotating equipment. Furthermore, the rotating axis is generally fixed. *Balancing operations* are used to change the distribution of mass about the rotational axis. A device, such as a rotating shaft, flywheel, or crank, is said to be *statically balanced* if its center of mass lies on the axis of rotation. It is said to be *dynamically balanced* if the center of mass lies on the axis of rotation and the products of inertia are zero.

<sup>3</sup>The symbol for radius of gyration can be either  $k$  or  $r$ .  $k$  is preferred when the radius of gyration is that of a solid body.  $r$  is the more common symbol for the radius of gyration of an area (not of a solid body), although that radius of gyration cannot be determined from Eq. 70.14. The symbol  $r$  can also be used (e.g., shaft radii) with shapes, objects, and mechanisms that are inherently noncircular, such as I-beam cross sections and pendulums, that do not have a circular (radial) dimension.

## 1. INTRODUCTION TO KINEMATICS

*Dynamics* is the study of moving objects. The subject is divided into kinematics and kinetics. *Kinematics* is the study of a body's motion independent of the forces on the body. It is a study of the geometry of motion without consideration of the causes of motion. Kinematics deals only with relationships among position, velocity, acceleration, and time.

## 2. PARTICLES AND RIGID BODIES

Bodies in motion can be considered *particles* if rotation is absent or insignificant. Particles do not possess rotational kinetic energy. All parts of a particle have the same instantaneous displacement, velocity, and acceleration.

A *rigid body* does not deform when loaded and can be considered a combination of two or more particles that remain at a fixed, finite distance from each other. At any given instant, the parts (particles) of a rigid body can have different displacements, velocities, and accelerations.

## 3. COORDINATE SYSTEMS

The position of a particle is specified with reference to a *coordinate system*. The description takes the form of an ordered sequence ( $q_1, q_2, q_3, \dots$ ) of numbers called *coordinates*. A coordinate can represent a position along an axis, as in the rectangular coordinate system, or it can represent an angle, as in the polar, cylindrical, and spherical coordinate systems.

In general, the number of *degrees of freedom* is equal to the number of coordinates required to completely specify

the state of an object. If each of the coordinates is independent of the others, the coordinates are known as *holonomic coordinates*.

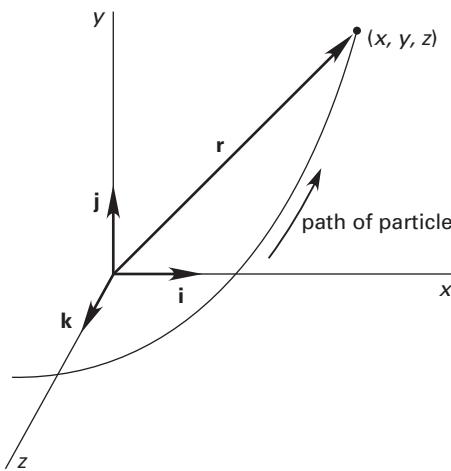

The state of a particle is completely determined by the particle's location. In three-dimensional space, the locations of particles in a system of  $m$  particles must be specified by  $3m$  coordinates. However, the number of required coordinates can be reduced in certain cases. The position of each particle constrained to motion on a surface (i.e., on a two-dimensional system) can be specified by only two coordinates. A particle constrained to moving on a curved path requires only one coordinate.<sup>1</sup>

The state of a rigid body is a function of orientation as well as position. Six coordinates are required to specify the state: three for orientation and three for location.

#### 4. CONVENTIONS OF REPRESENTATION

Consider the particle shown in Fig. 71.1. Its position (as well as its velocity and acceleration) can be specified in three primary forms: vector form, rectangular coordinate form, and unit vector form.

**Figure 71.1** Position of a Particle

The vector form of the particle's position is  $\mathbf{r}$ , where the vector  $\mathbf{r}$  has both magnitude and direction. The rectangular coordinate form is  $(x, y, z)$ . The unit vector form is given by Eq. 71.1.

$$\mathbf{r} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k} \quad 71.1$$

<sup>1</sup>The curve can be a straight line, as in the case of a mass hanging on a spring and oscillating up and down. In this case, the coordinate will be a linear coordinate.

#### 5. LINEAR PARTICLE MOTION

A *linear system* is one in which particles move only in straight lines. (It is also known as a *rectilinear system*.) The relationships among position, velocity, and acceleration for a linear system are given by Eq. 71.2 through Eq. 71.4. When values of  $t$  are substituted into these equations, the position, velocity, and acceleration are known as *instantaneous values*.

$$s(t) = \int v(t) dt = \int \left( \int a(t) dt \right) dt \quad 71.2$$

$$v(t) = \frac{ds(t)}{dt} = \int a(t) dt \quad 71.3$$

$$a(t) = \frac{dv(t)}{dt} = \frac{d^2 s(t)}{dt^2} \quad 71.4$$

The average velocity and acceleration over a period from  $t_1$  to  $t_2$  are

$$v_{ave} = \frac{\int_{t_1}^{t_2} v(t) dt}{t_2 - t_1} = \frac{s_2 - s_1}{t_2 - t_1} \quad 71.5$$

$$a_{ave} = \frac{\int_{t_1}^{t_2} a(t) dt}{t_2 - t_1} = \frac{v_2 - v_1}{t_2 - t_1} \quad 71.6$$

#### Example 71.1

A particle is constrained to move along a straight line. The velocity and location are both zero at  $t = 0$ . The particle's velocity as a function of time is

$$v(t) = 8t - 6t^2$$

- (a) What are the acceleration and position functions?
- (b) What is the instantaneous velocity at  $t = 5$ ?

*Solution*

- (a) From Eq. 71.4,

$$\begin{aligned} a(t) &= \frac{dv(t)}{dt} = \frac{d(8t - 6t^2)}{dt} \\ &= 8 - 12t \end{aligned}$$

From Eq. 71.2,

$$\begin{aligned} s(t) &= \int v(t) dt = \int (8t - 6t^2) dt \\ &= 4t^2 - 2t^3 \text{ when } s(t=0) = 0 \end{aligned}$$

- (b) Substituting  $t = 5$  into the  $v(t)$  function given in the problem statement,

$$\begin{aligned} v(5) &= (8)(5) - (6)(5)^2 \\ &= -110 \quad [\text{backward}] \end{aligned}$$

## 6. DISTANCE AND SPEED

The terms “displacement” and “distance” have different meanings in kinematics. *Displacement* (or *linear displacement*) is the net change in a particle’s position as determined from the position function,  $s(t)$ . *Distance traveled* is the accumulated length of the path traveled during all direction reversals, and it can be found by adding the path lengths covered during periods in which the velocity sign does not change. Therefore, distance is always greater than or equal to displacement.

$$\text{displacement} = s(t_2) - s(t_1) \quad 71.7$$

Similarly, “velocity” and “speed” have different meanings: *velocity* is a vector, having both magnitude and direction; *speed* is a scalar quantity, equal to the magnitude of velocity. When specifying speed, direction is not considered.

### Example 71.2

What distance is traveled during the period  $t = 0$  to  $t = 6$  by the particle described in Ex. 71.1?

*Solution*

Start by determining when, if ever, the velocity becomes negative. (This can be done by inspection, graphically, or algebraically.) Solving for the roots of the velocity equation,  $v(t) = 8t - 6t^2$ , the velocity changes from positive to negative at

$$t = \frac{4}{3}$$

The initial displacement is zero. From the position function found in Ex. 71.1(a), the position at  $t = \frac{4}{3}$  is

$$s\left(\frac{4}{3}\right) = (4)\left(\frac{4}{3}\right)^2 - (2)\left(\frac{4}{3}\right)^3 = 2.37$$

The displacement while the velocity is positive is

$$\begin{aligned} \Delta s &= s\left(\frac{4}{3}\right) - s(0) = 2.37 - 0 \\ &= 2.37 \end{aligned}$$

The position at  $t = 6$  is

$$s(6) = (4)(6)^2 - (2)(6)^3 = -288$$

The displacement while the velocity is negative is

$$\begin{aligned} \Delta s &= s(6) - s\left(\frac{4}{3}\right) = -288 - 2.37 \\ &= -290.37 \end{aligned}$$

The total distance traveled is

$$2.37 + 290.37 = 292.74$$

## 7. UNIFORM MOTION

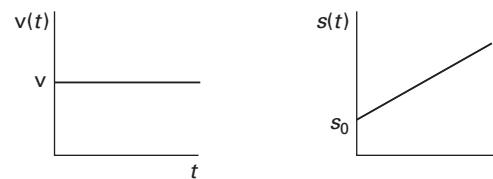

The term *uniform motion* means uniform velocity. The velocity is constant and the acceleration is zero. For a constant velocity system, the position function varies linearly with time. (See Fig. 71.2.)

$$s(t) = s_0 + vt \quad 71.8$$

$$v(t) = v \quad 71.9$$

$$a(t) = 0 \quad 71.10$$

Figure 71.2 Constant Velocity

## 8. UNIFORM ACCELERATION

The acceleration is constant in many cases, as shown in Fig. 71.3. (Gravitational acceleration, where  $a = g$ , is a notable example.) If the acceleration is constant, the  $a$  term can be taken out of the integrals in Eq. 71.2 and Eq. 71.3.

$$a(t) = a \quad 71.11$$

$$v(t) = a \int dt = v_0 + at \quad 71.12$$

$$s(t) = a \iint dt^2 = s_0 + v_0 t + \frac{1}{2}at^2 \quad 71.13$$

Figure 71.3 Uniform Acceleration

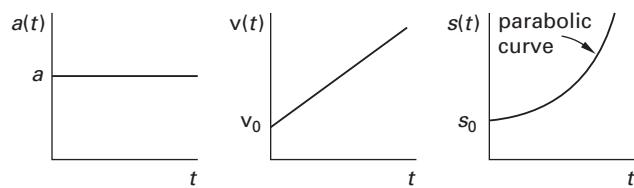

Table 71.1 summarizes the equations required to solve most uniform acceleration problems.

**Table 71.1** Uniform Acceleration Formulas\*

to find	given these	use this equation
$a$	$t, v_0, v$	$a = \frac{v - v_0}{t}$
$a$	$t, v_0, s$	$a = \frac{2s - 2v_0 t}{t^2}$
$a$	$v_0, v, s$	$a = \frac{v^2 - v_0^2}{2s}$
$s$	$t, a, v_0$	$s = v_0 t + \frac{1}{2} a t^2$
$s$	$a, v_0, v$	$s = \frac{v^2 - v_0^2}{2a}$
$s$	$t, v_0, v$	$s = \frac{1}{2} t(v_0 + v)$
$t$	$a, v_0, v$	$t = \frac{v - v_0}{a}$
$t$	$a, v_0, s$	$t = \frac{\sqrt{v_0^2 + 2as} - v_0}{a}$
$t$	$v_0, v, s$	$t = \frac{2s}{v_0 + v}$
$v_0$	$t, a, v$	$v_0 = v - at$
$v_0$	$t, a, s$	$v_0 = \frac{s}{t} - \frac{1}{2} a t$
$v_0$	$a, v, s$	$v_0 = \sqrt{v^2 - 2as}$
$v$	$t, a, v_0$	$v = v_0 + at$
$v$	$a, v_0, s$	$v = \sqrt{v_0^2 + 2as}$

\*The table can be used for rotational problems by substituting  $\alpha$ ,  $\omega$ , and  $\theta$  for  $a$ ,  $v$ , and  $s$ , respectively.

### Example 71.3

A locomotive traveling at 80 km/h locks its wheels and skids 95 m before coming to a complete stop. If the deceleration is constant, how many seconds will it take for the locomotive to come to a standstill?

*Solution*

First, convert the 80 km/h to meters per second.

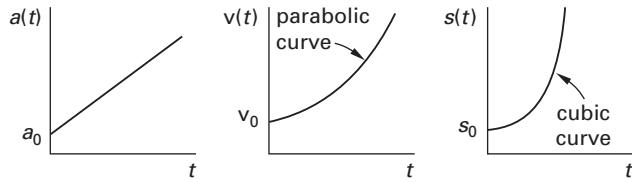

$$v_0 = \frac{(80 \text{ km}) (1000 \text{ m})}{3600 \frac{\text{s}}{\text{h}}} = 22.22 \text{ m/s}$$

In this problem,  $v_0 = 22.2 \text{ m/s}$ ,  $v = 0 \text{ m/s}$ , and  $s = 95 \text{ m}$  are known.  $t$  is the unknown. From Table 71.1,

$$\begin{aligned} t &= \frac{2s}{v_0 + v} = \frac{(2)(95 \text{ m})}{22.22 \frac{\text{m}}{\text{s}} + 0 \frac{\text{m}}{\text{s}}} \\ &= 8.55 \text{ s} \end{aligned}$$

### 9. LINEAR ACCELERATION

Linear acceleration means that the acceleration increases uniformly with time. Figure 71.4 shows how the velocity and position vary with time.<sup>2</sup>

**Figure 71.4** Linear Acceleration

### 10. PROJECTILE MOTION

A projectile is placed into motion by an initial impulse. (Kinematics deals only with dynamics during the flight. Projectile motion is a special case of motion under constant acceleration. The force acting on the projectile during the launch phase is covered in kinetics.) Neglecting air drag, once the projectile is in motion, it is acted upon only by the downward gravitational acceleration (i.e., its own weight).

Consider a general projectile set into motion at an angle of  $\phi$  (from the horizontal plane) and initial velocity  $v_0$ . Its range is  $R$ , the maximum altitude attained is  $H$ , and the total flight time is  $T$ . In the absence of air drag, the following rules apply to the case of a level target.<sup>3</sup>

- The trajectory is parabolic.
- The impact velocity is equal to the initial velocity,  $v_0$ .
- The impact angle is equal to the initial launch angle,  $\phi$ .
- The range is maximum when  $\phi = 45^\circ$ .
- The time for the projectile to travel from the launch point to the apex is equal to the time to travel from apex to impact point.

<sup>2</sup>Because of the successive integrations, if the acceleration function is a polynomial of degree  $n$ , the velocity function will be a polynomial of degree  $n + 1$ . Similarly, the position function will be a polynomial of degree  $n + 2$ .

<sup>3</sup>The case of projectile motion with air friction cannot be handled in kinematics, since a retarding force acts continuously on the projectile. In kinetics, various assumptions (e.g., friction varies linearly with the velocity or with the square of the velocity) can be made to include the effect of air friction.

- The time for the projectile to travel from the apex of its flight path to impact is the same time an initially stationary object would take to fall a distance  $H$ .

Table 71.2 contains the solutions to most common projectile problems. These equations are derived from the laws of uniform acceleration and conservation of energy.

**Table 71.2** Projectile Motion Equations  
( $\phi$  may be negative for projection downward)

	level target	target above	target below	horizontal projection
$x(t)$		$(v_0 \cos \phi)t$		$v_0 t$
$y(t)$		$(v_0 \sin \phi)t - \frac{1}{2}gt^2$		$H - \frac{1}{2}gt^2$
$v_x(t)^a$	$v_0 \cos \phi$			$v_0$
$v_y(t)^b$		$v_0 \sin \phi - gt$		$-gt$
$v(t)^c$	$\sqrt{v_0^2 - 2gy} = \sqrt{v_0^2 - 2gtv_0 \sin \phi + g^2t^2}$			$\sqrt{v_0^2 + g^2t^2}$
$v(y)^d$		$\sqrt{v_0^2 - 2gy}$		$\sqrt{v_0^2 + 2g(H - y)}$
$H$	$\frac{v_0^2 \sin^2 \phi}{2g}$	$\frac{v_0^2 \sin^2 \phi}{2g}$	$z + \frac{v_0^2 \sin^2 \phi}{2g}$	$\frac{1}{2}gT^2$
$R$		$v_0 T \cos \phi$		
	$\frac{v_0^2 \sin 2\phi}{g}$	$\left(\frac{v_0 \cos \phi}{g}\right)(v_0 \sin \phi + \sqrt{v_0^2 \sin^2 \phi - 2gz})$	$\left(\frac{v_0 \cos \phi}{g}\right)(v_0 \sin \phi + \sqrt{2gz + v_0^2 \sin^2 \phi})$	$v_0 T$
$T$		$\frac{R}{v_0 \cos \phi}$		
	$\frac{2v_0 \sin \phi}{g}$	$\frac{v_0 \sin \phi}{g} + \sqrt{\frac{2(H - z)}{g}}$	$\frac{v_0 \sin \phi}{g} + \sqrt{\frac{2H}{g}}$	$\sqrt{\frac{2H}{g}}$
$t_H$	$\frac{v_0 \sin \phi}{g} = \frac{T}{2}$		$\frac{v_0 \sin \phi}{g}$	

<sup>a</sup>horizontal velocity component

<sup>b</sup>vertical velocity component

<sup>c</sup>resultant velocity as a function of time

<sup>d</sup>resultant velocity as a function of vertical elevation above the launch point

**SI Solution**

The maximum altitude above the impact plane includes the height of the plateau and the elevation achieved by the projectile. From Table 71.2,

$$H = z + \frac{v_0^2 \sin^2 \phi}{2g} = 150 \text{ m} + \frac{\left(180 \frac{\text{m}}{\text{s}}\right)^2 (\sin 30^\circ)^2}{(2)(9.81 \frac{\text{m}}{\text{s}^2})}$$

$$= 562.8 \text{ m}$$

The total flight time includes the time to reach the maximum altitude and the time to fall from the maximum altitude to the impact plane below, both of which can be found in Table 71.2.

$$T = t_H + t_{\text{fall}} = \frac{v_0 \sin \phi}{g} + \sqrt{\frac{2H}{g}}$$

$$= \frac{\left(180 \frac{\text{m}}{\text{s}}\right) (\sin 30^\circ)}{9.81 \frac{\text{m}}{\text{s}^2}} + \sqrt{\frac{(2)(562.8 \text{ m})}{9.81 \frac{\text{m}}{\text{s}^2}}}$$

$$= 19.89 \text{ s}$$

Also from Table 71.2, the  $x$ -component of velocity is

$$v_x = v_0 \cos \phi = \left(180 \frac{\text{m}}{\text{s}}\right) (\cos 30^\circ)$$

$$= 155.9 \text{ m/s}$$

The range is

$$R = v_x T = \left(155.9 \frac{\text{m}}{\text{s}}\right) (19.89 \text{ s})$$

$$= 3101 \text{ m}$$

**Customary U.S. Solution**

The maximum altitude above the impact plane includes the height of the plateau and the elevation achieved by the projectile. From Table 71.2,

$$H = z + \frac{v_0^2 \sin^2 \phi}{2g} = 500 \text{ ft} + \frac{\left(600 \frac{\text{ft}}{\text{sec}}\right)^2 (\sin 30^\circ)^2}{(2)(32.2 \frac{\text{ft}}{\text{sec}^2})}$$

$$= 1897.5 \text{ ft}$$

The total flight time includes the time to reach the maximum altitude and the time to fall from the maximum

altitude to the impact plane below, both of which can be found in Table 71.2.

$$T = t_H + t_{\text{fall}} = \frac{v_0 \sin \phi}{g} + \sqrt{\frac{2H}{g}}$$

$$= \frac{\left(600 \frac{\text{ft}}{\text{sec}}\right) (\sin 30^\circ)}{32.2 \frac{\text{ft}}{\text{sec}^2}} + \sqrt{\frac{(2)(1897.5 \text{ ft})}{32.2 \frac{\text{ft}}{\text{sec}^2}}}$$

$$= 20.17 \text{ sec}$$

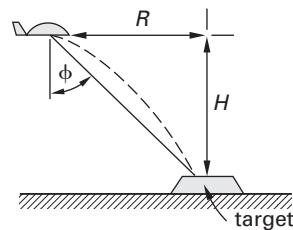

The maximum range is

$$R = v_x T = v_0 T \cos \phi = \left(600 \frac{\text{ft}}{\text{sec}}\right) (20.17 \text{ sec}) (\cos 30^\circ)$$

$$= 10,481 \text{ ft} \quad (1.98 \text{ mi})$$

**Example 71.5**

A bomber flies horizontally at 275 mi/hr at an altitude of 9000 ft. At what viewing angle,  $\phi$ , from the bomber to the target should the bombs be dropped?

**Solution**

This is a case of horizontal projection. The falling time depends only on the altitude of the bomber. From Table 71.2,

$$T = \sqrt{\frac{2H}{g}} = \sqrt{\frac{(2)(9000 \text{ ft})}{32.2 \frac{\text{ft}}{\text{sec}^2}}}$$

$$= 23.64 \text{ sec}$$

If air friction is neglected, the bomb has the same horizontal velocity as the bomber. Since the time of flight,  $T$ , is known, the distance traveled during that time can be calculated.

$$R = v_0 T = \frac{\left(275 \frac{\text{mi}}{\text{hr}}\right) \left(5280 \frac{\text{ft}}{\text{mi}}\right) (23.64 \text{ sec})}{3600 \frac{\text{sec}}{\text{hr}}}$$

$$= 9535 \text{ ft}$$

The viewing angle is found from trigonometry.

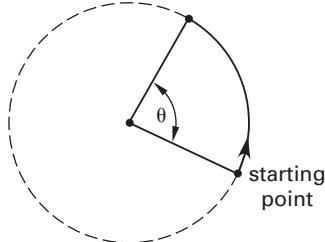

$$\phi = \arctan \frac{R}{H} = \arctan \frac{9535 \text{ ft}}{9000 \text{ ft}}$$

$$= 46.7^\circ$$

## 11. ROTATIONAL PARTICLE MOTION

*Rotational particle motion* (also known as *angular motion* and *circular motion*) is motion of a particle around a circular path. (See Fig. 71.5.) The particle travels through  $2\pi$  radians per complete revolution.

Figure 71.5 Rotational Particle Motion

The behavior of a rotating particle is defined by its *angular position*,  $\theta$ , *angular velocity*,  $\omega$ , and *angular acceleration*,  $\alpha$ , functions. These variables are analogous to the  $s(t)$ ,  $v(t)$ , and  $a(t)$  functions for linear systems. Angular variables can be substituted one-for-one in place of linear variables in most equations.

The relationships among angular position, velocity, and acceleration for a rotational system are given by Eq. 71.14 through Eq. 71.16. When values of  $t$  are substituted into these equations, the position, velocity, and acceleration are known as *instantaneous values*.

$$\theta(t) = \int \omega(t) dt = \iint \alpha(t) dt^2 \quad 71.14$$

$$\omega(t) = \frac{d\theta(t)}{dt} = \int \alpha(t) dt \quad 71.15$$

$$\alpha(t) = \frac{d\omega(t)}{dt} = \frac{d^2\theta(t)}{dt^2} \quad 71.16$$

The average velocity and acceleration are

$$\omega_{ave} = \frac{\int_1^2 \omega(t) dt}{t_2 - t_1} = \frac{\theta_2 - \theta_1}{t_2 - t_1} \quad 71.17$$

$$\alpha_{ave} = \frac{\int_1^2 \alpha(t) dt}{t_2 - t_1} = \frac{\omega_2 - \omega_1}{t_2 - t_1} \quad 71.18$$

### Example 71.6

A turntable starts from rest and accelerates uniformly at  $1.5 \text{ rad/sec}^2$ . How many revolutions will it take before a rotational speed of  $33\frac{1}{3}$  rpm is attained?

*Solution*

First, convert  $33\frac{1}{3}$  rpm into radians per second. Since there are  $2\pi$  radians per complete revolution,

$$\omega = \frac{\left(33\frac{1}{3} \frac{\text{rev}}{\text{min}}\right)\left(2\pi \frac{\text{rad}}{\text{rev}}\right)}{60 \frac{\text{sec}}{\text{min}}} = 3.49 \text{ rad/sec}$$

$\alpha$ ,  $\omega_0$ , and  $\omega$  are known.  $\theta$  is unknown. (This is analogous to knowing  $a$ ,  $v_0$ , and  $v$ , and not knowing  $s$ .) From Table 71.1,

$$\theta = \frac{\omega^2 - \omega_0^2}{2\alpha} = \frac{\left(3.49 \frac{\text{rad}}{\text{sec}}\right)^2 - \left(0 \frac{\text{rad}}{\text{sec}}\right)^2}{(2)\left(1.5 \frac{\text{rad}}{\text{sec}^2}\right)} \\ = 4.06 \text{ rad}$$

Converting from radians to revolutions,

$$n = \frac{4.06 \text{ rad}}{2\pi \frac{\text{rad}}{\text{rev}}} = 0.646 \text{ rev}$$

### Example 71.7

A flywheel is brought to a standstill from 400 rpm in 8 sec. (a) What was its average angular acceleration in  $\text{rad/sec}^2$  during that period? (b) How far (in radians) did the flywheel travel?

*Solution*

(a) The initial rotational speed must be expressed in radians per second. Since there are  $2\pi$  radians per revolution,

$$\omega_0 = \frac{\left(400 \frac{\text{rev}}{\text{min}}\right)\left(2\pi \frac{\text{rad}}{\text{rev}}\right)}{60 \frac{\text{sec}}{\text{min}}} \\ = 41.89 \text{ rad/sec}$$

$t$ ,  $\omega_0$ , and  $\omega$  are known, and  $\alpha$  is unknown. These variables are analogous to  $t$ ,  $v_0$ ,  $v$ , and  $a$  in Table 71.1.

$$\alpha = \frac{\omega - \omega_0}{t} = \frac{0 \frac{\text{rad}}{\text{sec}} - 41.89 \frac{\text{rad}}{\text{sec}}}{8 \text{ sec}} \\ = -5.236 \text{ rad/sec}^2$$

(b)  $t$ ,  $\omega_0$ , and  $\omega$  are known, and  $\theta$  is unknown. Again, from Table 71.1,

$$\begin{aligned}\theta = \frac{1}{2}t(\omega + \omega_0) &= (\frac{1}{2})(8 \text{ sec})\left(41.89 \frac{\text{rad}}{\text{sec}} + 0 \frac{\text{rad}}{\text{sec}}\right) \\ &= 167.6 \text{ rad} \quad (26.67 \text{ rev})\end{aligned}$$

## 12. RELATIONSHIP BETWEEN LINEAR AND ROTATIONAL VARIABLES

A particle moving in a curvilinear path will also have instantaneous linear velocity and linear acceleration. These linear variables will be directed tangentially to the path and, therefore, are known as *tangential velocity* and *tangential acceleration*, respectively. (See Fig. 71.6.) In general, the linear variables can be obtained by multiplying the rotational variables by the path radius,  $r$ .

$$v_t = \omega r \quad 71.19$$

$$v_{t,x} = v_t \cos \phi = \omega r \cos \phi \quad 71.20$$

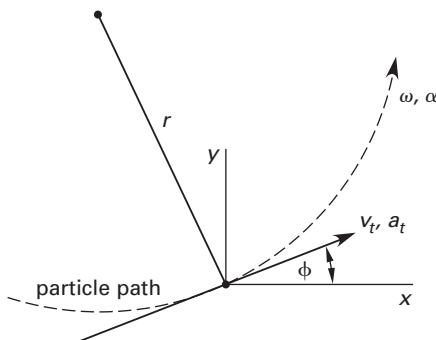

$$v_{t,y} = v_t \sin \phi = \omega r \sin \phi \quad 71.21$$

$$a_t = \frac{dv_t}{dt} = \alpha r \quad 71.22$$

If the path radius is constant, as it would be in rotational motion, the linear distance (i.e., the *arc length*) traveled is

$$s = \theta r \quad 71.23$$

**Figure 71.6** Tangential Variables

## 13. NORMAL ACCELERATION

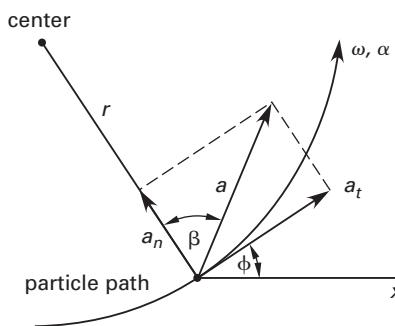

A moving particle will continue tangentially to its path unless constrained otherwise. For example, a rock twirled on a string will move in a circular path only as long as there is tension in the string. When the string is released, the rock will move off tangentially.

The twirled rock is acted upon by the tension in the string. In general, a restraining force will be directed

toward the center of rotation. Whenever a mass experiences a force, an acceleration is acting.<sup>4</sup> The acceleration has the same sense as the applied force (i.e., is directed toward the center of rotation). Since the inward acceleration is perpendicular to the tangential velocity and acceleration, it is known as *normal acceleration*,  $a_n$ . (See Fig. 71.7.)

$$a_n = \frac{v_t^2}{r} = r\omega^2 = v_t\omega \quad 71.24$$

**Figure 71.7** Normal Acceleration

The *resultant acceleration*,  $a$ , is the vector sum of the tangential and normal accelerations. The magnitude of the resultant acceleration is

$$a = \sqrt{a_t^2 + a_n^2} \quad 71.25$$

The  $x$ - and  $y$ -components of the resultant acceleration are

$$a_x = a_n \sin \phi \pm a_t \cos \phi \quad 71.26$$

$$a_y = a_n \cos \phi \mp a_t \sin \phi \quad 71.27$$

The normal and tangential accelerations can be expressed in terms of the  $x$ - and  $y$ -components of the resultant acceleration (not shown in Fig. 71.7).

$$a_n = a_x \sin \phi \pm a_y \cos \phi \quad 71.28$$

$$a_t = a_x \cos \phi \mp a_y \sin \phi \quad 71.29$$

## 14. CORIOLIS ACCELERATION

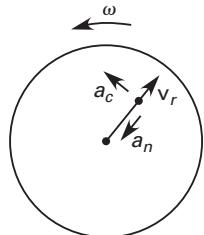

Consider a particle moving with linear radial velocity  $v_r$  away from the center of a flat disk rotating with constant velocity  $\omega$ . Since  $v_t = \omega r$ , the particle's tangential velocity will increase as it moves away from the center of

<sup>4</sup>This is a direct result of Newton's second law of motion.

rotation. This increase is believed to be produced by the tangential *Coriolis acceleration*,  $a_c$ . (See Fig. 71.8.)

$$a_c = 2v_r\omega \quad 71.30$$

**Figure 71.8** Coriolis Acceleration on a Rotating Disk

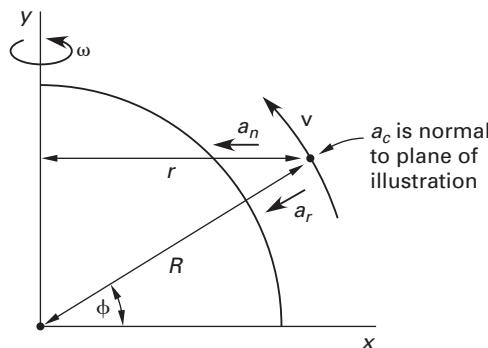

Coriolis acceleration also acts on particles moving on rotating spheres. Consider an aircraft flying with constant air speed  $v$  from the equator to the north pole while the earth (a sphere of radius  $R$ ) rotates below it. Three accelerations act on the aircraft: normal, radial, and Coriolis accelerations, shown in Fig. 71.9. The Coriolis acceleration depends on the latitude,  $\phi$ , because the earth's tangential velocity is less near the poles than at the equator.

$$a_n = r\omega^2 = R\omega^2 \cos \phi \quad 71.31$$

$$a_r = \frac{v^2}{R} \quad 71.32$$

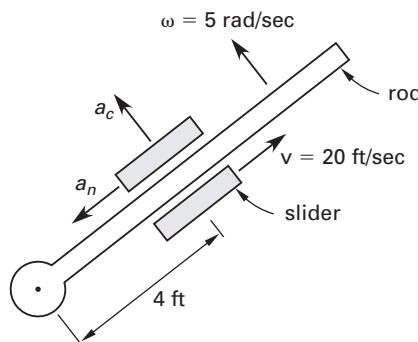

$$a_c = 2\omega v \sin \phi \quad 71.33$$

**Figure 71.9** Coriolis Acceleration on a Rotating Sphere

### Example 71.8

A slider moves with a constant velocity of 20 ft/sec along a rod rotating at 5 rad/sec. What is the magnitude of the slider's total acceleration when the slider is 4 ft from the center of rotation?

### Solution

The normal acceleration is given by Eq. 71.31.

$$\begin{aligned} a_n &= r\omega^2 = (4 \text{ ft}) \left(5 \frac{\text{rad}}{\text{sec}}\right)^2 \\ &= 100 \text{ ft/sec}^2 \end{aligned}$$

The Coriolis (tangential) acceleration is given by Eq. 71.33.

$$\begin{aligned} a_c &= 2\omega v = (2) \left(5 \frac{\text{rad}}{\text{sec}}\right) \left(20 \frac{\text{ft}}{\text{sec}}\right) \\ &= 200 \text{ ft/sec}^2 \end{aligned}$$

The total acceleration is given by Eq. 71.25.

$$\begin{aligned} a &= \sqrt{a_c^2 + a_n^2} = \sqrt{\left(200 \frac{\text{ft}}{\text{sec}^2}\right)^2 + \left(100 \frac{\text{ft}}{\text{sec}^2}\right)^2} \\ &= 223.6 \text{ ft/sec}^2 \end{aligned}$$

## 15. PARTICLE MOTION IN POLAR COORDINATES

In polar coordinates, the path of a particle is described by a radius vector,  $\mathbf{r}$ , and an angle,  $\phi$ . Since the velocity of a particle is not usually directed radially out from the center of the coordinate system, it can be divided into two perpendicular components. The terms *normal* and *tangential* are not used with polar coordinates. Rather, the terms *radial* and *transverse* are used. Figure 71.10 illustrates the *radial* and *transverse components* of velocity in a polar coordinate system.

Figure 71.10 also illustrates the unit radial and unit transverse vectors,  $\mathbf{e}_r$  and  $\mathbf{e}_\phi$ , used in the vector forms of the motion equations.

$$\text{position: } \mathbf{r} = r\mathbf{e}_r \quad 71.34$$

$$\text{velocity: } \mathbf{v} = v_r\mathbf{e}_r + v_\phi\mathbf{e}_\phi = \frac{dr}{dt}\mathbf{e}_r + r\frac{d\phi}{dt}\mathbf{e}_\phi \quad 71.35$$

acceleration:  $\mathbf{a} = a_r \mathbf{e}_r + a_\phi \mathbf{e}_\phi$

$$= \left( \frac{d^2 r}{dt^2} - r \left( \frac{d\phi}{dt} \right)^2 \right) \mathbf{e}_r + \left( r \frac{d^2 \phi}{dt^2} + 2 \frac{dr}{dt} \frac{d\phi}{dt} \right) \mathbf{e}_\phi \quad 71.36$$

The magnitudes of the radial and transverse components of velocity and acceleration are given by Eq. 71.37 through Eq. 71.40.

$$v_r = \frac{dr}{dt} \quad 71.37$$

$$v_\phi = r \frac{d\phi}{dt} \quad 71.38$$

$$a_r = \frac{d^2 r}{dt^2} - r \left( \frac{d\phi}{dt} \right)^2 \quad 71.39$$

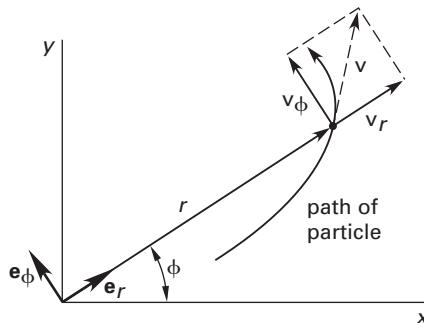

$$a_\phi = r \frac{d^2 \phi}{dt^2} + 2 \frac{dr}{dt} \frac{d\phi}{dt} \quad 71.40$$

If the radial and transverse components of acceleration and velocity are known, they can be used to calculate the tangential and normal accelerations in a rectangular coordinate system.

$$a_t = \frac{a_r v_r + a_\phi v_\phi}{v_t} \quad 71.41$$

$$a_n = \frac{a_\phi v_r - a_r v_\phi}{v_t} \quad 71.42$$

**Figure 71.10** Radial and Transverse Components

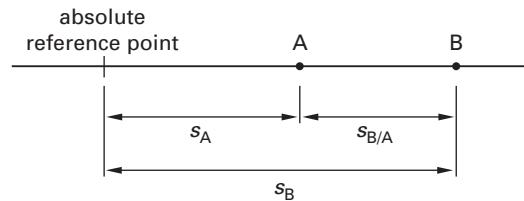

## 16. RELATIVE MOTION

The term *relative motion* is used when motion of a particle is described with respect to something else in motion. The particle's position, velocity, and acceleration may be specified with respect to another moving particle or with respect to a moving frame of reference, known as a *Newtonian* or *inertial frame of reference*.

In Fig. 71.11, two particles, A and B, are moving with different velocities along a straight line. The separation between the two particles at any specific instant is the *relative position*,  $s_{B/A}$ , of B with respect to A, calculated as the difference between their two *absolute positions*.

$$s_{B/A} = s_B - s_A \quad 71.43$$

**Figure 71.11** Relative Positions of Two Particles

Similarly, the *relative velocity* and *relative acceleration* of B with respect to A are the differences between the two *absolute velocities* and *absolute accelerations*, respectively.

$$\mathbf{v}_{B/A} = \mathbf{v}_B - \mathbf{v}_A \quad 71.44$$

$$\mathbf{a}_{B/A} = \mathbf{a}_B - \mathbf{a}_A \quad 71.45$$

Particles A and B are not constrained to move along a straight line. However, the subtraction must be done in vector or graphical form in all but the simplest cases.

$$\mathbf{s}_{B/A} = \mathbf{s}_B - \mathbf{s}_A \quad 71.46$$

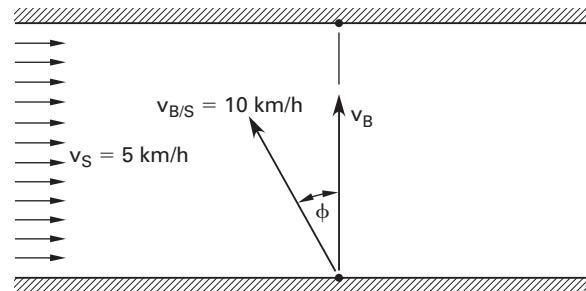

$$\mathbf{v}_{B/A} = \mathbf{v}_B - \mathbf{v}_A \quad 71.47$$

$$\mathbf{a}_{B/A} = \mathbf{a}_B - \mathbf{a}_A \quad 71.48$$

Since vector subtraction and addition operations can be performed graphically, many relative motion problems can be solved by a simplified graphical process.

### Example 71.9

A stream flows at 5 km/h. At what upstream angle,  $\phi$ , should a 10 km/h boat be piloted in order to reach the shore directly opposite the initial point?

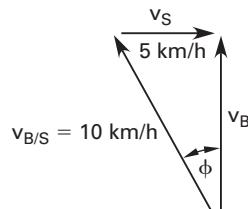

**Solution**

From Eq. 71.47, the absolute velocity of the boat,  $v_B$ , with respect to the shore is equal to the vector sum of the absolute velocity of the stream,  $v_S$ , and the relative velocity of the boat with respect to the stream,  $v_{B/S}$ . The magnitudes of these two velocities are known.

$$v_B = v_S + v_{B/S}$$

Since vector addition is accomplished graphically by placing the two vectors head to tail, the angle can be determined from trigonometry.

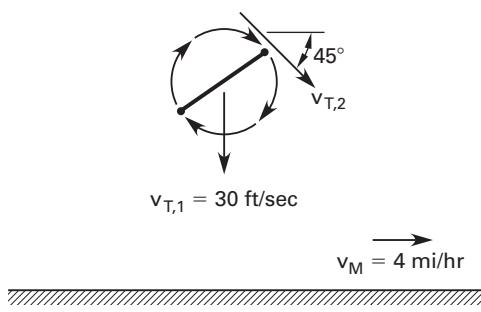

$$\sin \phi = \frac{v_S}{v_{B/S}} = \frac{5 \frac{\text{km}}{\text{h}}}{10 \frac{\text{km}}{\text{h}}} = 0.5$$

$$\phi = \arcsin 0.5 = 30^\circ$$

**Example 71.10**

A stationary member of a marching band tosses a 2.0 ft long balanced baton straight up into the air and then begins walking forward at 4 mi/hr. At a particular moment, the baton is 20 ft in the air and is falling back toward the earth with a velocity of 30 ft/sec. The tip of the baton is rotating at 140 rpm in the orientation shown.

- (a) What is the speed of the baton tip with respect to the ground? (b) What is the speed of the baton tip with respect to the band member?

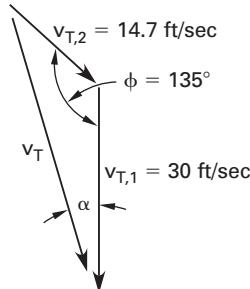

**Solution**

(a) The baton tip has two absolute velocity components. The first, with a magnitude of  $v_{T,1} = 30 \text{ ft/sec}$ , is directed vertically downward. The second, with a magnitude of  $v_{T,2}$ , is directed as shown in the illustration. The baton's radius,  $r$ , is 1 ft, center of rotation to tip. From Eq. 71.19,

$$v_{T,2} = \omega r = \frac{(140 \frac{\text{rev}}{\text{min}})(2\pi \frac{\text{rad}}{\text{rev}})(1 \text{ ft})}{60 \frac{\text{sec}}{\text{min}}} = 14.7 \text{ ft/sec}$$

The vector sum of these two absolute velocities is the velocity of the tip,  $v_T$ , with respect to the earth.

$$v_T = v_{T,1} + v_{T,2}$$

The velocity of the tip is found from the law of cosines.

$$v_T = \sqrt{v_{T,1}^2 + v_{T,2}^2 - 2v_{T,1}v_{T,2} \cos \phi}$$

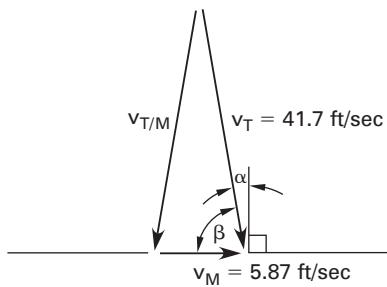

$$= \sqrt{\left(30 \frac{\text{ft}}{\text{sec}}\right)^2 + \left(14.7 \frac{\text{ft}}{\text{sec}}\right)^2 - (2)\left(30 \frac{\text{ft}}{\text{sec}}\right)\left(14.7 \frac{\text{ft}}{\text{sec}}\right)(\cos 135^\circ)}$$

$$= 41.7 \text{ ft/sec}$$

- (b) From Eq. 71.44, the velocity of the tip with respect to the band member is

$$v_{T/M} = v_T - v_M$$

Subtracting a vector is equivalent to adding its negative. The velocity triangle is as shown. The law of cosines is used again to determine the relative velocity.

The angle  $\alpha$  is found from the law of sines.

$$\frac{\sin \alpha}{14.7 \frac{\text{ft}}{\text{sec}}} = \frac{\sin 135^\circ}{41.7 \frac{\text{ft}}{\text{sec}}}$$

$$\alpha = 14.4^\circ$$

$$\beta = 90^\circ - \alpha = 90^\circ - 14.4^\circ$$

$$= 75.6^\circ$$

The band member's absolute velocity,  $v_M$ , is

$$v_M = \frac{(4 \frac{\text{mi}}{\text{hr}})(5280 \frac{\text{ft}}{\text{mi}})}{3600 \frac{\text{sec}}{\text{hr}}} = 5.87 \text{ ft/sec}$$

$$v_{T/M} = \sqrt{v_T^2 + v_M^2 - 2v_T v_M \cos \beta}$$

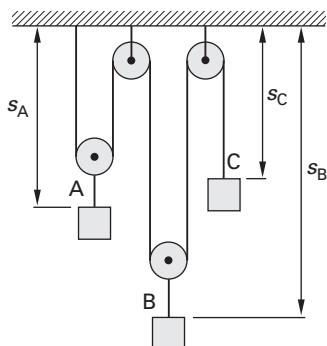

$$= \sqrt{\left(41.7 \frac{\text{ft}}{\text{sec}}\right)^2 + \left(5.87 \frac{\text{ft}}{\text{sec}}\right)^2 - (2)\left(41.7 \frac{\text{ft}}{\text{sec}}\right)\left(5.87 \frac{\text{ft}}{\text{sec}}\right)(\cos 75.6^\circ)}$$

$$= 40.6 \text{ ft/sec } (27.7 \text{ mi/hr})$$

## 17. DEPENDENT MOTION

When the position of one particle in a multiple-particle system depends on the position of one or more other particles, the motions are said to be "dependent." A block-and-pulley system with one fixed rope end, as illustrated by Fig. 71.12, is a *dependent system*.

**Figure 71.12** Dependent System

The following statements define the behavior of a dependent block-and-pulley system.

- Since the length of the rope is constant, the sum of the rope segments representing distances between the blocks and pulleys is constant. By convention, the distances are measured from the top of the block to the support point.<sup>5</sup> Since in Fig. 71.12 there are two ropes supporting block A, two ropes supporting block B, and one rope supporting block C,

$$2s_A + 2s_B + s_C = \text{constant} \quad 71.49$$

- Since the position of the  $n$ th block in an  $n$ -block system is determined when the remaining  $n - 1$  positions are known, the number of *degrees of freedom* is one less than the number of blocks.
- The movement, velocity, and acceleration of a block supported by two ropes are half the same quantities of a block supported by one rope.
- The relative relationships between the blocks' velocities or accelerations are the same as the relationships between the blocks' positions. For Fig. 71.12,

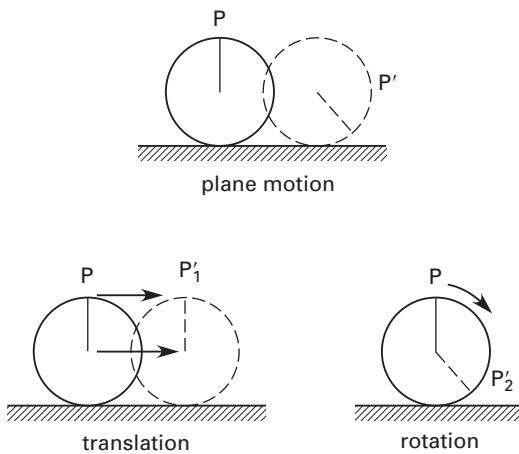

$$2v_A + 2v_B + v_C = 0 \quad 71.50$$

$$2a_A + 2a_B + a_C = 0 \quad 71.51$$

## 18. GENERAL PLANE MOTION

Rigid body *plane motion* can be described in two dimensions. Examples include rolling wheels, gear sets, and linkages. Plane motion can be considered as the sum of a translational component and a rotation about a fixed axis, as illustrated by Fig. 71.13.

**Figure 71.13** Components of Plane Motion

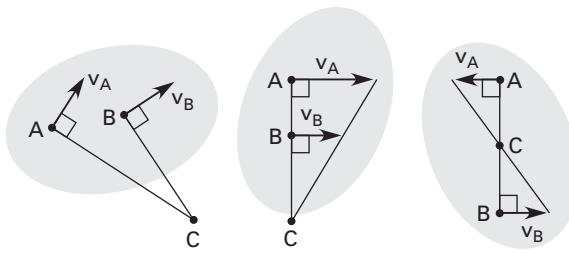

<sup>5</sup>In measuring distances, the finite diameters of the pulleys and the lengths of rope wrapped around the pulleys are disregarded.

## 19. ROTATION ABOUT A FIXED AXIS

Analysis of the rotational component of a rigid body's plane motion can sometimes be simplified if the location of the body's instantaneous center is known. Using the instantaneous center reduces many relative motion problems to simple geometry. The *instantaneous center* (also known as the *instant center* and IC) is a point at which the body could be fixed (pinned) without changing the instantaneous angular velocities of any point on the body. With the angular velocities, the body seems to rotate about a fixed instantaneous center.

The instantaneous center is located by finding two points for which the absolute velocity directions are known. Lines drawn perpendicular to these two velocities will intersect at the instantaneous center. (This graphical procedure is slightly different if the two velocities are parallel, as Fig. 71.14 shows. In that case, use is made of the fact that the tangential velocity is proportional to the distance from the instantaneous center.) For a rolling wheel, the instantaneous center is the point of contact with the supporting surface.

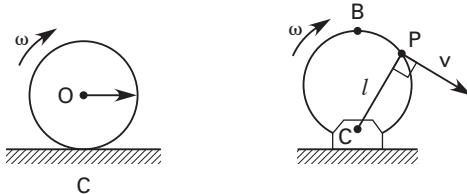

**Figure 71.14** Graphical Method of Finding the Instantaneous Center

The absolute velocity of any point, P, on a wheel rolling (see Fig. 71.15) with translational velocity,  $v_O$ , can be found by geometry. Assume that the wheel is pinned at C and rotates with its actual angular velocity,  $\omega = v_O/r$ . The direction of the point's velocity will be perpendicular to the line of length  $l$  between the instantaneous center and the point.

$$v = l\omega = \frac{lv_O}{r} \quad 71.52$$

**Figure 71.15** Instantaneous Center of a Rolling Wheel

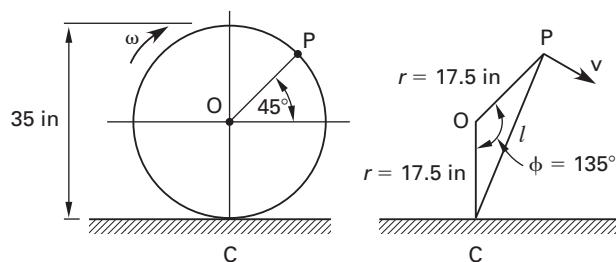

Equation 71.52 is valid only for a velocity referenced to the instantaneous center, point C. Table 71.3 can be used to find the velocities with respect to other points.

**Table 71.3** Relative Velocities of a Rolling Wheel

point	reference point		
	O	C	B
$v_O$	0	$v_O \rightarrow$	$\leftarrow v_O$
$v_C$	$\leftarrow v_O$	0	$\leftarrow 2v_O$
$v_B$	$v_O \rightarrow$	$2v_O \rightarrow$	0

### Example 71.11

A truck with 35 in diameter tires travels at a constant 35 mi/hr. What is the absolute velocity of point P on the circumference of the tire?

### Solution

The translational velocity of the center of the wheel is

$$v_O = \frac{(35 \frac{\text{mi}}{\text{hr}})(5280 \frac{\text{ft}}{\text{mi}})}{3600 \frac{\text{sec}}{\text{hr}}} = 51.33 \text{ ft/sec}$$

The wheel radius is

$$r = \frac{35 \text{ in}}{(2)(12 \frac{\text{in}}{\text{ft}})} = 1.458 \text{ ft}$$

The angular velocity of the wheel is

$$\omega = \frac{v_O}{r} = \frac{51.33 \frac{\text{ft}}{\text{sec}}}{1.458 \text{ ft}} = 35.21 \text{ rad/sec}$$

The instantaneous center is the contact point, C. The law of cosines is used to find the distance  $l$ .

$$l^2 = r^2 + r^2 - 2r^2 \cos \phi = 2r^2(1 - \cos \phi)$$

$$l = \sqrt{(2)(1.458 \text{ ft})^2(1 - \cos 135^\circ)} = 2.694 \text{ ft}$$

From Eq. 71.52, the absolute velocity of point P is

$$v_P = l\omega = (2.694 \text{ ft})(35.21 \frac{\text{rad}}{\text{sec}}) = 94.9 \text{ ft/sec}$$

## 20. INSTANTANEOUS CENTER OF ACCELERATION

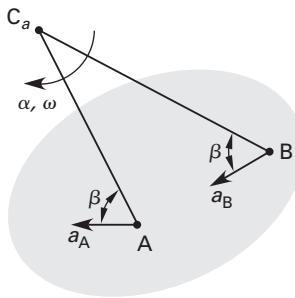

The *instantaneous center of acceleration* is used to compute the absolute acceleration of a point as if a body were in pure rotation about that point. It is the same as the instantaneous center of rotation, only for a body starting from rest and accelerating uniformly with angular acceleration,  $\alpha$ . The absolute acceleration,  $a$ , determined from Eq. 71.53 is the same as the *resultant acceleration* in Fig. 71.7.

$$a = l\alpha = \frac{la_0}{r} \quad 71.53$$

In general, the instantaneous center of acceleration,  $C_a$ , will be deflected at angle  $\beta$  from the absolute acceleration vectors, as shown in Fig. 71.16. The relationship among the angle,  $\beta$ , the instantaneous acceleration,  $\alpha$ , and the instantaneous velocity,  $\omega$ , is

$$\tan \beta = \frac{\alpha}{\omega^2} \quad 71.54$$

**Figure 71.16** Instantaneous Center of Acceleration

## 21. SLIDER RODS

The absolute velocity of any point, P, on a slider rod assembly can be found from the instantaneous center concept. (See Fig. 71.17.) The instantaneous center, C, is located by extending perpendiculars from the velocity vectors.

If the velocity with respect to point C of one end of the slider is known, for example  $v_A$ , then  $v_B$  can be found from geometry. Since the slider can be assumed to rotate about point C with angular velocity  $\omega$ ,

$$\omega = \frac{v_A}{AC} = \frac{v_A}{l \cos \beta} = \frac{v_B}{BC} = \frac{v_B}{l \cos \alpha} \quad 71.55$$

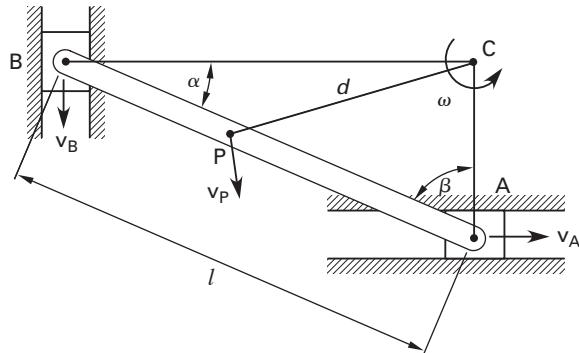

Since  $\cos \alpha = \sin \beta$ ,

$$v_B = v_A \tan \beta \quad 71.56$$

If the velocity with respect to point C of any other point P is required, it can be found from

$$v_P = d\omega \quad 71.57$$

**Figure 71.17** Instantaneous Center of Slider Rod Assembly

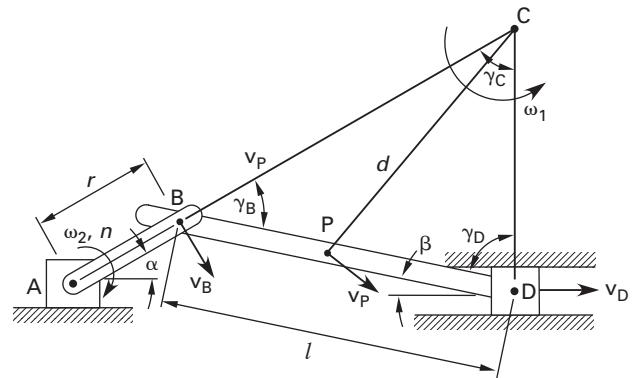

## 22. SLIDER-CRANK ASSEMBLIES

Figure 71.18 illustrates a slider-crank assembly for which points A and D are in the same plane and at the same elevation. The instantaneous velocity of any point, P, on the rod can be found if the distance to the instantaneous center is known.

$$v_P = d\omega_1 \quad 71.58$$

**Figure 71.18** Slider-Crank Assembly

The tangential velocity of point B on the crank with respect to point A is perpendicular to the end of the crank. Slider D moves with a horizontal velocity. The intersection of lines drawn perpendicular to these velocity vectors locates the instantaneous center, point C. At any given instant, the connecting rod seems to rotate about point C with instantaneous angular velocity  $\omega_1$ .

The velocity of point D,  $v_D$ , is

$$v_D = (CD)\omega_1 = v_B \left( \frac{CD}{BC} \right) = \omega_2 \left( \frac{AB \times CD}{BC} \right) \quad 71.59$$

Similarly, the velocity of point B,  $v_B$ , is

$$v_B = (AB)\omega_2 = (BC)\omega_1 = v_D \left( \frac{BC}{CD} \right) \quad 71.60$$

$$\omega_2 = \frac{2\pi n}{60} \quad 71.61$$

The following geometric relationships exist between the various angles.

$$\frac{\omega_1}{\omega_2} = \frac{AB}{BC} \quad 71.62$$

$$\frac{\sin \alpha}{l} = \frac{\sin \beta}{r} \quad 71.63$$

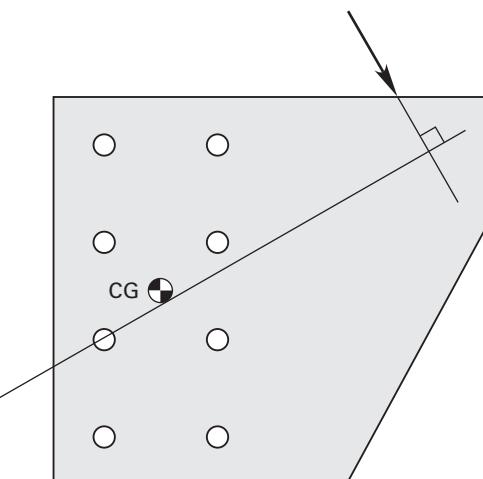

$$\frac{\sin \gamma_D}{BC} = \frac{\sin \gamma_B}{CD} = \frac{\sin \gamma_C}{l} \quad 71.64$$

$$\gamma_B = \alpha + \beta \quad 71.65$$

$$\gamma_D = 90 - \beta \quad 71.66$$

$$\gamma_C = 90 - \alpha \quad 71.67$$

**Figure 71.19** Connector Group Instantaneous Center

For the special cases of an applied load that is either vertical or horizontal, the IC lies on the line that is perpendicular to the line of force and passes through the center of gravity of the bolt group, although the location on the line must still be found. In other cases, finding both the line and IC is done by trial and error using a combination of theory and empirical assumptions to establish a relationship between the applied force and the connector forces.

In the case of bolted connections, the relationship depends on whether the bolted pieces are allowed to slip and bring the bolts into bearing against the sides of their holes (i.e., a bearing connection) or are strong (tight) enough to hold the pieces in alignment (i.e., a slip critical connection). In practical structural design, however, the step of finding the location of the IC is skipped by using tabulations of parameters for the most common geometries of bolted and welded connections, including those that are out of plane with the line of eccentricity. Knowing the location of the IC is inconsequential compared to knowing the capacity of the connection.

### 23. INSTANTANEOUS CENTER OF CONNECTOR GROUPS

Parts that are bolted or welded do not generally experience significant differential rotation, but even so, a point around which rotation would occur can be imagined. With traditional elastic analysis, that point is the centroid (i.e., center of gravity) of the connector group. However, rotation is not always about the centroid, and stresses in the connectors do not always develop in proportion to distance from the centroid, particularly when the connected parts simultaneously translate and rotate. The actual instantaneous center (IC) will generally not coincide with the centroid of the connector group, as shown in Fig. 71.19. Also, the connection's centroid may shift as loading increases and the parts slip.

IC methods for structural connector analysis and design assume that translational and rotational events happen simultaneously about an instantaneous center of rotation that is located near a line that is perpendicular to the applied force and that passes near the original center of gravity of the connector group. The challenge is to find the location of the IC along this line.

<i>w</i>	weight	lbf	N
<i>W</i>	work	ft-lbf	J
<i>y</i>	superelevation	ft	m

## Symbols

$\alpha$	angular acceleration	rad/sec <sup>2</sup>	rad/s <sup>2</sup>
$\delta$	deflection	ft	m
$\epsilon$	eccentricity	—	—
$\theta$	angular position	rad	rad
$\sigma$	stress	lbf/ft <sup>2</sup>	Pa
$\phi$	angle	deg or rad	deg or rad
$\omega$	angular velocity	rad/sec	rad/s

## Subscripts

0	initial
<i>b</i>	braking
<i>c</i>	centripetal
<i>C</i>	instant center
<i>f</i>	final or frictional
<i>k</i>	kinetic (dynamic)

<i>n</i>	normal
O	center or centroidal
<i>p</i>	periodic
<i>r</i>	rolling
<i>s</i>	static
<i>t</i>	tangential or terminal
<i>w</i>	wedge

## 1. INTRODUCTION TO KINETICS

*Kinetics* is the study of motion and the forces that cause motion. Kinetics includes an analysis of the relationship between the force and mass for translational motion and between torque and moment of inertia for rotational motion. Newton's laws form the basis of the governing theory in the subject of kinetics.

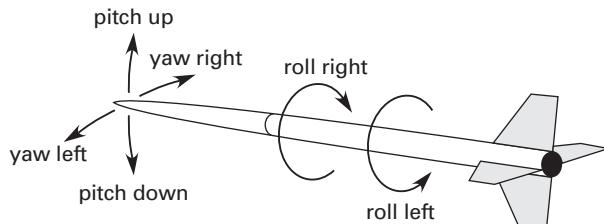

## 2. RIGID BODY MOTION

The most general type of motion is *rigid body motion*. There are five types.

- *pure translation*: The orientation of the object is unchanged as its position changes. (Motion can be in straight or curved paths.)
- *rotation about a fixed axis*: All particles within the body move in concentric circles around the *axis of rotation*.
- *general plane motion*: The motion can be represented in two dimensions (i.e., in the *plane of motion*).
- *motion about a fixed point*: This describes any three-dimensional motion with one fixed point, such as a spinning top or a truck-mounted crane. The distance from a fixed point to any particle in the body is constant.
- *general motion*: This is any motion not falling into one of the other four categories.

Figure 72.1 illustrates the terms yaw, pitch, and roll as they relate to general motion. *Yaw* is a left or right swinging motion of the leading edge. *Pitch* is an up or down swinging motion of the leading edge. *Roll* is rotation about the leading edge's longitudinal axis.

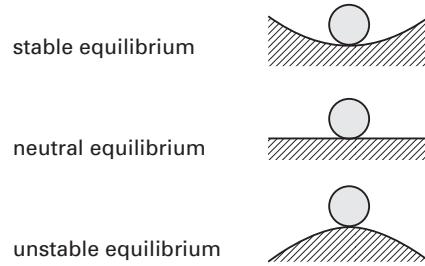

Figure 72.1 Yaw, Pitch, and Roll

## 3. STABILITY OF EQUILIBRIUM POSITIONS

*Stability* is defined in terms of a body's relationship with an equilibrium position. *Neutral equilibrium* exists if a body, when displaced from its equilibrium position, remains in its displaced state. *Stable equilibrium* exists if the body returns to the original equilibrium position after experiencing a displacement. *Unstable equilibrium* exists if the body moves away from the equilibrium position. These terms are illustrated by Fig. 72.2.

Figure 72.2 Types of Equilibrium

## 4. CONSTANT FORCES

*Force* is a push or a pull that one body exerts on another, including gravitational, electrostatic, magnetic, and contact influences. Forces that do not vary with time are *constant forces*.

Actions of other bodies on a rigid body are known as *external forces*. External forces are responsible for external motion of a body. *Internal forces* hold together parts of a rigid body.

## 5. LINEAR MOMENTUM

The vector *linear momentum* (usually just *momentum*) is defined by Eq. 72.1.<sup>1</sup> It has the same direction as the velocity vector. Momentum has units of force × time (e.g., lbf·sec or N·s).

$$\mathbf{P} = m\mathbf{v} \quad [\text{SI}] \quad 72.1(a)$$

$$\mathbf{P} = \frac{m\mathbf{v}}{g_c} \quad [\text{U.S.}] \quad 72.1(b)$$

Momentum is conserved when no external forces act on a particle. If no forces act on the particle, the velocity and direction of the particle are unchanged. The *law of conservation of momentum* states that the linear momentum is unchanged if no unbalanced forces act on the particle. This does not prohibit the mass and velocity from changing, however. Only the product of mass and velocity is constant. Depending on the nature

<sup>1</sup>The symbols  $\mathbf{P}$ ,  $\text{mom}$ ,  $mv$ , and others are also used for momentum. Some authorities assign no symbol and just use the word momentum.

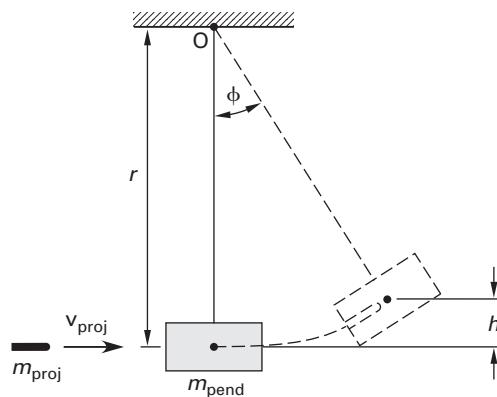

of the problem, momentum can be conserved in any or all of the three coordinate directions.

$$\sum m_0 \mathbf{v}_0 = \sum m_f \mathbf{v}_f \quad 72.2$$

## 6. BALLISTIC PENDULUM

Figure 72.3 illustrates a *ballistic pendulum*. A projectile of known mass but unknown velocity is fired into a hanging target (the *pendulum*). The projectile is captured by the pendulum, which moves forward and upward. Kinetic energy is not conserved during impact because some of the projectile's kinetic energy is transformed into heat. However, momentum is conserved during impact, and the movement of the pendulum can be used to calculate the impact velocity of the projectile.<sup>2</sup>

**Figure 72.3** Ballistic Pendulum

Since no external forces act on the block during impact, the momentum of the system is conserved.

$$\mathbf{P}_{\text{before impact}} = \mathbf{P}_{\text{after impact}} \quad 72.3$$

$$m_{\text{proj}} \mathbf{v}_{\text{proj}} = (m_{\text{proj}} + m_{\text{pend}}) \mathbf{v}_{\text{pend}} \quad 72.4$$

Although kinetic energy before impact is not conserved, the total remaining energy after impact is conserved. That is, once the projectile has been captured by the pendulum, the kinetic energy of the pendulum-projectile combination is converted totally to potential energy as the pendulum swings upward.

$$\frac{1}{2} (m_{\text{proj}} + m_{\text{pend}}) v_{\text{pend}}^2 = (m_{\text{proj}} + m_{\text{pend}}) g h \quad 72.5$$

$$v_{\text{pend}} = \sqrt{2gh} \quad 72.6$$

<sup>2</sup>In this type of problem, it is important to be specific about when the energy and momentum are evaluated. During impact, kinetic energy is not conserved, but momentum is conserved. After impact, as the pendulum swings, energy is conserved but momentum is not conserved because gravity (an external force) acts on the pendulum during its swing.

The relationship between the rise of the pendulum,  $h$ , and the swing angle,  $\phi$ , is

$$h = r(1 - \cos \phi) \quad 72.7$$

Since the time during which the force acts is not well defined, there is no single equivalent force that can be assumed to initiate the motion. Any force that produces the same impulse over a given contact time will be applicable.

## 7. ANGULAR MOMENTUM

The vector *angular momentum* (also known as *moment of momentum*) taken about a point O is the moment of the linear momentum vector. Angular momentum has units of distance  $\times$  force  $\times$  time (e.g., ft-lbf-sec or N·m·s). It has the same direction as the rotation vector and can be determined by use of the right-hand rule. (That is, it acts in a direction perpendicular to the plane containing the position and linear momentum vectors.) (See Fig. 72.4.)

$$\mathbf{h}_O = \mathbf{r} \times m\mathbf{v} \quad [\text{SI}] \quad 72.8(a)$$

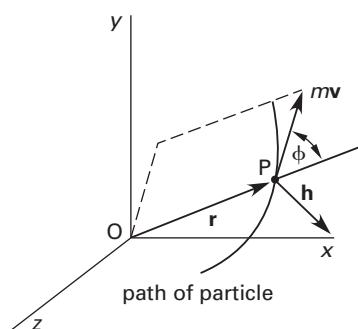

$$\mathbf{h}_O = \frac{\mathbf{r} \times m\mathbf{v}}{g_c} \quad [\text{U.S.}] \quad 72.8(b)$$

Any of the methods normally used to evaluate cross-products can be used with angular momentum. The scalar form of Eq. 72.8 is

$$h_O = rmv \sin \phi \quad [\text{SI}] \quad 72.9(a)$$

$$h_O = \frac{rmv \sin \phi}{g_c} \quad [\text{U.S.}] \quad 72.9(b)$$

**Figure 72.4** Angular Momentum

For a rigid body rotating about an axis passing through its center of gravity located at point O, the scalar value of angular momentum is given by Eq. 72.10.

$$h_O = I\omega \quad [\text{SI}] \quad 72.10(a)$$

$$h_O = \frac{I\omega}{g_c} \quad [\text{U.S.}] \quad 72.10(b)$$

## 8. NEWTON'S FIRST LAW OF MOTION

Much of this chapter is based on Newton's laws of motion. *Newton's first law of motion* can be stated in several forms.

- *common form:* A particle will remain in a state of rest or will continue to move with constant velocity unless an unbalanced external force acts on it.
- *law of conservation of momentum form:* If the resultant external force acting on a particle is zero, then the linear momentum of the particle is constant.

## 9. NEWTON'S SECOND LAW OF MOTION

*Newton's second law of motion* is stated as follows.

- *second law:* The acceleration of a particle is directly proportional to the force acting on it and inversely proportional to the particle mass. The direction of acceleration is the same as the direction of the force.

This law can be stated in terms of the force vector required to cause a change in momentum. The resultant force is equal to the rate of change of linear momentum.

$$\mathbf{F} = \frac{d\mathbf{p}}{dt} \quad 72.11$$

If the mass is constant with respect to time, the scalar form of Eq. 72.11 is<sup>3</sup>

$$F = m\left(\frac{dv}{dt}\right) = ma \quad [\text{SI}] \quad 72.12(a)$$

$$F = \left(\frac{m}{g_c}\right)\left(\frac{dv}{dt}\right) = \frac{ma}{g_c} \quad [\text{U.S.}] \quad 72.12(b)$$

Equation 72.12 can be written in rectangular coordinates form (i.e., in terms of  $x$ - and  $y$ -component forces), in polar coordinates form (i.e., tangential and normal components), and in cylindrical coordinates form (i.e., radial and transverse components).

Although Newton's laws do not specifically deal with rotation, there is an analogous relationship between torque and change in angular momentum. For a rotating body, the torque,  $\mathbf{T}$ , required to change the angular momentum is

$$\mathbf{T} = \frac{d\mathbf{h}_0}{dt} \quad 72.13$$

<sup>3</sup>Equation 72.12 shows that force is a scalar multiple of acceleration. Any consistent set of units can be used. For example, if both sides are divided by the acceleration of gravity (i.e., so that acceleration in Eq. 72.12 is in gravities), the force will have units of *g-forces* or *gees* (i.e., multiples of the gravitational force).

If the moment of inertia is constant, the scalar form of Eq. 72.13 is given by Eq. 72.14.

$$T = I\left(\frac{d\omega}{dt}\right) = I\alpha \quad [\text{SI}] \quad 72.14(a)$$

$$T = \left(\frac{I}{g_c}\right)\left(\frac{d\omega}{dt}\right) = \frac{I\alpha}{g_c} \quad [\text{U.S.}] \quad 72.14(b)$$

### Example 72.1

The acceleration in  $\text{m/s}^2$  of a 40 kg body is specified by the equation

$$a(t) = 8 - 12t$$

What is the instantaneous force acting on the body at  $t = 6 \text{ s}$ ?

*Solution*

The acceleration is

$$a(6) = 8 \frac{\text{m}}{\text{s}^2} - \left(12 \frac{\text{m}}{\text{s}^3}\right)(6 \text{ s}) = -64 \text{ m/s}^2$$

From Newton's second law, the instantaneous force is

$$f = ma = (40 \text{ kg})\left(-64 \frac{\text{m}}{\text{s}^2}\right) = -2560 \text{ N}$$

## 10. CENTRIPETAL FORCE

Newton's second law says there is a force for every acceleration a body experiences. For a body moving around a curved path, the total acceleration can be separated into tangential and normal components. By Newton's second law, there are corresponding forces in the tangential and normal directions. The force associated with the normal acceleration is known as the *centripetal force*.<sup>4</sup>

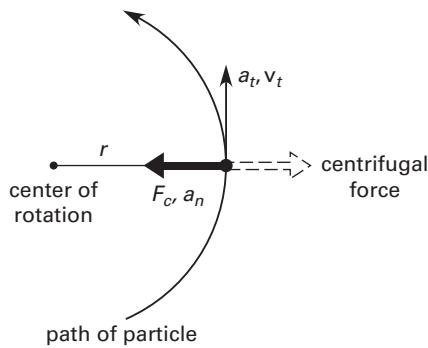

$$F_c = ma_n = \frac{mv_t^2}{r} \quad [\text{SI}] \quad 72.15(a)$$

$$F_c = \frac{ma_n}{g_c} = \frac{mv_t^2}{g_c r} \quad [\text{U.S.}] \quad 72.15(b)$$

The centripetal force is a real force on the body toward the center of rotation. The so-called *centrifugal force* is an apparent force on the body directed away from the center of rotation. The centripetal and centrifugal forces are equal in magnitude but opposite in sign, as shown in Fig. 72.5.

An unbalanced rotating body (vehicle wheel, clutch disk, rotor of an electrical motor, etc.) will experience a dynamic *unbalanced force*. Though the force is essentially centripetal in nature and is given by Eq. 72.15, it is generally difficult to assign a value to the radius.

<sup>4</sup>The term *normal force* is reserved for the plane reaction in friction calculations.

**Figure 72.5** Centripetal Force

For that reason, the force is often determined directly on the rotating body or from the deflection of its supports.

Since the body is rotating, the force will be experienced in all directions perpendicular to the axis of rotation. If the supports are flexible, the force will cause the body to vibrate, and the frequency of vibration will essentially be the rotational speed. If the supports are rigid, the bearings will carry the unbalanced force and transmit it to other parts of the frame.

### Example 72.2

A 4500 lbm (2000 kg) car travels at 40 mph (65 kph) around a curve with a radius of 200 ft (60 m). What is the centripetal force?

*SI Solution*

The tangential velocity is

$$v_t = \frac{(65 \text{ km}) (1000 \text{ m/km})}{3600 \text{ s/h}} = 18.06 \text{ m/s}$$

From Eq. 72.15(a), the centripetal force is

$$F_c = \frac{mv_t^2}{r} = \frac{(2000 \text{ kg})(18.06 \text{ m/s})^2}{60 \text{ m}} = 10872 \text{ N}$$

*Customary U.S. Solution*

The tangential velocity is

$$v_t = \frac{(40 \text{ mi/hr}) (5280 \text{ ft/mi})}{3600 \text{ sec/hr}} = 58.67 \text{ ft/sec}$$

From Eq. 72.15(b), the centripetal force is

$$F_c = \frac{mv_t^2}{g_c r} = \frac{(4500 \text{ lbm}) (58.67 \text{ ft/sec})^2}{(32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2})(200 \text{ ft})} = 2405 \text{ lbf}$$

### 11. NEWTON'S THIRD LAW OF MOTION

Newton's third law of motion is as follows.

- third law: For every acting force between two bodies, there is an equal but opposite reacting force on the same line of action.

$$\mathbf{F}_{\text{reacting}} = -\mathbf{F}_{\text{acting}}$$

72.16

### 12. DYNAMIC EQUILIBRIUM

An accelerating body is not in static equilibrium. Accordingly, the familiar equations of statics ( $\sum F = 0$  and  $\sum M = 0$ ) do not apply. However, if the *inertial force*,  $ma$ , is included in the static equilibrium equation, the body is said to be in *dynamic equilibrium*.<sup>5,6</sup> This is known as *D'Alembert's principle*. Since the inertial force acts to oppose changes in motion, it is negative in the summation.

$$\sum \mathbf{F} - ma = 0 \quad [\text{SI}] \quad 72.17(a)$$

$$\sum \mathbf{F} - \frac{ma}{g_c} = 0 \quad [\text{U.S.}] \quad 72.17(b)$$

It should be clear that D'Alembert's principle is just a different form of Newton's second law, with the  $ma$  term transposed to the left-hand side.

The analogous rotational form of the dynamic equilibrium principle is

$$\sum \mathbf{T} - I\alpha = 0 \quad [\text{SI}] \quad 72.18(a)$$

$$\sum \mathbf{T} - \frac{I\alpha}{g_c} = 0 \quad [\text{U.S.}] \quad 72.18(b)$$

### 13. FLAT FRICTION

Friction is a force that always resists motion or impending motion. It always acts parallel to the contacting surfaces. The frictional force,  $F_f$ , exerted on a stationary body is known as *static friction*, *Coulomb friction*, and *fluid friction*. If the body is moving, the friction is known as *dynamic friction* and is less than the static friction.

<sup>5</sup>Other names for the inertial force are *inertia vector* (when written as  $ma$ ), *dynamic reaction*, and *reversed effective force*. The term  $\sum \mathbf{F}$  is known as the *effective force*.

<sup>6</sup>*Dynamic* and *equilibrium* are contradictory terms. A better term is *simulated equilibrium*, but this form has not caught on.

The actual magnitude of the frictional force depends on the *normal force*,  $N$ , and the *coefficient of friction*,  $f$ , between the body and the surface.<sup>7</sup> For a body resting on a horizontal surface, the normal force is the weight of the body. (See Fig. 72.6.)

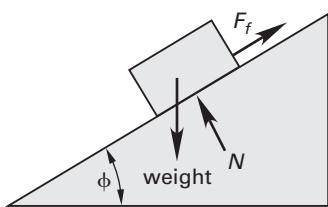

$$N = mg$$

[SI] 72.19(a)

$$N = \frac{mg}{g_c}$$

[U.S.] 72.19(b)

**Figure 72.6** Frictional and Normal Forces

If the body rests on an inclined surface, the normal force depends on the incline angle.

$$N = mg \cos \phi$$

[SI] 72.20(a)

$$N = \frac{mg \cos \phi}{g_c}$$

[U.S.] 72.20(b)

The maximum static frictional force,  $F_f$ , is the product of the coefficient of friction,  $f$ , and the normal force,  $N$ . (The subscripts  $s$  and  $k$  are used to distinguish between the static and dynamic (kinetic) coefficients of friction.)

$$F_{f,\max} = f_s N$$

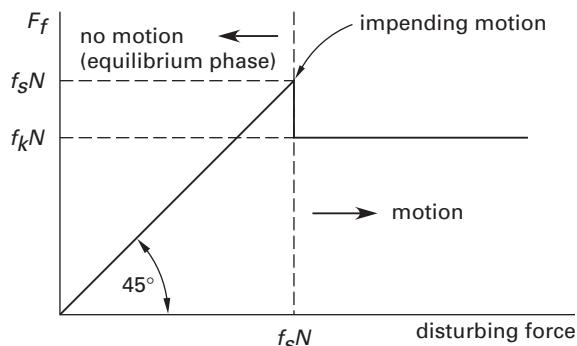

72.21

The frictional force acts only in response to a disturbing force. If a small disturbing force (i.e., a force less than  $F_{f,\max}$ ) acts on a body, then the frictional force will equal the disturbing force, and the maximum frictional force will not develop. This occurs during the *equilibrium phase*. The *motion impending phase* is when the disturbing force equals the maximum frictional force,  $F_{f,\max}$ . Once motion begins, however, the coefficient of friction drops slightly, and a lower frictional force opposes movement. These cases are illustrated in Fig. 72.7.

A body on an inclined plane will not begin to slip down the plane until the component of weight parallel to the plane exceeds the frictional force. If the plane's inclination angle can be varied, the body will not slip until the angle reaches a critical angle known as the *angle of*

<sup>7</sup>The symbol  $\mu$  is also widely used by engineers to represent the coefficient of friction.

**Figure 72.7** Frictional Force Versus Disturbing Force

*repose* or *angle of static friction*,  $\phi$ . Equation 72.22 relates this angle to the coefficient of static friction.

$$\tan \phi = f_s$$

72.22

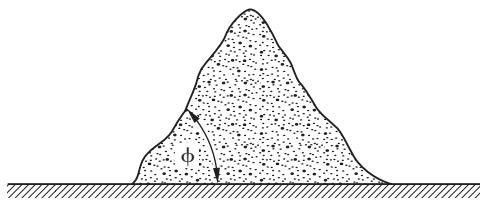

Tabulations of coefficients of friction distinguish between types of surfaces and between static and dynamic cases. They might also list values for dry conditions and oiled conditions. The term *dry* is synonymous with *nonlubricated*. The ambiguous term *wet*, although a natural antonym for *dry*, is sometimes used to mean *oily*. However, it usually means wet with water, as in tires on a wet roadway after a rain. Typical values of the coefficient of friction are given in Table 72.1.<sup>8</sup>

**Table 72.1** Typical Coefficients of Friction

materials	condition	dynamic	static
cast iron on cast iron	dry	0.15	1.00
plastic on steel	dry	0.35	0.45
grooved rubber on	dry	0.40	0.55
pavement			
bronze on steel	oiled	0.07	0.09
steel on graphite	dry	0.16	0.21
steel on steel	dry	0.42	0.78
steel on steel	oiled	0.08	0.10
steel on asbestos-faced	dry	0.11	0.15
steel			
steel on asbestos-faced	oiled	0.09	0.12
steel			
press fits (shaft in hole)	oiled	—	0.10–0.15

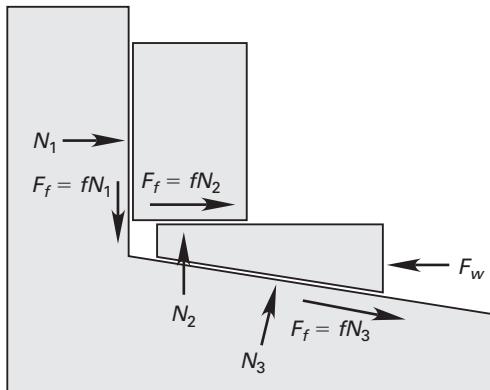

A special case of the angle of repose is the *angle of internal friction*,  $\phi$ , of soil, grain, or other granular material. (See Fig. 72.8.) The angle made by a pile of granular material depends on how much friction there is between the granular particles. Liquids have angles of internal friction of zero, because they do not form piles.

<sup>8</sup>Experimental and reported values of the coefficient of friction vary greatly from researcher to researcher and experiment to experiment. The values in Table 72.1 are more for use in solving practice problems than serving as the last word in available data.

**Figure 72.8** Angle of Internal Friction of a Pile

## 14. WEDGES

Wedges are machines that are able to raise heavy loads. The wedge angles are chosen so that friction will keep the wedge in place once it is driven between the load and support. As with any situation where friction is present, the frictional force is parallel to the contacting surfaces. (See Fig. 72.9.)

**Figure 72.9** Using a Wedge to Raise a Load

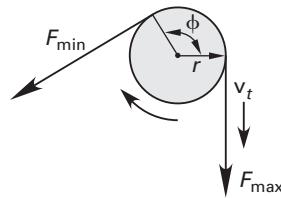

## 15. BELT FRICTION

Friction from a flat belt, rope, or band wrapped around a pulley or sheave is responsible for the transfer of torque. Except at start-up, one side of the belt (the tight side) will have a higher tension than the other (the slack side). The basic relationship between these belt tensions and the coefficient of friction neglects centrifugal effects and is given by Eq. 72.23.<sup>9</sup> (The angle of wrap,  $\phi$ , must be expressed in radians.) (See Fig. 72.10.)

$$\frac{F_{\max}}{F_{\min}} = e^{f\phi} \quad 72.23$$

The net transmitted torque is

$$T = (F_{\max} - F_{\min})r \quad 72.24$$

**Figure 72.10** Flat Belt Friction

The power transmitted by the belt running at tangential velocity  $v_t$  is given by Eq. 72.25.<sup>10</sup>

$$P = (F_{\max} - F_{\min})v_t \quad 72.25$$

The change in belt tension caused by centrifugal force should be considered when the velocity or belt mass is very large. Equation 72.26 can be used, where  $m$  is the mass per unit length of belt.

$$\frac{F_{\max} - mv_t^2}{F_{\min} - mv_t^2} = e^{f\phi} \quad [\text{SI}] \quad 72.26(a)$$

$$\frac{F_{\max} - \frac{mv_t^2}{g_c}}{F_{\min} - \frac{mv_t^2}{g_c}} = e^{f\phi} \quad [\text{U.S.}] \quad 72.26(b)$$

### Example 72.3

During start-up, a 4.0 ft diameter pulley with centroidal moment of inertia of 1610 lbm-ft<sup>2</sup> is subjected to tight-side and loose-side belt tensions of 200 lbf and 100 lbf, respectively. A frictional torque of 15 ft-lbf is acting to resist pulley rotation. (a) What is the angular acceleration? (b) How long will it take the pulley to reach a speed of 120 rpm?

*Solution*

(a) From Eq. 72.24, the net torque is

$$\begin{aligned} T &= rF_{\text{net}} = (2 \text{ ft})(200 \text{ lbf} - 100 \text{ lbf}) - 15 \text{ ft-lbf} \\ &= 185 \text{ ft-lbf} \end{aligned}$$

From Eq. 72.14, the angular acceleration is

$$\begin{aligned} \alpha &= \frac{g_c T}{I} = \frac{\left(32.2 \frac{\text{lbf}\cdot\text{sec}^2}{\text{lbf}\cdot\text{sec}^2}\right)(185 \text{ ft-lbf})}{1610 \text{ lbm}\cdot\text{ft}^2} \\ &= 3.7 \text{ rad/sec}^2 \end{aligned}$$

<sup>9</sup>This equation does not apply to V-belts. V-belt design and analysis is dependent on the cross-sectional geometry of the belt.

<sup>10</sup>When designing a belt system, the horsepower to be transmitted should be multiplied by a *service factor* to obtain the *design power*. Service factors range from 1.0 to 1.5 and depend on the nature of the power source, the load, and the starting characteristics.

(b) The angular velocity is

$$\omega = \frac{\left(120 \frac{\text{rev}}{\text{min}}\right)\left(2\pi \frac{\text{rad}}{\text{rev}}\right)}{60 \frac{\text{sec}}{\text{min}}}$$

$$= 12.6 \text{ rad/sec}$$

This is a case of constant angular acceleration starting from rest.

$$t = \frac{\omega}{\alpha} = \frac{12.6 \frac{\text{rad}}{\text{sec}}}{3.7 \frac{\text{rad}}{\text{sec}^2}}$$

$$= 3.4 \text{ sec}$$

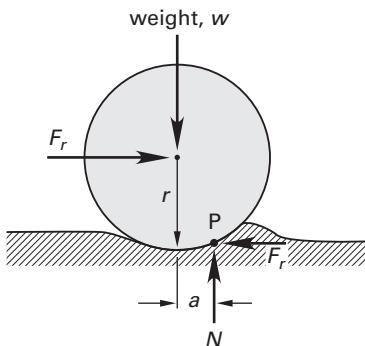

## 16. ROLLING RESISTANCE

*Rolling resistance* is a force that opposes motion, but it is not friction. Rather, it is caused by the deformation of the rolling body and the supporting surface. Rolling resistance is characterized by a *coefficient of rolling resistance*,  $a$ , which has units of length.<sup>11</sup> (See Fig. 72.11.) Since this deformation is very small, the rolling resistance in the direction of motion is

$$F_r = \frac{mga}{r} \quad [\text{SI}] \quad 72.27(a)$$

$$F_r = \frac{mga}{rg_c} = \frac{wa}{r} \quad [\text{U.S.}] \quad 72.27(b)$$

Figure 72.11 Wheel Rolling Resistance

<sup>11</sup>Rolling resistance is traditionally derived by assuming the roller encounters a small step in its path a distance  $a$  in front of the center of gravity. The forces acting on the roller are the weight and driving force acting through the centroid and the normal force and rolling resistance acting at the contact point, P. Equation 72.27 is derived by taking moments about the contact point, P.

The term *coefficient of rolling friction*,  $f_r$ , is occasionally encountered, although friction is not the cause of rolling resistance.

$$f_r = \frac{F_r}{w} = \frac{a}{r} \quad 72.28$$

## 17. ROADWAY/CONVEYOR BANKING

If an object (e.g., a vehicle) travels in a circular path with instantaneous radius  $r$  and tangential velocity  $v_t$ , it will experience an apparent centrifugal force. The centrifugal force is resisted by a combination of surface (e.g., roadway) banking (*superelevation rate*) and *sideways friction*.<sup>12</sup> If the surface is banked so that friction is not required to resist the centrifugal force, the superelevation angle,  $\phi$ , can be calculated from Eq. 72.29.<sup>13</sup>

$$\tan \phi = \frac{v_t^2}{gr} \quad 72.29$$

Equation 72.29 can be solved for the *normal speed* corresponding to the geometry of a curve.

$$v_t = \sqrt{gr \tan \phi} \quad 72.30$$

When friction is used to counteract some of the centrifugal force, the *side friction factor*,  $f$ , between the object and surface (e.g., the tires and the roadway) is incorporated into the calculation of the superelevation angle.

$$e = \tan \phi = \frac{v_t^2 - fgr}{gr + fv_t^2} \quad 72.31$$

If the banking angle,  $\phi$ , is set to zero, Eq. 72.31 can be used to calculate the maximum velocity of an object in a turn when there is no banking.

For highway design, *superelevation rate*,  $e$ , is the amount of rise or fall of the cross slope per unit amount of horizontal width (i.e., the tangent of the slope angle above or below horizontal). Customary U.S. units are expressed in feet per foot, such as 0.06 ft/ft, or inch fractions per foot, such as  $\frac{3}{4}$  in./ft. SI units are millimeters per meter, such as 60 mm/m. The slope can also be expressed as a percent cross slope, such as 6% cross slope; or as a ratio, 1:17. The *superelevation*,  $y$ , is the difference in heights of the inside and outside edges of the curve.

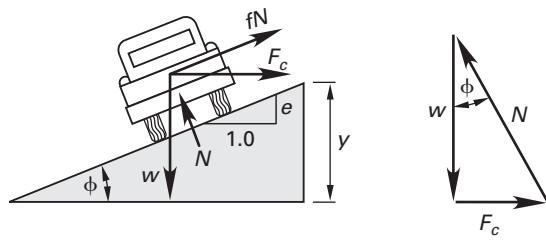

When the speed, superelevation, and radius are such that no friction is required to resist sliding, the curve is said to be "balanced." There is no tendency for a vehicle to slide up or down the slope at the *balanced speed*. At any speed other than the balanced speed, some friction is needed to hold the vehicle on the slope. Given a

<sup>12</sup>The *superelevation rate* is the slope (in ft/ft or m/m) in the transverse direction (i.e., across the roadway).

<sup>13</sup>Generally it is not desirable to rely on roadway banking alone, since a particular superelevation angle would correspond to a single speed only.

friction factor,  $f$ , the required value of the superelevation rate,  $e$ , can be calculated. (See Fig. 72.12.)

**Figure 72.12** Roadway Banking

Equation 72.31 can be solved for the curve radius. For small banking angles (i.e.,  $\phi \leq 8^\circ$ ), this simplifies to

$$r \approx \frac{v_t^2}{g(e + f)} \quad 72.32$$

$$r_m = \frac{v_{\text{km/h}}^2}{127(e_{m/m} + f)} \quad [\text{SI}] \quad 72.33(a)$$

$$r_{\text{ft}} = \frac{v_{\text{mph}}^2}{15(e_{\text{ft/ft}} + f)} \quad [\text{U.S.}] \quad 72.33(b)$$

#### Example 72.4

A 4000 lbm (1800 kg) car travels at 40 mph (65 km/h) around a banked curve with a radius of 500 ft (150 m). What should be the superelevation rate so that the tire friction is not needed to prevent the car from sliding?

*SI Solution*

From Eq. 72.33,

$$\begin{aligned} e + f &= \frac{v^2}{127r} \\ e + 0 &= \frac{\left(65 \frac{\text{km}}{\text{hr}}\right)^2}{(127)(150 \text{ m})} \\ &= 0.222 \text{ m/m} \end{aligned}$$

*Customary U.S. Solution*

From Eq. 72.33,

$$\begin{aligned} e + f &= \frac{v^2}{15r} \\ e + 0 &= \frac{\left(40 \frac{\text{mi}}{\text{hr}}\right)^2}{(15)(500 \text{ ft})} \\ &= 0.213 \text{ ft/ft} \end{aligned}$$

#### Example 72.5

A 4000 lbm car travels at 40 mph around a banked curve with a radius of 500 ft. What should be the superelevation angle so that tire friction is not needed to prevent the car from sliding?

*Solution*

The tangential velocity of the car is

$$\begin{aligned} v_t &= \frac{\left(40 \frac{\text{mi}}{\text{hr}}\right)\left(5280 \frac{\text{ft}}{\text{mi}}\right)}{3600 \frac{\text{sec}}{\text{hr}}} \\ &= 58.67 \text{ ft/sec} \end{aligned}$$

From Eq. 72.29,

$$\begin{aligned} \phi &= \arctan \frac{v_t^2}{gr} \\ &= \arctan \frac{\left(58.67 \frac{\text{ft}}{\text{sec}}\right)^2}{\left(32.2 \frac{\text{ft}}{\text{sec}^2}\right)(500 \text{ ft})} \\ &= 12.07^\circ \end{aligned}$$

#### Example 72.6

A vehicle is traveling at 70 mph when it enters a circular curve of a test track. The curve radius is 240 ft. The sideways sliding coefficient of friction between the tires and the roadway is 0.57. (a) At what minimum angle from the horizontal must the curve be banked in order to prevent the vehicle from sliding off the top of the curve? (b) If the roadway is banked at  $20^\circ$  from the horizontal, what is the maximum vehicle speed such that no sliding occurs?

*Solution*

(a) The speed of the vehicle is

$$\begin{aligned} v_t &= \frac{\left(70 \frac{\text{mi}}{\text{hr}}\right)\left(5280 \frac{\text{ft}}{\text{mi}}\right)}{3600 \frac{\text{sec}}{\text{hr}}} \\ &= 102.7 \text{ ft/sec} \end{aligned}$$

From Eq. 72.31, the required banking angle is

$$\begin{aligned}\phi &= \arctan\left(\frac{v_t^2 - fgr}{gr + fv_t^2}\right) \\ &= \arctan\left(\frac{\left(102.7 \frac{\text{ft}}{\text{sec}}\right)^2 - (0.57)\left(32.2 \frac{\text{ft}}{\text{sec}^2}\right)(240 \text{ ft})}{\left(32.2 \frac{\text{ft}}{\text{sec}^2}\right)(240 \text{ ft}) + (0.57)\left(102.7 \frac{\text{ft}}{\text{sec}}\right)^2}\right) \\ &= 24.1^\circ\end{aligned}$$

(b) Solve Eq. 72.31 for the velocity.

$$\begin{aligned}v_t &= \sqrt{\frac{rg(\tan \phi + f)}{1 - f \tan \phi}} \\ &= \sqrt{\frac{(240 \text{ ft})\left(32.2 \frac{\text{ft}}{\text{sec}^2}\right)(\tan 20^\circ + 0.57)}{1 - 0.57 \tan 20^\circ}} \\ &= 95.4 \text{ ft/sec} \quad (65.1 \text{ mi/hr})\end{aligned}$$

## 18. MOTION OF RIGID BODIES

When a rigid body experiences pure translation, its position changes without any change in orientation. At any instant, all points on the body have the same displacement, velocity, and acceleration. The behavior of a rigid body in translation is given by Eq. 72.34 and Eq. 72.35. All equations are written for the center of mass. (These equations represent Newton's second law written in component form.)

$$\sum F_x = ma_x \quad [\text{consistent units}] \quad 72.34$$

$$\sum F_y = ma_y \quad [\text{consistent units}] \quad 72.35$$

When a torque acts on a rigid body, the rotation will be about the center of gravity unless the body is constrained otherwise. In the case of rotation, the torque and angular acceleration are related by Eq. 72.36.

$$T = I\alpha \quad [\text{SI}] \quad 72.36(a)$$

$$T = \frac{I\alpha}{g_c} \quad [\text{U.S.}] \quad 72.36(b)$$

*Euler's equations of motion* are used to analyze the motion of a rigid body about a fixed point, O. This class of problem is particularly difficult because the mass moments of products of inertia change with time if a fixed set of axes is used. Therefore, it is more convenient to define the x-, y-, and z-axes with respect to the body. Such an action is acceptable because the angular momentum about the origin,  $\mathbf{h}_O$ , corresponding to a

given angular velocity,  $\omega$ , is independent of the choice of coordinate axes.

An infinite number of axes can be chosen. (A general relationship between moments and angular momentum is given in most dynamics textbooks.) However, if the origin is at the mass center and the x-, y-, and z-axes coincide with the principal axes of inertia of the body (such that the product of inertia is zero), the angular momentum of the body about the origin (i.e., point O at (0, 0, 0)) is given by the simplified relationship

$$\mathbf{h}_O = I_x \omega_x \mathbf{i} + I_y \omega_y \mathbf{j} + I_z \omega_z \mathbf{k} \quad 72.37$$

The three scalar Euler equations of motion can be derived from this simplified relationship.

$$\sum M_x = I_x \alpha_x - (I_y - I_z) \omega_y \omega_z \quad 72.38$$

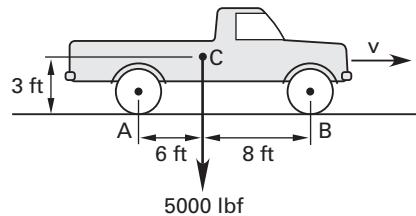

$$\sum M_y = I_y \alpha_y - (I_z - I_x) \omega_z \omega_x \quad 72.39$$

$$\sum M_z = I_z \alpha_z - (I_x - I_y) \omega_x \omega_y \quad 72.40$$

### Example 72.7

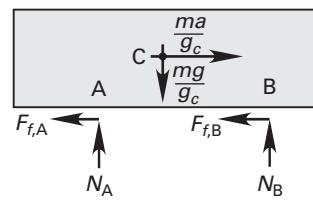

A 5000 lbm truck skids with a deceleration of 15 ft/sec<sup>2</sup>.

- (a) What is the coefficient of sliding friction? (b) What are the frictional forces and normal reactions (per axle) at the tires?

*Solution*

- (a) The free-body diagram of the truck in equilibrium with the inertial force is shown.

The equation of dynamic equilibrium in the horizontal direction is

$$\begin{aligned}\sum F_x &= \frac{ma}{g_c} - F_{f,A} - F_{f,B} = 0 \\ &= \frac{ma}{g_c} - (N_A + N_B)f = 0 \\ \frac{(5000 \text{ lbm})\left(15 \frac{\text{ft}}{\text{sec}^2}\right)}{32.2 \frac{\text{lbf-ft}}{\text{lbf-sec}^2}} - (5000 \text{ lbf})f &= 0\end{aligned}$$

The coefficient of friction is

$$f = 0.466$$

(b) The vertical reactions at the tires can be found by taking moments about one of the contact points.

$$\sum M_A: 14N_B - (6 \text{ ft})(5000 \text{ lbf})$$

$$- (3 \text{ ft}) \left( \frac{5000 \text{ lbf}}{32.2 \frac{\text{lbf} \cdot \text{ft}}{\text{lbf} \cdot \text{sec}^2}} \right) (15 \frac{\text{ft}}{\text{sec}^2}) = 0$$

$$N_B = 2642 \text{ lbf}$$

The remaining vertical reaction is found by summing vertical forces.

$$\sum F_y: N_A + N_B - \frac{mg}{g_c} = 0$$

$$N_A + 2642 \text{ lbf} - 5000 \text{ lbf} = 0$$

$$N_A = 2358 \text{ lbf}$$

The horizontal frictional forces at the front and rear axles are

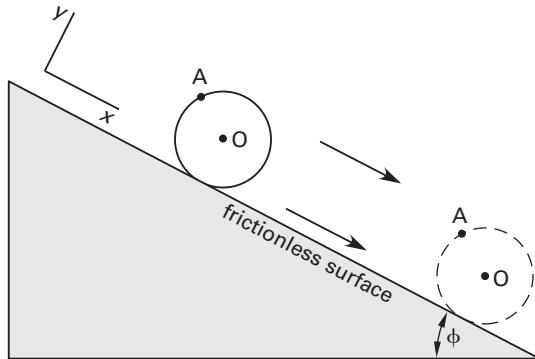

$$F_{f,A} = (0.466)(2358 \text{ lbf}) = 1099 \text{ lbf}$$

$$F_{f,B} = (0.466)(2642 \text{ lbf}) = 1231 \text{ lbf}$$

## 19. CONSTRAINED MOTION

Figure 72.13 shows a cylinder (or sphere) on an inclined plane. If there is no friction, there will be no torque to start the cylinder rolling. Regardless of the angle, the cylinder will slide down the incline in *unconstrained motion*.

**Figure 72.13** Unconstrained Motion

The acceleration sliding down the incline can be calculated by writing Newton's second law for an axis parallel to the plane.<sup>14</sup> Once the acceleration is known, the

<sup>14</sup>Most inclined plane problems are conveniently solved by resolving all forces into components parallel and perpendicular to the plane.

velocity can be found from the constant-acceleration equations.

$$ma_{O,x} = mg \sin \phi \quad 72.41$$

If friction is sufficiently large, or if the inclination is sufficiently small, there will be no slipping. This condition occurs if

$$\phi < \arctan f_s \quad 72.42$$

The frictional force acting at the cylinder's radius,  $r$ , supplies a torque that starts and keeps the cylinder rolling. The frictional force is

$$F_f = fN \quad 72.43$$

$$F_f = fmg \cos \phi \quad [\text{SI}] \quad 72.44(a)$$

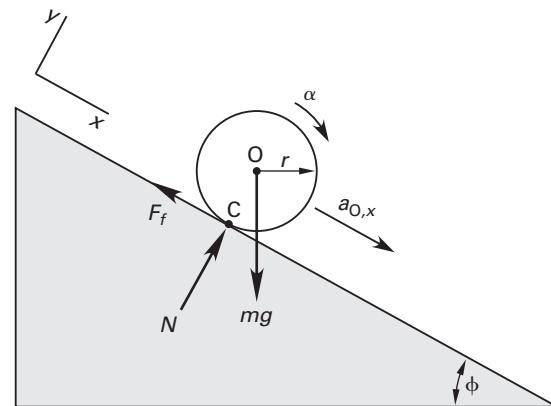

$$F_f = \frac{fmg \cos \phi}{g_c} \quad [\text{U.S.}] \quad 72.44(b)$$

With no slipping, the cylinder has two degrees of freedom (the  $x$ -directional and angle of rotation), and motion of the center of mass must simultaneously satisfy (i.e., is constrained by) two equations. (This excludes motion perpendicular to the plane.) This is called *constrained motion*. (See Fig. 72.14.)

$$mg \sin \phi - F_f = ma_{O,x} \quad [\text{consistent units}] \quad 72.45$$

$$F_f r = I_O \alpha \quad [\text{consistent units}] \quad 72.46$$

**Figure 72.14** Constrained Motion

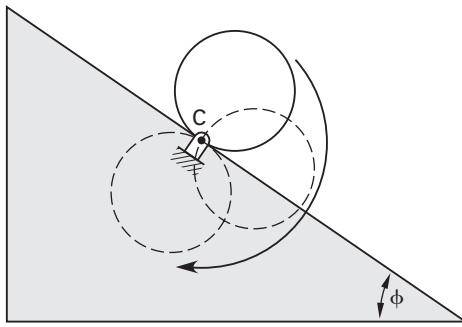

The mass moment of inertia used in calculating angular acceleration can be either the centroidal moment of inertia,  $I_O$ , or the moment of inertia taken about the contact point,  $I_C$ , depending on whether torques (moments) are evaluated with respect to point O or point C, respectively.

If moments are evaluated with respect to point O, the coefficient of friction,  $f$ , must be known, and the centroidal moment of inertia can be used. If moments are evaluated with respect to the contact point, the

frictional and normal forces drop out of the torque summation. The cylinder instantaneously rotates as though it were pinned at point C. (See Fig. 72.15.) If the centroidal moment of inertia,  $I_O$ , is known, the parallel axis theorem can be used to find the required moment of inertia.

$$I_C = I_O + mr^2 \quad 72.47$$

**Figure 72.15** Instantaneous Center of a Constrained Cylinder

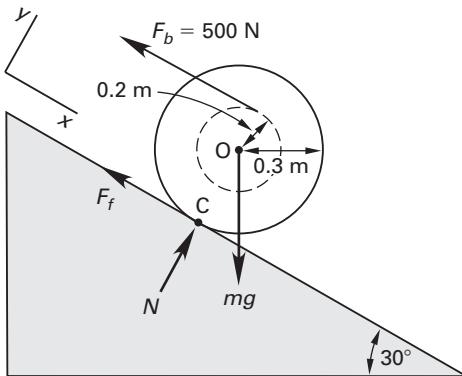

When there is no slipping, the cylinder will roll with constant linear and angular accelerations. The distance traveled by the center of mass can be calculated from the angle of rotation.

$$s_O = r\theta \quad 72.48$$

If  $\phi \geq \arctan f_s$ , the cylinder will simultaneously roll and slide down the incline. The analysis is similar to the no-sliding case, except that the coefficient of sliding friction is used. Once sliding has started, the inclination angle can be reduced to  $\arctan f_k$ , and rolling with sliding will continue.

### Example 72.8

A 150 kg cylinder with radius 0.3 m is pulled up a plane inclined at  $30^\circ$  as fast as possible without the cylinder slipping. The coefficient of friction is 0.236. There is a groove in the cylinder at radius = 0.2 m. A rope in the groove applies a force of 500 N up the ramp. What is the linear acceleration of the cylinder?

### Solution

To solve by summing forces in the  $x$ -direction:

The normal force is

$$\begin{aligned} N &= mg \cos \phi = (150 \text{ kg}) \left( 9.81 \frac{\text{m}}{\text{s}^2} \right) (\cos 30^\circ) \\ &= 1274.4 \text{ N} \end{aligned}$$

The frictional maximum (friction impending) force is

$$\begin{aligned} F_f &= fN = (0.236)(1274.4 \text{ N}) \\ &= 300.8 \text{ N} \end{aligned}$$

The summation of forces in the  $x$ -direction is

$$\begin{aligned} ma_{O,x} &= mg \sin \phi - F_f - F_b \\ a_{O,x} &= \frac{(150 \text{ kg}) \left( 9.81 \frac{\text{m}}{\text{s}^2} \right) (\sin 30^\circ) - 300.8 \text{ N} - 500 \text{ N}}{150 \text{ kg}} \\ &= -0.434 \text{ m/s}^2 \quad [\text{up the incline}] \end{aligned}$$

To solve by taking moment about the contact point.<sup>15</sup>

From App. 70.A, the centroidal mass moment of inertia of the cylinder is

$$\begin{aligned} I_O &= \frac{1}{2}mr^2 = (0.5)(150 \text{ kg})(0.3 \text{ m})^2 \\ &= 6.75 \text{ kg}\cdot\text{m}^2 \end{aligned}$$

The mass moment of inertia with respect to the contact point, C, is given by the parallel axis theorem.

$$\begin{aligned} I_C &= I_O + mr^2 = \frac{1}{2}mr^2 + mr^2 = \frac{3}{2}mr^2 \\ &= \left(\frac{3}{2}\right)(150 \text{ kg})(0.3 \text{ m})^2 \\ &= 20.25 \text{ kg}\cdot\text{m}^2 \end{aligned}$$

The  $x$ -component of the weight acts through the center of gravity. (This term dropped out when moments were taken with respect to the center of gravity.)

$$\begin{aligned} (mg)_x &= mg \sin \phi = (150 \text{ kg}) \left( 9.81 \frac{\text{m}}{\text{s}^2} \right) (\sin 30^\circ) \\ &= 735.8 \text{ N} \end{aligned}$$

<sup>15</sup>This example can also be solved by summing moments about the center. If this is done, the governing equations are

$$\begin{aligned} I_O &= \frac{1}{2}mr^2 \\ M_O &= I_O \alpha = F_b r' - F_f r \\ \frac{1}{2}mr^2 \alpha &= F_b r' - fmgr \cos \phi \\ a_{O,x} &= r\alpha \end{aligned}$$

The summation of torques about point C gives the angular acceleration with respect to point C.

$$(735.8 \text{ N})(0.3 \text{ m})$$

$$-(500 \text{ N})(0.3 \text{ m} + 0.2 \text{ m}) = (20.25 \text{ kg}\cdot\text{m}^2)\alpha$$

$$\alpha = -1.445 \text{ rad/s}^2$$

The linear acceleration can be calculated from the angular acceleration and the distance between points C and O.

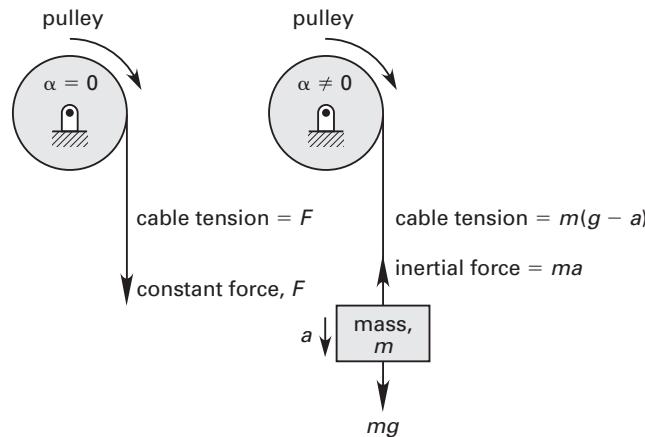

$$a_{O,x} = r\alpha = (0.3 \text{ m})\left(-1.445 \frac{\text{rad}}{\text{s}^2}\right)$$

$$= -0.433 \text{ m/s}^2 \quad [\text{up the incline}]$$

## 20. CABLE TENSION FROM AN ACCELERATING SUSPENDED MASS

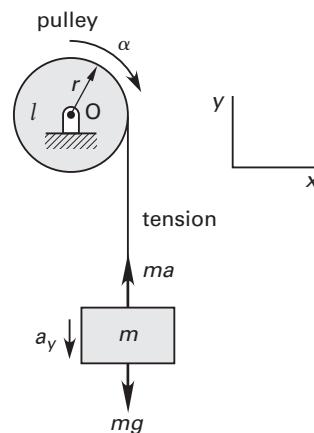

When a mass hangs motionless from a cable, or when the mass is moving with a uniform velocity, the cable tension will equal the weight of the mass. However, when the mass is accelerating downward, the weight must be reduced by the inertial force. If the mass experiences a downward acceleration equal to the gravitational acceleration, there is no tension in the cable. Therefore, the two cases shown in Fig. 72.16 are not the same.

**Figure 72.16** Cable Tension from a Suspended Mass

### Example 72.9

A 10.0 lbm (4.6 kg) mass hangs from a rope wrapped around a 2.0 ft (0.6 m) diameter pulley with a centroidal moment of inertia of  $70 \text{ lbm}\cdot\text{ft}^2$  ( $2.9 \text{ kg}\cdot\text{m}^2$ ). (a) What is the angular acceleration of the pulley? (b) What is the linear acceleration of the mass?

*SI Solution*

(a) The two equations of motion are

$$\sum F_{y,\text{mass}}: T + ma - mg = 0$$

$$T - (4.6 \text{ kg})\left(9.81 \frac{\text{m}}{\text{s}^2}\right) = -(4.6 \text{ kg})a_y$$

$$\sum M_{O,\text{pulley}}: Tr = I\alpha$$

$$T(0.3 \text{ m}) = (2.9 \text{ kg}\cdot\text{m}^2)\alpha$$

Both  $a_y$  and  $\alpha$  are unknown but are related by  $a_y = r\alpha$ . Substituting into the  $\Sigma F$  equation and eliminating the tension,

$$\frac{(2.9 \text{ kg}\cdot\text{m}^2)\alpha}{0.3 \text{ m}} - 45.1 \text{ N} = -(4.6 \text{ kg})(0.3 \text{ m})\alpha$$

$$9.67\alpha - 45.1 \text{ N} = -1.38\alpha$$

$$\alpha = 4.08 \text{ rad/s}^2$$

(b) The linear acceleration of the mass is

$$a_y = r\alpha = (0.3 \text{ m})\left(4.08 \frac{\text{rad}}{\text{s}^2}\right)$$

$$= 1.22 \text{ m/s}^2$$

*Customary U.S. Solution*

(a) The two equations of motion are

$$\sum F_{y,\text{mass}}: T + \frac{ma_y}{g_c} - \frac{mg}{g_c} = 0$$

$$T - \frac{(10 \text{ lbm})\left(32.2 \frac{\text{ft}}{\text{sec}^2}\right)}{32.2 \frac{\text{lbf}\cdot\text{ft}}{\text{lbf}\cdot\text{sec}^2}} = -\frac{(10 \text{ lbm})a_y}{32.2 \frac{\text{lbf}\cdot\text{ft}}{\text{lbf}\cdot\text{sec}^2}}$$

$$\sum M_{O,\text{pulley}}: Tr = I\alpha$$

$$T(1.0 \text{ ft}) = (70 \text{ lbm}\cdot\text{ft}^2)\alpha$$

$$a_y = r\alpha$$

(b) Substituting into the  $\sum F$  equation and eliminating the tension,

$$\frac{(70 \text{ lbm-ft}^2)\alpha}{(32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2})(1.0 \text{ ft})} - 10 \text{ lbf} = -\frac{(10 \text{ lbm})(1.0 \text{ ft})\alpha}{32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}}$$

$$2.174\alpha - 10 \text{ lbf} = -0.311\alpha$$

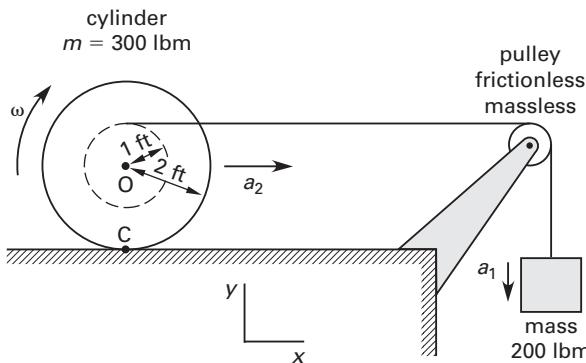

$$\alpha = 4.03 \text{ rad/sec}^2$$

The linear acceleration of the mass is

$$\begin{aligned} a_y &= r\alpha \\ &= (1.0 \text{ ft})\left(4.03 \frac{\text{rad}}{\text{sec}^2}\right) \\ &= 4.03 \text{ ft/sec}^2 \end{aligned}$$

### Example 72.10

A 300 lbm cylinder ( $I_O = 710 \text{ lbm-ft}^2$ ) has a narrow groove cut in it as shown. One end of the cable is wrapped around the cylinder in the groove, while the other end supports a 200 lbm mass. The pulley is massless and frictionless, and there is no slipping. Starting from a standstill, what are the linear accelerations of the 200 lbm mass and the cylinder?

### Solution

Since there is no slipping, there is friction between the cylinder and the plane. However, the coefficient of friction is not given. Therefore, moments must be taken about the contact point (the instantaneous center). The moment of inertia about the contact point is

$$\begin{aligned} I_C &= I_O + mr^2 \\ &= 710 \text{ lbm-ft}^2 + (300 \text{ lbm})(2 \text{ ft})^2 \\ &= 1910 \text{ lbm-ft}^2 \end{aligned}$$

The first equation is a summation of forces on the mass.

$$\sum F_y: T + \frac{ma_1}{g_c} - \frac{mg}{g_c} = 0$$

The second equation is a summation of moments about the instantaneous center. The frictional force passes through the instantaneous center and is disregarded.

$$\sum M_C: T(2.0 \text{ ft} + 1.0 \text{ ft}) = \frac{I_C\alpha}{g_c}$$

Since there are three unknowns, a third equation is needed. This is the relationship between the linear and angular accelerations.  $a_2$  is the acceleration of point O, located 2 ft from point C.  $a_1$  is the acceleration of the cable, whose groove is located 3 ft from point C.

$$\begin{aligned} \alpha &= \frac{a}{r} = \frac{a_2}{2.0 \text{ ft}} = \frac{a_1}{3.0 \text{ ft}} \\ a_1 &= \frac{3}{2}a_2 \end{aligned}$$

Solving the three equations simultaneously yields

$$\text{cylinder: } a_2 = 10.4 \text{ ft/sec}^2$$

$$\text{mass: } a_1 = 15.6 \text{ ft/sec}^2$$

$$T = 103 \text{ lbf}$$

$$\alpha = 5.2 \text{ rad/sec}^2$$

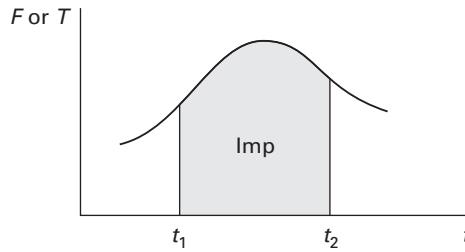

## 21. IMPULSE

**Impulse**, **Imp**, is a vector quantity equal to the change in momentum.<sup>16</sup> Units of linear impulse are the same as for linear momentum: lbf-sec and N·s. Units of lbf-ft-sec and N·m·s are used for angular impulse. Equation 72.49 and Eq. 72.50 define the scalar magnitudes of *linear impulse* and *angular impulse*. Figure 72.17 illustrates that impulse is represented by the area under the  $F$ - $t$  (or  $T$ - $t$ ) curve.

$$\text{Imp} = \int_{t_1}^{t_2} F dt \quad [\text{linear}] \quad 72.49$$

$$\text{Imp} = \int_{t_1}^{t_2} T dt \quad [\text{angular}] \quad 72.50$$

Figure 72.17 Impulse

<sup>16</sup>Although **Imp** is the most common notation, engineers have no universal symbol for impulse. Some authors use  $I$ ,  $\mathbf{I}$ , and  $i$ , but these symbols can be mistaken for moment of inertia. Other authors merely use the word *impulse* in their equations.

If the applied force or torque is constant, impulse is easily calculated. A large force acting for a very short period of time is known as an *impulsive force*.

$$\text{Imp} = F(t_2 - t_1) \quad [\text{linear}] \quad 72.51$$

$$\text{Imp} = T(t_2 - t_1) \quad [\text{angular}] \quad 72.52$$

If the impulse is known, the average force acting over the duration of the impulse is

$$F_{\text{ave}} = \frac{\text{Imp}}{\Delta t} \quad 72.53$$

## 22. IMPULSE-MOMENTUM PRINCIPLE

The change in momentum is equal to the applied *impulse*. This is known as the *impulse-momentum principle*. For a linear system with constant force and mass, the scalar magnitude form of this principle is

$$\text{Imp} = \Delta p \quad 72.54$$

$$F(t_2 - t_1) = m(v_2 - v_1) \quad [\text{SI}] \quad 72.55(a)$$

$$F(t_2 - t_1) = \frac{m(v_2 - v_1)}{g_c} \quad [\text{U.S.}] \quad 72.55(b)$$

For an angular system with constant torque and moment of inertia, the analogous equations are

$$T(t_2 - t_1) = I(\omega_2 - \omega_1) \quad [\text{SI}] \quad 72.56(a)$$

$$T(t_2 - t_1) = \frac{I(\omega_2 - \omega_1)}{g_c} \quad [\text{U.S.}] \quad 72.56(b)$$

### Example 72.11

A 1.62 oz (0.046 kg) marble attains a velocity of 170 mph (76 m/s) in a hunting slingshot. Contact with the sling is 1/25th of a second. What is the average force on the marble during contact?

*SI Solution*

From Eq. 72.55(a), the average force is

$$\begin{aligned} F &= \frac{m\Delta v}{\Delta t} \\ &= \frac{(0.046 \text{ kg})(76 \frac{\text{m}}{\text{s}})}{\frac{1}{25} \text{ s}} \\ &= 87.4 \text{ N} \end{aligned}$$

*Customary U.S. Solution*

The mass of the marble is

$$m = \frac{1.62 \text{ oz}}{16 \frac{\text{oz}}{\text{lbm}}} = 0.101 \text{ lbm}$$

The velocity of the marble is

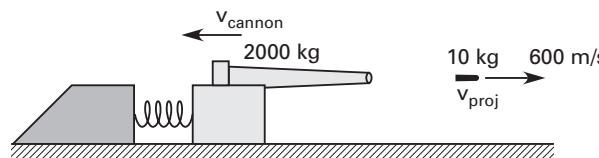

$$v = \frac{(170 \frac{\text{mi}}{\text{hr}})(5280 \frac{\text{ft}}{\text{mi}})}{3600 \frac{\text{sec}}{\text{hr}}} = 249.3 \text{ ft/sec}$$

From Eq. 72.55(b), the average force is

$$\begin{aligned} F &= \frac{m\Delta v}{g_c \Delta t} = \frac{(0.101 \text{ lbm})(249.3 \frac{\text{ft}}{\text{sec}})}{\left(32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}\right)\left(\frac{1}{25} \text{ sec}\right)} \\ &= 19.5 \text{ lbf} \end{aligned}$$

### Example 72.12

A 2000 kg cannon fires a 10 kg projectile horizontally at 600 m/s. It takes 0.007 s for the projectile to pass through the barrel and 0.01 s for the cannon to recoil. The cannon has a spring mechanism to absorb the recoil. (a) What is the cannon's initial recoil velocity? (b) What force is exerted on the recoil spring?

*Solution*

(a) The accelerating force is applied to the projectile quickly, and external forces such as gravity and friction are not significant factors. Therefore, momentum is conserved.

$$\begin{aligned} \sum p: m_{\text{proj}}\Delta v_{\text{proj}} &= m_{\text{cannon}}\Delta v_{\text{cannon}} \\ (10 \text{ kg})\left(600 \frac{\text{m}}{\text{s}}\right) &= (2000 \text{ kg})v_{\text{cannon}} \\ v_{\text{cannon}} &= 3 \text{ m/s} \end{aligned}$$

(b) From Eq. 72.55(a), the recoil force is

$$\begin{aligned} F &= \frac{m\Delta v}{\Delta t} = \frac{(2000 \text{ kg})(3 \frac{\text{m}}{\text{s}})}{0.01 \text{ s}} \\ &= 6 \times 10^5 \text{ N} \end{aligned}$$

### 23. IMPULSE-MOMENTUM PRINCIPLE IN OPEN SYSTEMS

The impulse-momentum principle can be used to determine the forces acting on flowing fluids (i.e., in open systems). This is the method used to calculate forces in jet engines and on pipe bends, and forces due to other changes in flow geometry. Equation 72.57 is rearranged in terms of a mass flow rate.

$$F = \frac{m\Delta v}{\Delta t} = \dot{m}\Delta v \quad [\text{SI}] \quad 72.57(a)$$

$$F = \frac{m\Delta v}{g_c \Delta t} = \frac{\dot{m}\Delta v}{g_c} \quad [\text{U.S.}] \quad 72.57(b)$$

#### Example 72.13

Air enters a jet engine at 1500 ft/sec (450 m/s) and leaves at 3000 ft/sec (900 m/s). The thrust produced is 10,000 lbf (44 500 N). Disregarding the small amount of fuel added during combustion, what is the mass flow rate?

*SI Solution*

From Eq. 72.57(a),

$$\dot{m} = \frac{F}{\Delta v} = \frac{44500 \text{ N}}{900 \frac{\text{m}}{\text{s}} - 450 \frac{\text{m}}{\text{s}}} = 98.9 \text{ kg/s}$$

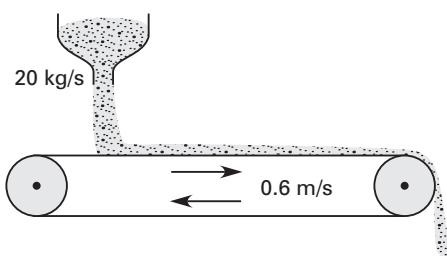

*Customary U.S. Solution*

From Eq. 72.57(b),

$$\begin{aligned} \dot{m} &= \frac{F g_c}{\Delta v} = \frac{(10,000 \text{ lbf})(32.2 \frac{\text{lbf-ft}}{\text{lbf-sec}^2})}{3000 \frac{\text{ft}}{\text{sec}} - 1500 \frac{\text{ft}}{\text{sec}}} \\ &= 215 \text{ lbm/sec} \end{aligned}$$

#### Example 72.14

20 kg of sand fall continuously each second on a conveyor belt moving horizontally at 0.6 m/s. What power is required to keep the belt moving?

*Solution*

From Eq. 72.57(a), the force on the sand is

$$F = \dot{m}\Delta v = \left(20 \frac{\text{kg}}{\text{s}}\right)\left(0.6 \frac{\text{m}}{\text{s}}\right) = 12 \text{ N}$$

The power required is

$$\begin{aligned} P &= Fv = (12 \text{ N})\left(0.6 \frac{\text{m}}{\text{s}}\right) \\ &= 7.2 \text{ W} \end{aligned}$$

#### Example 72.15

A 6 × 9, 5/8 in diameter hoisting cable (area of 0.158 in<sup>2</sup>, modulus of elasticity of  $12 \times 10^6$  lbf/in<sup>2</sup>) carries a 1000 lbm load at its end. The load is being lowered vertically at the rate of 4 ft/sec. When 200 ft of cable have been reeled out, the take-up reel suddenly locks. Neglect the cable mass. What are the (a) cable stretch, (b) maximum dynamic force in the cable, (c) maximum dynamic stress in the cable, and (d) approximate time for the load to come to a stop vertically?

*Solution*

(a) The stiffness of the cable is

$$\begin{aligned} k &= \frac{F}{x} = \frac{AE}{L} = \frac{(0.158 \text{ in}^2)(12 \times 10^6 \frac{\text{lbf}}{\text{in}^2})}{(200 \text{ ft})(12 \frac{\text{in}}{\text{ft}})} \\ &= 790 \text{ lbf/in} \end{aligned}$$

Neglecting the cable mass, the kinetic energy of the moving load is

$$\begin{aligned} E_k &= \frac{mv^2}{2g_c} = \frac{(1000 \text{ lbm})\left(4 \frac{\text{ft}}{\text{sec}}\right)^2\left(12 \frac{\text{in}}{\text{ft}}\right)}{(2)(32.2 \frac{\text{lbf-ft}}{\text{lbf-sec}^2})} \\ &= 2981 \text{ in-lbf} \end{aligned}$$

By the work-energy principle, the decrease in kinetic energy is equal to the work of lengthening the cable (i.e., the energy stored in the spring).

$$\Delta E_k = \frac{1}{2}k\delta^2$$

$$2981 \text{ in-lbf} = \left(\frac{1}{2}\right)(790 \frac{\text{lbf}}{\text{in}})\delta^2$$

$$\delta = 2.75 \text{ in}$$

(b) The maximum dynamic force in the cable is

$$\begin{aligned} F &= k\delta = \left(790 \frac{\text{lbf}}{\text{in}}\right)(2.75 \text{ in}) \\ &= 2173 \text{ lbf} \end{aligned}$$

(c) The maximum dynamic tensile stress in the cable is

$$\sigma = \frac{F}{A} = \frac{2173 \text{ lbf}}{0.158 \text{ in}^2} = 13,753 \text{ lbf/in}^2$$

(d) Since the tensile force in the cable increases from zero to the maximum while the load decelerates, the average decelerating force is half of the maximum force. From the impulse momentum principle, Eq. 72.55,

$$F\Delta t = \frac{m\Delta v}{g_c}$$

$$\left(\frac{1}{2}\right)(2173 \text{ lbf})\Delta t = \frac{(1000 \text{ lbm})(4 \frac{\text{ft}}{\text{sec}})}{32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}}$$

$$\Delta t = 0.114 \text{ sec}$$

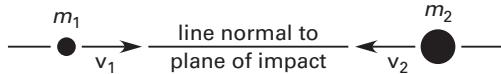

## 24. IMPACTS

According to Newton's second law, momentum is conserved unless a body is acted upon by an external force such as gravity or friction from another object. In an *impact* or *collision*, contact is very brief and the effect of external forces is insignificant. Therefore, momentum is conserved, even though energy may be lost through heat generation and deformation of the bodies.

Consider two particles, initially moving with velocities  $v_1$  and  $v_2$  on a collision path, as shown in Fig. 72.18. The conservation of momentum equation can be used to find the velocities after impact,  $v'_1$  and  $v'_2$ . (Observe algebraic signs with velocities.)

$$m_1 v_1 + m_2 v_2 = m_1 v'_1 + m_2 v'_2 \quad 72.58$$

**Figure 72.18** Direct Central Impact

The impact is said to be an *inelastic impact* if kinetic energy is lost. (Other names for an inelastic impact are *plastic impact* and *endoergic impact*).<sup>17</sup> The impact is said to be *perfectly inelastic* or *perfectly plastic* if the two particles stick together and move on with the same final velocity.<sup>18</sup> The impact is said to be *elastic* only if kinetic energy is conserved.

$$m_1 v_1^2 + m_2 v_2^2 = m_1 v'_1^2 + m_2 v'_2^2 \mid_{\text{elastic impact}} \quad 72.59$$

<sup>17</sup>Theoretically, there is also an *exoergic impact* (i.e., one in which kinetic energy is gained during the impact). However, this can occur only in special cases, such as in nuclear reactions.

<sup>18</sup>In traditional textbook problems, clay balls should be considered perfectly inelastic.

## 25. COEFFICIENT OF RESTITUTION

A simple way to determine whether the impact is elastic or inelastic is by calculating the *coefficient of restitution*,  $e$ . The collision is inelastic if  $e < 1.0$ , perfectly inelastic if  $e = 0$ , and elastic if  $e = 1.0$ . The coefficient of restitution is the ratio of relative velocity differences along a mutual straight line. (When both impact velocities are not directed along the same straight line, the coefficient of restitution should be calculated separately for each velocity component.)

$$e = \frac{\text{relative separation velocity}}{\text{relative approach velocity}} = \frac{v'_1 - v'_2}{v_2 - v_1} \quad 72.60$$

## 26. REBOUND FROM STATIONARY PLANES

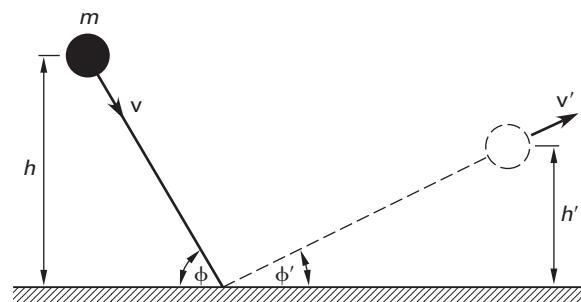

Figure 72.19 illustrates the case of an object rebounding from a massive, stationary plane.<sup>19</sup> This is an impact where  $m_2 = \infty$  and  $v_2 = 0$ . The impact force acts perpendicular to the plane, regardless of whether the impact is elastic or inelastic. Therefore, the  $x$ -component of velocity is unchanged. Only the  $y$ -component of velocity is affected, and even then, only if the impact is inelastic.

$$v_x = v'_x \quad 72.61$$

The coefficient of restitution can be used to calculate the *rebound angle*, *rebound height*, and *rebound velocity*.

$$e = \frac{\tan \phi'}{\tan \phi} = \sqrt{\frac{h'}{h}} = \frac{-v'_y}{v_y} \quad 72.62$$

**Figure 72.19** Rebound from a Stationary Plane

### Example 72.16

A golf ball dropped vertically from a height of 8.0 ft (2.4 m) onto a hard surface rebounds to a height of 6.0 ft (1.8 m). What are the (a) impact velocity, (b) rebound velocity, and (c) coefficient of restitution?

<sup>19</sup>The particle path is shown as a straight line in Fig. 72.19 for convenience. The path will be a straight line only when the particle is dropped straight down, or essentially a straight line when velocities are high, time in flight is short, and distances are short. Otherwise, the path will be parabolic.

*SI Solution*

The impact velocity of the golf ball is found by equating the decrease in potential energy to the increase in kinetic energy.

$$\begin{aligned} -\frac{1}{2}mv^2 &= mgh \\ v &= -\sqrt{2gh} = -\sqrt{(2)\left(9.81 \frac{\text{m}}{\text{s}^2}\right)(2.4 \text{ m})} \\ &= -6.86 \text{ m/s} \quad [\text{negative because down}] \end{aligned}$$

The rebound velocity can be found from the rebound height.

$$\begin{aligned} v' &= \sqrt{2gh'} = \sqrt{(2)\left(9.81 \frac{\text{m}}{\text{s}^2}\right)(1.8 \text{ m})} \\ &= 5.94 \text{ m/s} \end{aligned}$$

From Eq. 72.60 (or Eq. 72.62) with  $v_2 = v'_2 = 0 \text{ m/s}$ ,

$$\begin{aligned} e &= \frac{v'_1 - v'_2}{v_2 - v_1} = \frac{5.94 \frac{\text{m}}{\text{s}} - 0 \frac{\text{m}}{\text{s}}}{0 \frac{\text{m}}{\text{s}} - (-6.86 \frac{\text{m}}{\text{s}})} \\ &= 0.866 \end{aligned}$$

*Customary U.S. Solution*

The impact velocity is

$$\begin{aligned} v &= -\sqrt{2gh} = -\sqrt{(2)\left(32.2 \frac{\text{ft}}{\text{sec}^2}\right)(8.0 \text{ ft})} \\ &= -22.7 \text{ ft/sec} \quad [\text{negative because down}] \end{aligned}$$

Similarly, the rebound velocity is

$$\begin{aligned} v' &= \sqrt{2gh'} = \sqrt{(2)\left(32.2 \frac{\text{ft}}{\text{sec}^2}\right)(6.0 \text{ ft})} \\ &= 19.7 \text{ ft/sec} \end{aligned}$$

From Eq. 72.60 with  $v_2 = v'_2 = 0 \text{ ft/sec}$ ,

$$\begin{aligned} e &= \frac{v'_1 - v'_2}{v_2 - v_1} = \frac{19.7 \frac{\text{ft}}{\text{sec}} - 0 \frac{\text{ft}}{\text{sec}}}{0 \frac{\text{ft}}{\text{sec}} - (-22.7 \frac{\text{ft}}{\text{sec}})} \\ &= 0.868 \end{aligned}$$

**27. COMPLEX IMPACTS**

The simplest type of impact is the direct central impact, shown in Fig. 72.18. An impact is said to be a *direct impact* when the velocities of the two bodies are perpendicular to the contacting surfaces. *Central impact* occurs when the force of the impact is along the line of connecting centers of gravity. Round bodies (i.e., spheres) always experience central impact, whether or not the impact is direct.

When the velocities of the bodies are not along the same line, the impact is said to be an *oblique impact*, as illustrated in Fig. 72.20. The coefficient of restitution can be used to find the  $x$ -components of the resultant velocities. Since impact is central, the  $y$ -components of velocities will be unaffected by the collision.

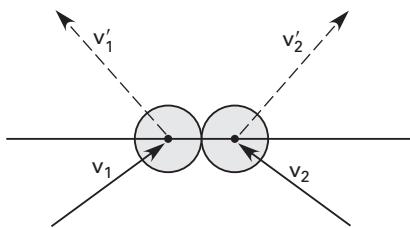

$$v_{1y} = v'_{1y} \quad 72.63$$

$$v_{2y} = v'_{2y} \quad 72.64$$

$$e = \frac{v'_{1x} - v'_{2x}}{v_{2x} - v_{1x}} \quad 72.65$$

$$m_1 v_{1x} + m_2 v_{2x} = m_1 v'_{1x} + m_2 v'_{2x} \quad 72.66$$

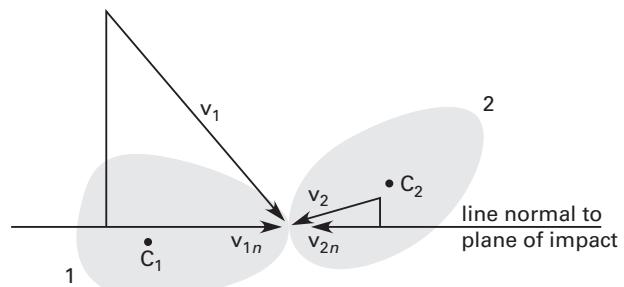

**Figure 72.20** Central Oblique Impact

*Eccentric impacts* are neither direct nor central. The coefficient of restitution can be used to calculate the linear velocities immediately after impact along a line normal to the contact surfaces. Since the impact is not central, the bodies will rotate. Other methods must be used to calculate the rate of rotation. (See Fig. 72.21.)

$$e = \frac{v'_{1n} - v'_{2n}}{v_{2n} - v_{1n}} \quad 72.67$$

**Figure 72.21** Eccentric Impact

**28. VELOCITY-DEPENDENT FORCE**

A force that is a function of velocity is known as a *velocity-dependent force*. A common example of a velocity-dependent force is the *viscous drag* a particle experiences when falling through a fluid. There are two main cases of viscous drag: linear and quadratic.

A *linear velocity-dependent force* is proportional to the first power of the velocity. A linear relationship is

typical of a particle falling slowly through a fluid (i.e., viscous drag in laminar flow). In Eq. 72.68,  $C$  is a constant of proportionality known as the *viscous coefficient* or *coefficient of viscous damping*.

$$F_b = Cv \quad 72.68$$

In the case of a particle falling slowly through a viscous liquid, the differential equation of motion and its solution are derived from Newton's second law.

$$mg - Cv = ma \quad [\text{SI}] \quad 72.69(a)$$

$$\frac{mg}{g_c} - Cv = \frac{ma}{g_c} \quad [\text{U.S.}] \quad 72.69(b)$$

$$v(t) = v_t(1 - e^{-Ct/m}) \quad [\text{SI}] \quad 72.70(a)$$

$$v(t) = v_t(1 - e^{-Cg_ct/m}) \quad [\text{U.S.}] \quad 72.70(b)$$

Equation 72.70 shows that the velocity asymptotically approaches a final value known as the *terminal velocity*,  $v_t$ . For laminar flow, the terminal velocity is

$$v_t = \frac{mg}{C} \quad [\text{SI}] \quad 72.71(a)$$

$$v_t = \frac{mg}{Cg_c} \quad [\text{U.S.}] \quad 72.71(b)$$

A *quadratic velocity-dependent force* is proportional to the second power of the velocity. A quadratic relationship is typical of a particle falling quickly through a fluid (i.e., turbulent flow).

$$F_b = Cv^2 \quad 72.72$$

In the case of a particle falling quickly through a liquid under the influence of gravity, the differential equation of motion is

$$mg - Cv^2 = ma \quad [\text{SI}] \quad 72.73(a)$$

$$\frac{mg}{g_c} - Cv^2 = \frac{ma}{g_c} \quad [\text{U.S.}] \quad 72.73(b)$$

For turbulent flow, the terminal velocity is

$$v_t = \sqrt{\frac{mg}{C}} \quad [\text{SI}] \quad 72.74(a)$$

$$v_t = \sqrt{\frac{mg}{Cg_c}} \quad [\text{U.S.}] \quad 72.74(b)$$

If a skydiver falls far enough, a turbulent terminal velocity of approximately 125 mph (200 kph) will be achieved. With a parachute (but still in turbulent flow), the terminal velocity is reduced to approximately 25 mph (40 kph).

## 29. VARYING MASS

Integral momentum equations must be used when the mass of an object varies with time. Most varying mass problems are complex, but the simplified case of an ideal rocket can be evaluated. This discussion assumes constant gravitational force, constant fuel usage, and constant exhaust velocity. (For brevity of presentation, all of the following equations are presented in consistent form only.)

The forces acting on the rocket are its thrust,  $F$ , and gravity. Newton's second law is

$$F(t) - F_{\text{gravity}} = \frac{d}{dt}(m(t)v(t)) \quad 72.75$$

If  $\dot{m}$  is the constant fuel usage, the thrust and gravitational forces are

$$\begin{aligned} F(t) &= \dot{m}v_{\text{exhaust,absolute}} \\ &= \dot{m}(v_{\text{exhaust}} - v(t)) \end{aligned} \quad 72.76$$

$$F_{\text{gravity}} = m(t)g \quad 72.77$$

The velocity as a function of time is found by solving the following differential equation.

$$\dot{m}v_{\text{exhaust,absolute}} - m(t)g = \dot{m}v(t) + m(t)\frac{dv(t)}{dt} \quad 72.78$$

$$v(t) = v_0 - gt + v_{\text{exhaust}} \ln \frac{m_0}{m_0 - \dot{m}t} \quad 72.79$$

The final burnout velocity,  $v_f$ , depends on the initial mass,  $m_0$ , and the final mass,  $m_f$ .

$$v_f = v_0 - g \left( \frac{m_0}{\dot{m}} \right) \left( 1 - \frac{m_f}{m_0} \right) + v_{\text{exhaust}} \ln \frac{m_0}{m_f} \quad 72.80$$

A simple relationship exists for a rocket starting from standstill in a gravity-free environment (i.e.,  $v_0 = 0$  and  $g = 0$ ).

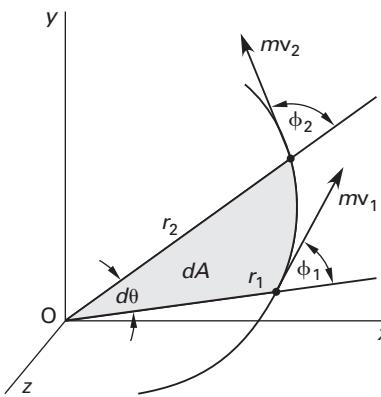

$$\frac{m_f}{m_0} = e^{-v_f/v_{\text{exhaust}}} \quad 72.81$$

## 30. CENTRAL FORCE FIELDS

When the force on a particle is always directed toward or away from a fixed point, the particle is moving in a *central force field*. Examples of central force fields are gravitational fields (*inverse-square attractive fields*) and electrostatic fields (*inverse-square repulsive fields*). Particles traveling in inverse-square attractive fields can have circular, elliptical, parabolic, or hyperbolic paths. Particles traveling in inverse-square repulsive fields always travel in hyperbolic paths.

The fixed point, O in Fig. 72.22, is known as the *center of force*. The magnitude of the force depends on the distance between the particle and the center of force.

**Figure 72.22** Motion in a Central Force Field

The angular momentum of a particle moving in a central force field is constant.

$$\mathbf{h}_0 = \mathbf{r} \times m\mathbf{v} = \text{constant} \quad 72.82$$

Equation 72.82 can be written in scalar form.

$$r_1 m v_1 \sin \phi_1 = r_2 m v_2 \sin \phi_2 \quad 72.83$$

For a particle moving in a central force field, the *areal velocity* is constant.

$$\text{areal velocity} = \frac{dA}{dt} = \frac{1}{2} r^2 \frac{d\theta}{dt} = \frac{h_0}{2m} \quad 72.84$$

### 31. NEWTON'S LAW OF GRAVITATION

For a particle far enough away from a large body, gravity can be considered to be a central force field. *Newton's law of gravitation*, also known as *Newton's law of universal gravitation*, describes the force of attraction between the two masses. The law states that the attractive gravitational force between the two masses is directly proportional to the product of masses, is inversely proportional to the square of the distance between their centers of mass, and is directed along a line passing through the centers of gravity of both masses.

$$F = \frac{G m_1 m_2}{r^2} \quad 72.85$$

$G$  is *Newton's gravitational constant* (*Newton's universal constant*). Approximate values of  $G$  for the earth are given in Table 72.2 for different sets of units. For an earth-particle combination, the product  $Gm_{\text{earth}}$  has the value of  $4.39 \times 10^{14}$  lbf-ft<sup>2</sup>/lbm ( $4.00 \times 10^{14}$  N·m<sup>2</sup>/kg).

**Table 72.2** Approximate Values of Newton's Gravitational Constant,  $G$

$6.674 \times 10^{-11}$	N·m <sup>2</sup> /kg <sup>2</sup> (m <sup>3</sup> /kg·s <sup>2</sup> )
$6.674 \times 10^{-8}$	cm <sup>3</sup> /g·s <sup>2</sup>
$3.440 \times 10^{-8}$	lbf·ft <sup>2</sup> /slug <sup>2</sup>
$3.323 \times 10^{-11}$	lbf·ft <sup>2</sup> /lbm <sup>2</sup>
$3.440 \times 10^{-8}$	ft <sup>4</sup> /lbf·sec <sup>4</sup>

### 32. KEPLER'S LAWS OF PLANETARY MOTION

Kepler's three *laws of planetary motion* are as follows.

- *law of orbits:* The path of each planet is an ellipse with the sun at one focus.
- *law of areas:* The radius vector drawn from the sun to a planet sweeps equal areas in equal times. (The areal velocity is constant. This is equivalent to the statement, "The angular velocity is constant.")

$$\frac{dA}{dt} = \text{constant} \quad 72.86$$

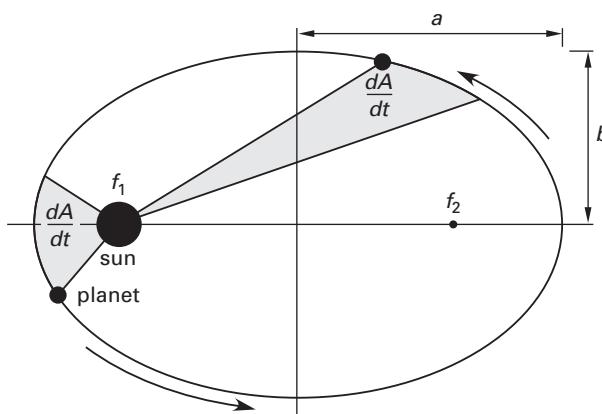

- *law of periods:* The square of a planet's periodic time is proportional to the cube of the semimajor axis of its orbit.

$$t_p^2 \propto a^3 \quad 72.87$$

The *periodic time* referenced in Kepler's third law is the time required for a satellite to travel once around the parent body. If the parent body rotates in the same plane and with the same periodic time as the satellite, the satellite will always be above the same point on the parent body. This condition defines a *geostationary orbit*. Referring to Fig. 72.23, the periodic time is

$$t_p = \frac{2\pi ab}{h_0} = \frac{\pi ab}{\frac{dA}{dt}} = \frac{\pi ab}{\text{areal velocity}} \quad 72.88$$

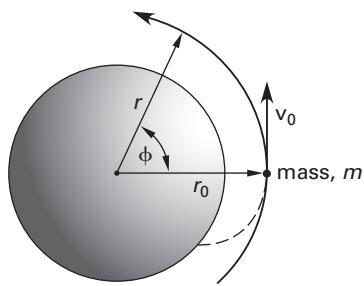

**Figure 72.23** Planetary Motion

### 33. SPACE MECHANICS

Figure 72.24 illustrates the motion of a satellite that is released in a path parallel to the earth's surface. (The dotted line represents the launch phase and is not relevant to the analysis.)

**Figure 72.24** Space Mechanics Nomenclature

At the instant of release, the magnitude of the specific relative angular momentum (angular momentum per mass),  $\mathbf{h}$ , is

$$|\mathbf{h}| = |\mathbf{r}_0 \mathbf{v}_0| = h_0 = r_0 v_0 \quad 72.89$$

The force exerted on the satellite by the earth is given by Newton's law of gravitation. For any angle,  $\phi$ , swept out by the satellite, the separation distance can be found from Eq. 72.90.  $C$  is a constant.

$$\frac{1}{r} = \frac{GM}{h^2} + C \cos \phi \quad 72.90$$

$$C = \frac{1}{r_0} - \frac{GM}{h_0^2} \quad 72.91$$

**Table 72.3** Orbit Eccentricities

value of $\epsilon$	type of orbit
$> 1.0$	nonreturning hyperbola
$= 1.0$	nonreturning parabola
$< 1.0$	ellipse
$= 0.0$	circle

The unitless *orbit eccentricity*,  $\epsilon$ , can be calculated and used to determine the type of orbit, as listed in Table 72.3.

$$\epsilon = \frac{Ch^2}{GM} \quad 72.92$$

The limiting value of the initial release velocity,  $v_{0,\max}$ , to prevent a nonreturning orbit ( $\epsilon = 1.0$ ) is known as the *escape velocity*. For the earth, the escape velocity is approximately 7.0 mi/sec (25,000 mph or 11.2 km/s).

$$v_{\text{escape}} = v_{0,\max} = \sqrt{\frac{2GM}{r_0}} \quad 72.93$$

The release velocity,  $v_{0,\text{circular}}$ , that results in a circular orbit is

$$v_{0,\text{circular}} = \sqrt{\frac{GM}{r_0}} \quad 72.94$$

For an elliptical orbit, the minimum separation is known as the *perigee distance*. The maximum separation distance is known as the *apogee*. The terms perigee and apogee are traditionally used for earth satellites. The terms *perihelion* (closest) and *aphelion* (farthest) are used to describe distances between the sun and earth.

RT	right turn
<i>s</i>	speed
<i>S</i>	short
<i>T</i>	trucks and buses
<i>w</i>	width

## 1. STANDARD TRAFFIC REFERENCES

The standard references for the subject matter in this chapter include the *Highway Capacity Manual*, referred to as the *HCM* (Transportation Research Board, National Research Council); AASHTO's *A Policy on Geometric Design of Highways and Streets*, known as the AASHTO *Green Book*, *PGDHS*, or just *GDHS*; and the Federal Highway Administration's *Manual on Uniform Traffic Control Devices*, referred to as the *MUTCD*. Except for trivial exercises, traffic or transportation designs and analyses cannot be performed without these references. Calculations using the *HCM* and *Green Book* may be performed in either customary U.S. or SI units.<sup>1</sup>

Many of the methods used to design and analyze specific facilities are highly proceduralized. These methods often rely on empirical correlations and graphical or nomographical solutions rather than on pure engineering fundamentals. In that sense, they are not difficult to implement. However, each feature uses a unique procedure, different nomenclature, and specific criteria. Due to the variety and complexity of these procedures, it is not possible to present them without making significant reference to the major supporting documents, particularly the *HCM*. Even with the supporting documents, it soon becomes apparent why the majority of traffic design is computer-assisted. Analysis of existing facilities is somewhat more tractable.

In recent years and in response to mounting liability issues, these references (the AASHTO *Green Book*, in

particular) have backed away from appearing to be mandatory standards by softening their unequivocal language. These documents are currently considered to be "suggested policies" by their originating organizations. State departments of transportation are expected to accept responsibility for proper evaluation and implementation of these "nonstandards."

## 2. ABBREVIATIONS AND UNITS

Following standard practice, the units and abbreviations shown in Table 73.1 are used in this chapter. (Explicit units are shown in numerical calculations to facilitate cancellation.) Some *HCM* abbreviations differ from this book and from commonly used SI abbreviations, so some inconsistencies may be noted.

- The letter "p" signifying "per" is not used in SI units. While the *HCM* still uses "pcph" for calculations in English units, it has adopted "pc/h" for calculations in SI units.
- "ln" is used for "lane" in SI calculations.
- The word "seat" is spelled out to avoid confusion with "s" for "seconds."
- "Minute" is abbreviated "min"; "minimum" is abbreviated "Min."

Where material in the standard traffic references is given only in customary U.S. units, approximate conversions (e.g., 0.305 m/ft instead of 0.3048 m/ft) may be used. Engineering judgment should be used when rounding values for design applications.

**Table 73.1 Abbreviations**

abbreviation	meaning
ln	lane
km/h	kilometers per hour
mph	miles per hour
p	people, person, or pedestrian
pc	passenger car
pcph	passenger cars per hour
pcphg	passenger cars per hour of green signal
pcphpl	passenger cars per hour per lane
pcphgpl	passenger cars per hour of green signal per lane
pc/km/ln	passenger cars per kilometer per lane
pcpmpl	passenger cars per mile per lane
ped	pedestrian
pers	person
veh	vehicle
vph	vehicles per hour
veh/km	vehicles per kilometer
vph/lane	vehicles per hour per lane
vpk	vehicles per kilometer
vpm	vehicles per mile

## 3. FACILITIES TERMINOLOGY

Although common usage does not always distinguish between highways, freeways, and other types of roadways, the major traffic/transportation references are

<sup>1</sup>As of the 2010 edition, the Transportation Research Board no longer publishes a separate metric version of the *HCM*. In Chap. 1, the *HCM* recommends making soft conversions from the customary U.S. values and provides recommended conversion factors [*HCM* Exh. 1-1]. The Transportation Research Board advises caution when using the *HCM* in countries outside the United States.

more specific. (See Table 73.2.) For example, “vehicle” and “car” have different meanings. “Vehicle” encompasses trucks, buses, and recreational vehicles, as well as passenger cars.

**Table 73.2 General Functional Classifications of Roadways\***

road designation	ADT (vpd)
local road	2000 or less
collector road	2000–12,000
arterial/urban road	12,000–40,000
freeway	30,000 and above

\*Classifications can also be established based on percentages of total length and travel volume.

A *freeway* is a divided corridor with at least two lanes in each direction that operates in an *uninterrupted flow* mode (i.e., without *fixed elements* such as signals, stop signs, and at-grade intersections). *Access points* are limited to ramp locations. Since grades, curves, and other features can change along a freeway, performance measures (e.g., capacity) are evaluated along shorter *freeway segments*.

Multilane and two-lane *highways*, on the other hand, contain some fixed elements and access points from at-grade intersections, though relatively uninterrupted flow can occur if signal spacing is greater than 2 mi (3.2 km). Where signal spacing is less than 2 mi (3.2 km), the roadway is classified as an *urban street* (or *arterial*), and flow is considered to be interrupted. An urban street has a significant amount of driveway access, while an arterial does not. *Divided highways* have separate roadbeds for the opposing directions, whereas *undivided highways* do not.

Smaller roadways are classified as *local roads* and *streets*. All roadways can be classified as *urban*, *suburban*, or *rural*, depending on the surrounding population density. *Urban areas* have populations greater than 5000. *Rural areas* are outside the boundaries of urban areas. Urban and rural transportation facilities are further described in AASHTO *Green Book* Sec. 1.3.

#### 4. DESIGN VEHICLES

Standard *design vehicles* have been established to ensure that geometric features will accommodate all commonly sized vehicles. Standard design vehicles are given specific designations in the AASHTO *Green Book*, as listed in Table 73.3. The AASHTO *Green Book* also contains information on *wheelbase* and *turning radius*. (See AASHTO *Green Book* Fig. 2-1 through Fig. 2-23.)

#### 5. LEVELS OF SERVICE

A user’s quality of service through or over a specific facility (e.g., over a highway, through an intersection, across a crosswalk) is classified by a *level of service* (LOS). Levels of service are designated A through F. Level A represents unimpeded flow, which is ideal but

only possible when the volume of traffic is small. Level F represents a highly impeded, packed condition. Generally, level E will have the maximum flow rate (i.e., capacity).

The desired design condition is generally between levels A and F. Economic considerations favor higher volumes and more obstructed levels of service. However, political considerations favor less obstructed levels of service. The parameter used to define the level of service varies with the type of facility, as listed in Table 73.4.

Since levels of service can vary considerably during an hour, capacity and LOS evaluations focus on the peak 15 min of flow.

#### 6. SPEED PARAMETERS

Several measures of vehicle speed are used in highway design and capacity calculations. Most measures will not be needed in every capacity calculation. The *design speed* is the maximum safe speed that can be maintained over a specified section of roadway when conditions are so favorable that the design features of the roadway govern. Most elements of roadway design depend on the design speed. The *legal speed* on a roadway section is often set at approximately the *85th percentile speed*, determined by observation of a sizable sample of vehicles. In suburban and urban areas, the legal speed limit is often influenced by additional considerations such as visibility at intersections, the presence of driveways, parking and pedestrian activity, population density, and other local factors. Typical minimum design speeds are given in Table 73.5.

The *average highway speed*, AHS, is the weighted average of the observed speeds within a highway section based on each subsection’s proportional contribution to total mileage. The *running speed* is the speed over a specified section of roadway equal to the distance divided by the running time, or the total time required to travel over the roadway section, disregarding any stationary time. The *average running speed* is the running speed for all traffic equal to the distance summation for all cars divided by the time summation for all cars.

The *average spot speed*, also known as the *time mean speed*, is the arithmetic mean of the instantaneous speeds of all cars at a particular point. The *average travel speed* is the speed over a specified section of highway, including operational delays such as stops for traffic signals. The *free-flow speed* is measured using the mean speed of passenger cars under low to moderate flow conditions (up to 1400 pcphpl). The *operating speed* is the highest overall speed at which a driver can safely travel on a given highway under favorable weather conditions and prevailing traffic conditions. (The term *operating speed*, as used by AASHTO and in previous HCMs, is similar to free-flow speed when evaluated at low-volume conditions.) *Space mean speed* in a specific time period is calculated by taking the total distance traveled by all vehicles and dividing by the total of the travel times of all vehicles. *Crawl speed* is

**Table 73.3** Standard Design Vehicles

designation	symbol*	dimensions (ft (m))		
		height	width	length
passenger car	P	4.3 (1.30)	7.0 (2.13)	19.0 (5.79)
single-unit truck	SU-30 (SU-9)	11.0–13.5 (3.35–4.11)	8.0 (2.44)	30.0 (9.14)
single-unit bus	BUS-40 (BUS-12)	12.0 (3.66)	8.5 (2.59)	40.5 (12.36)
articulated bus	A-BUS	11.0 (3.35)	8.5 (2.59)	60.0 (18.29)
combination trucks				
intermediate semitrailer	WB-40 (WB-12)	13.5 (4.11)	8.0 (2.44)	45.5 (13.87)
“double-bottom” semitrailer or full trailer	WB-67D (WB-20D)	13.5 (4.11)	8.5 (2.59)	72.3 (22.04)
recreational vehicles				
motor home	MH	12.0 (3.66)	8.0 (2.44)	30.0 (9.14)
car and camper trailer	P/T	10.0 (3.05)	8.0 (2.44)	48.7 (14.84)
car and boat trailer	P/B	— —	8.0 (2.44)	42.0 (12.80)
motor home and boat trailer	MH/B	12.0 (3.66)	8.0 (2.44)	53.0 (16.15)

(Multiply ft by 0.3048 to obtain m.)

Symbols in parentheses represent the SI designations.

From *A Policy on Geometric Design of Highways and Streets*, 2011, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.**Table 73.4** Primary Measures of Level of Service

type of facility	level of service parameter
freeways	
basic freeway segment	density (pc/mi/ln or pc/km/ln)
weaving areas	density (pc/mi/ln or pc/km/ln)
ramp junctions	density (pc/mi/ln or pc/km/ln)
multilane highways	density (pc/mi/ln or pc/km/ln)
two-lane rural highways	speed or percent time spent following
signalized intersections	average control delay (sec/veh or s/veh)
unsignalized intersections	average control delay (sec/veh or s/veh)
urban streets	average travel speed (mph or km/h)
mass transit	various (pers/seat, veh/hr, people/hr, p/seat, veh/h, p/h)
pedestrians	space per pedestrian or delay (ft <sup>2</sup> /ped or m <sup>2</sup> /p)
bicycles	event, delay (sec/veh or s/veh)

Compiled from *Highway Capacity Manual 2010*.

the maximum sustained speed that heavy vehicles can maintain on a given extended upgrade.

The *HCM* uses average travel speed as the primary defining parameter. Except for LOS F, the average travel and average running speeds are identical.

## 7. SPOT SPEED STUDIES

The analysis of *spot speed data* draws on traditional statistical methods. The *mean*, *mode*, and *median***Table 73.5** Minimum Design Speeds (local and rural roads)

design volumes, ADT	terrain (mph (km/h))		
	level	rolling	mountainous
≥2000	50 (80)	40 (60)	30 (50)
1500–2000	50 (80)	40 (60)	30 (50)
400–1500	50 (80)	40 (60)	30 (50)
250–400	40 (60)	30 (50)	20 (30)
50–250	30 (50)	30 (50)	20 (30)
< 50	30 (50)	20 (30)	20 (30)

(Multiply mph by 1.609 to obtain km/h.)

From *A Policy on Geometric Design of Highways and Streets*, Table 5-1, copyright © 2011, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

speeds are commonly determined. Certain percentile rank speeds may also be needed. For example, the *50th percentile speed* (i.e., the median speed) and the *85th percentile speed* (i.e., the *design speed*) can be found from the frequency distribution. The *pace interval* (also known as the *pace range*, *group pace*, or just *pace*) is the 10 mph speed range containing the most observations.

## 8. VOLUME PARAMETERS

There are several volume parameters, and not all parameters will be needed in every capacity investigation. It is important to note if volumes are for both directions combined, for all lanes of one direction, or just for one lane.

The *average daily traffic*, ADT, and *average annual daily traffic*, AADT, may be one- or two-way. The *design hour volume*, DHV, is evaluated for the design year. DHV is

usually the 30th highest hourly expected volume in the design year, hence its nickname “30th hour volume.” It is not an average or a maximum. DHV is two-way unless noted otherwise. The ratio of DHV to AADT is designated as the *K-factor*. Values range from 0.07 to 0.15. (See *HCM* Exh. 3-9.)

$$K = \frac{\text{DHV}}{\text{AADT}} \quad 73.1$$

The *directional factor*, *D*, is the percentage of the dominant *peak flow direction*. It can range from up to 80% for rural roadways at peak hours, to 50% for central business district traffic, though values between 55% and 65% are more common. Values range from 0.51 to 0.70, and a typical value of *D* is 0.60. (See *HCM* Exh. 3-10.) The *directional design hour volume*, DDHV, is calculated as the product of the *directional factor*, *D* (also known as the *directionality factor* and the *D-factor*), and DHV.

$$\text{DDHV} = D(\text{DHV}) = DK(\text{AADT}) \quad 73.2$$

The *rate of flow*, *v*, is the equivalent hourly rate at which vehicles pass a given point during a given time interval of less than 1 hr, usually 15 min. The rate of flow changes every 15 min.

The *design capacity* is the maximum volume of traffic that the roadway can handle. The *ideal capacity*, *c*, for freeways is considered to be 2400 passenger cars per hour per lane (pcphpl). Different values apply for other levels of service, speeds, and types of facilities. The actual flow rate, *v*, can be used to calculate the *volume-capacity ratio*, *v/c*, for a particular level of service, *i*.

$$\text{volume-capacity ratio}_i = (v/c)_i \quad 73.3$$

The *maximum service flow rate* is the capacity in passenger cars per hour per lane under ideal conditions for a particular level of service, *i*.

$$v_{m,i} = c(v/c)_{m,i} \quad 73.4$$

The *peak hour factor*, PHF, is the ratio of the total actual hourly volume to the peak rate of flow within the hour.

$$\begin{aligned} \text{PHF} &= \frac{\text{actual hourly volume}_{\text{vph}}}{\text{peak rate of flow}_{\text{vph}}} = \frac{V_{\text{vph}}}{v_p} \\ &= \frac{V_{\text{vph}}}{4 V_{15 \text{ min,peak}}} \end{aligned} \quad 73.5$$

The *service flow rate* at level of service *i* is the actual capacity in passenger cars per hour under nonideal conditions. Service flow rate is calculated from the maximum service flow rate, the number of lanes, *N*, and other factors that correct for nonideal conditions.

$$V_i = v_{m,i} N(\text{adjustment factors}) \quad 73.6$$

### Example 73.1

Using the following traffic counts, determine the (a) peak hourly traffic volume and (b) peak hour factor.

interval	volume (veh)
4:15–4:30	520
4:30–4:45	580
4:45–5:00	670
5:00–5:15	790
5:15–5:30	700
5:30–5:45	630
5:45–6:00	570
6:00–6:15	510

#### Solution

(a) For the 1 hr time period of 4:15 through 5:15, the total hourly traffic volume is

$$520 \text{ veh} + 580 \text{ veh} + 670 \text{ veh} + 790 \text{ veh} = 2560 \text{ vph}$$

The hourly traffic volumes for the subsequent 1 hr intervals are found similarly.

4:15–5:15	2560 vph
4:30–5:30	2740 vph
4:45–5:45	2790 vph
5:00–6:00	2690 vph
5:15–6:15	2410 vph

The maximum hourly volume is 2790 vph.

(b) The peak 15 min volume occurs between 5:00 and 5:15 and is 790. From Eq. 73.5,

$$\begin{aligned} \text{PHF} &= \frac{V_{\text{vph}}}{4 V_{15 \text{ min,peak}}} = \frac{2790 \frac{\text{veh}}{\text{hr}}}{\left(4 \frac{\text{periods}}{\text{hr}}\right) \left(790 \frac{\text{veh}}{\text{period}}\right)} \\ &= 0.883 \end{aligned}$$

## 9. TRIP GENERATION

*Trip generation* requires estimating the number of trips that will result from a particular population or occupancy. Estimates can be obtained from general or area-specific tables or correlations. There are many general trip generation correlations that can be used if specific, targeted data are not available. Since predictive formulas are highly dependent on the characteristics of the local area and population, as well as on time of day and year, numerous assumptions must be made and verified before such correlations are relied upon.

Although linear equations with constant coefficients are often used, in the form of Eq. 73.7, more sophisticated correlations are easily obtained. Many take on the forms of either Eq. 73.8(a) or the equivalent Eq. 73.8(b). The

calling population parameter in these equations may be population quantity, number of homes, square footage (as in the case of retail shops), or any other convenient characteristic that can be quantified.

$$\text{no. of trips} = a + b \left( \frac{\text{calling population}}{\text{parameter}} \right) \quad 73.7$$

$$\log(\text{no. of trips}) = A + B \log \left( \frac{\text{calling population}}{\text{parameter}} \right) \quad 73.8(a)$$

$$\text{no. of trips} = \frac{C}{\left( \frac{\text{calling population}}{\text{parameter}} \right)^D} \quad 73.8(b)$$

The best trip data are actual counts obtained from *automatic traffic recorders* (ATRs). These devices can be used where roads are already in existence. Since ATRs count the number of vehicles (i.e., sets of axles) that pass over their detectors, counts must be corrected for trailer truck movement.

Logical methods, including straight-line extrapolation or exponential growth, should be used in the estimation of future traffic counts. Expansion factors can be determined for each axle classification.

### Example 73.2

An ATR record indicates that 966 axles passed over its detector. It is known that 10% of the vehicles were five-axle trucks. How many two-axle passenger cars and five-axle trucks actually passed over the detector?

*Solution*

The number of axles passing over the detector was

$$(2)(\text{no. of cars}) + (5)(\text{no. trucks}) = 966$$

The fraction of trucks is known to be 10%.

$$\frac{\text{no. of trucks}}{\text{no. of cars} + \text{no. of trucks}} = 0.10$$

Solving these two equations simultaneously,

$$\text{no. of cars} = 378$$

$$\text{no. of trucks} = 42$$

## 10. SPEED, FLOW, AND DENSITY RELATIONSHIPS

With uninterrupted flow, the speed of travel decreases as the number of cars occupying a freeway or multilane highway increases. The *free-flow speed*,  $S_f$  or FFS, is the maximum speed for which the density does not affect travel speed. Free-flow speed can be determined from actual measurements or estimated from the ideal value. Free-flow speed is measured in the field as the average

speed of passenger cars when flow rates are less than 1300 pcphpl.

*Density*,  $D$ , is defined as the number of vehicles per mile per lane (vpm/lane or vpk/lane) or, for pedestrians, in pedestrians per unit area. The *critical density*,  $D_o$  (also referred to as the *optimum density*), is the density at which maximum capacity occurs. The *jam density*,  $D_j$ , is the density when the vehicles (or pedestrians) are all at a standstill. The average travel speed,  $S$ , for any given density can be related to the free-flow speed by Eq. 73.9.

$$S = S_f \left( 1 - \frac{D}{D_j} \right) \quad 73.9$$

The *flow (rate of flow)*,  $v$  (number of vehicles or volume), crossing a point per hour per lane (vph/lane) is given in Eq. 73.10.

$$v = SD = \frac{3600 \frac{\text{sec}}{\text{hr}}}{\text{headway}_{\text{sec/veh}}} \quad 73.10$$

*Spacing* is the distance between common points (e.g., the front bumper) on successive vehicles. The *headway* is the time between successive vehicles.

$$\text{spacing}_{\text{m/veh}} = \frac{1000 \frac{\text{m}}{\text{km}}}{D_{\text{vpk/lane}}} \quad [\text{SI}] \quad 73.11(a)$$

$$\text{spacing}_{\text{ft/veh}} = \frac{5280 \frac{\text{ft}}{\text{mi}}}{D_{\text{vpm/lane}}} \quad [\text{U.S.}] \quad 73.11(b)$$

$$\text{headway}_{\text{s/veh}} = \frac{\text{spacing}_{\text{m/veh}}}{\text{space mean speed}_{\text{m/s}}} \quad [\text{SI}] \quad 73.12(a)$$

$$\text{headway}_{\text{sec/veh}} = \frac{\text{spacing}_{\text{ft/veh}}}{\text{space mean speed}_{\text{ft/sec}}} \quad [\text{U.S.}] \quad 73.12(b)$$

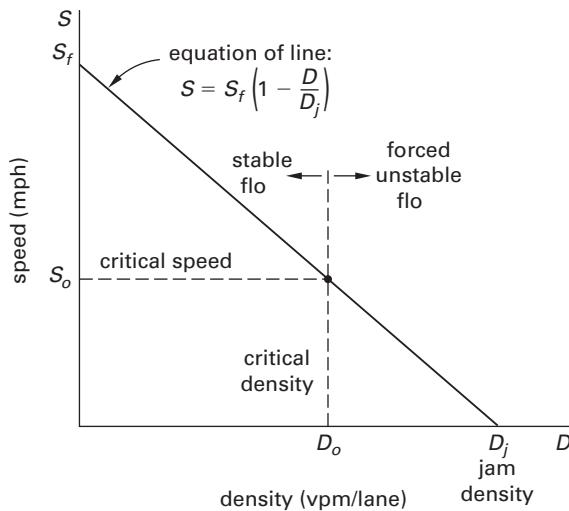

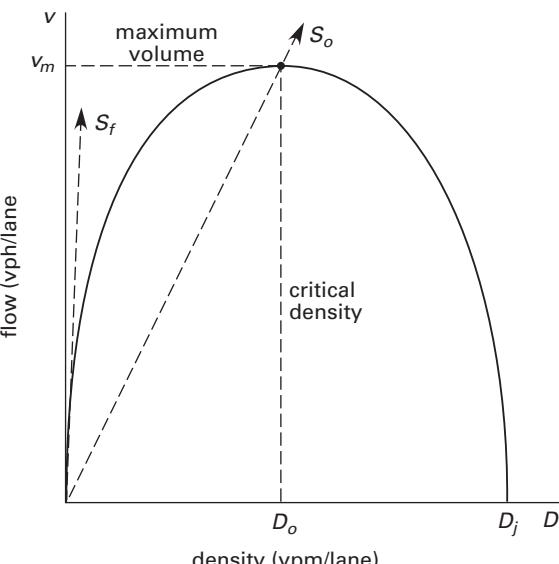

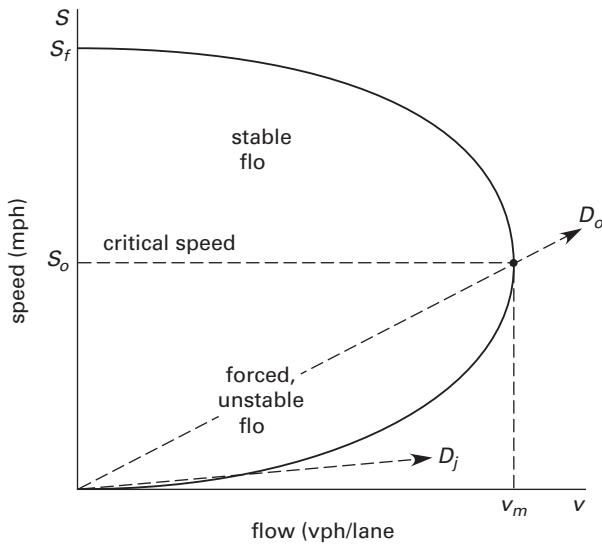

$$v_{\text{vph}} = \frac{3600 \frac{\text{sec}}{\text{hr}}}{\text{headway}_{\text{sec/veh}}} \quad 73.13$$

Gap is an important concept, particularly in unsignalized intersections where pedestrians or cross-street traffic are waiting for opportunities to cross. A *gap* is the time interval between vehicles in a major traffic stream. The *critical gap* is the minimum time interval between successive vehicles that will permit pedestrians or cross-street traffic to enter the intersection.

As Fig. 73.1, Fig. 73.2, and Fig. 73.3 indicate, the *optimum density (critical density)*, *optimum speed (critical speed)*, and *maximum flow (maximum capacity)* pass through the same point.

## 11. LANE DISTRIBUTION

It may be necessary to estimate the distribution of truck traffic on the various lanes of a multilane facility. The

**Figure 73.1** Space Mean Speed Versus Density**Figure 73.3** Flow Versus Density**Figure 73.2** Space Mean Speed Versus Flow

distribution of lane use varies widely, being dependent on traffic regulations, traffic composition, speed, volume, number and location of access points, origin-destination patterns of drivers, development environment, and local driver habits. Because there are so many factors, there are no typical values available for lane distribution.

Lane distribution values based on various vehicle types for selected freeways are provided in the *HCM*, but they are not intended to represent typical values.

## 12. VEHICLE EQUIVALENTS

It is convenient to designate a standard unit of measure for vehicular flow. Passenger cars make up the majority of highway traffic, so it is natural to use passenger cars as

the unit. Other types of vehicles are converted to *passenger car equivalents*. Since trucks, buses, and recreational vehicles (known as RVs) take up more space on a roadway than cars and since they tend to travel more slowly up grades, they degrade the quality of travel more than the same number of cars would. Therefore, their traffic volumes are converted to equivalent passenger car volumes,  $E$ , when computing flow.

Passenger car equivalents for trucks and RVs on grades depend on the percent grade, the length of the grade, the number of lanes, and the percentage of trucks and buses. Table 73.6 lists passenger car equivalents for general conditions. However, these values are applicable only to long sections of highways. For operation on specific grades of specific lengths, the *HCM* must be used.

*High-occupancy vehicles* (HOVs) include taxis, buses, and carpool vehicles. Special *HCM* procedures apply to HOV lanes.

**Table 73.6** Passenger Car Equivalents on Extended General Freeway Segments\*

terrain	$E_T$ (trucks and buses)	$E_R$ (RVs)
level	1.5	1.2
rolling	2.5	2.0
mountainous	4.5	4.0

\*Primarily for use in determining approximate capacity during planning stages when specific alignments are not known.

### 13. FREEWAYS

(Capacity analysis of basic freeway segments is covered in *HCM* Chap. 11.)

The process of determining *level of service* of a freeway section generally involves determining the vehicular density,  $D$ . Freeway conditions are classified into levels of service A through F. Level A represents conditions where there are no physical restrictions on operating speeds. Since there are only a few vehicles on the freeway, operation at highest speeds is possible. However, the traffic volume is small. Level F represents stop-and-go, low-speed conditions with poor safety and maneuverability. The desired design condition is between levels A and F. Typically, levels B and C are chosen for initial design in rural areas, and levels C and D are used for initial design in suburban and urban areas.

$$D = \frac{v_p}{S} \quad 73.14$$

The actual level of service is determined by comparing the actual density (in pcpmpl) with the density limits given in Table 73.7.

**Table 73.7** Levels of Service for Basic Freeway Sections

level	density range (pcpmpl)	description
A	0–11	free flow with low volumes and high speeds
B	> 11–18	stable flow, but speeds are beginning to be restricted by traffic conditions
C	> 18–26	stable flow, but most drivers cannot select their own speed
D	> 26–35	approaching unstable flow, and maneuvering room is noticeably limited
E	> 35–45	unstable flow with short stoppages, and maneuvering room is severely limited
F	> 45	forced flow at crawl speeds; localized lines of vehicles

(Multiply pcpmpl by 0.621 to obtain pc/km/ln.)

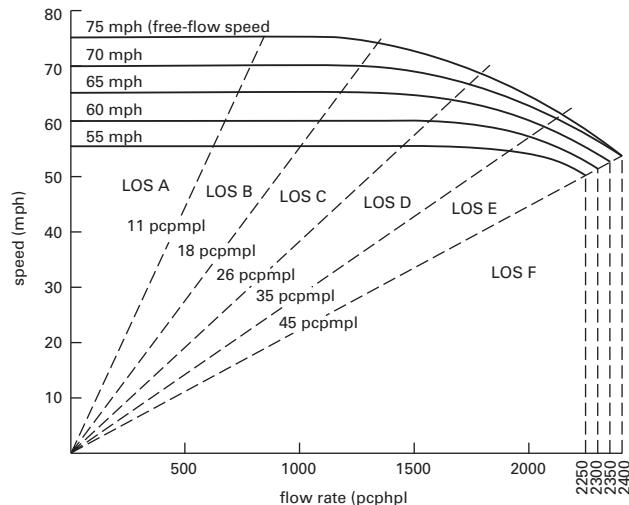

Adapted from *Highway Capacity Manual 2010*, Exhibit 11-5.

The *flow rate*,  $V$ , can be calculated from the number of lanes in the analysis,  $N$ ; a factor to adjust for the presence of heavy vehicles such as buses, trucks, and recreational vehicles,  $f_{HV}$ ; and a factor to adjust for the effect of the driver population,  $f_p$ . Figure 73.4 illustrates the speed-flow relationship between flow rate and the average passenger car. The passenger car equivalent flow rate for the peak 15 min is shown as  $v_p$  (pcphpl).

$$V = v_p(\text{PHF})Nf_{HV}f_p \quad 73.15$$

Table 73.8 shows maximum service flow rates for various levels of service.

**Figure 73.4** Speed-Flow Relationships

Adapted from *Highway Capacity Manual 2010*, Exhibits 11-2 and 11-6.

**Table 73.8** Maximum Freeway Service Flow Rate for Various LOS

FFS (mi/hr)	level of service (LOS)*				
	LOS A (pcphpl)	LOS B (pcphpl)	LOS C (pcphpl)	LOS D (pcphpl)	LOS E (pcphpl)
75	820	1310	1750	2110	2400
70	770	1250	1690	2070	2400
65	710	1170	1630	2030	2350
60	660	1080	1560	2010	2300
55	600	990	1430	1900	2250

\*All values are rounded to the nearest 10 pcphpl.

*Highway Capacity Manual 2010*. Copyright, National Academy of Sciences, Washington D.C., Exhibit 11-17. Reproduced with permission of the Transportation Research Board.

On freeways, the *HCM* suggests using estimated PHF values ranging from 0.85 to 0.98 for rural and urban-suburban freeways. Lower values are typical of rural and lower volume conditions, while higher values are typical of urban and suburban peak-hour conditions.

The *heavy vehicle factor*,  $f_{HV}$ , is a function of the truck, bus, and recreational vehicle fractions and is given by Eq. 73.16.  $E_T$  and  $E_R$  are the passenger car equivalents of trucks/buses and recreational vehicles, respectively, as given in the *HCM* as a function of specific grades. The fraction of trucks and buses,  $P_T$ , is sometimes referred to as the *T-factor*. Trucks do not include light delivery vans.

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)} \quad 73.16$$

Selection of the *driver population adjustment factor*,  $f_p$ , requires engineering judgment based on the characteristics of the drivers using the freeway. For example,

freeways used by commuter traffic familiar with the route are assigned high values of  $f_p$ : 1.0 for urban freeways and 0.975 for rural freeways. The value drops to 0.75–0.90 for weekend, recreational, and other types of traffic that are less familiar with the route, and thus, do not use the available space as efficiently.

A study<sup>2</sup> specific to driver performance in freeway work zones has indicated that the driver population adjustment factor can be modeled as the product of two numerical factors, a *familiarity factor* (which is dependent on the familiarity and aggressiveness and adaptability of the driver) and a *behavior factor* (which is dependent on the aggressiveness and accommodation of the driver). The results of the study are summarized in Table 73.9. While these results have not been incorporated into the *HCM* or extended beyond capacity studies in freeway work zones, they do indicate a wide range of possible values and, in extreme cases, that  $f_p$  can even exceed 1.0.

**Table 73.9** Driver Population Adjustment Factors for Freeway Work Zone Capacity

	adaptability	aggressiveness	accommodation	driver population factor
high	high	medium	high	1.375
medium	medium	medium	medium	0.9
low	low	low	low	0.64

For analysis of a basic freeway segment, *free-flow speed*, FFS, is used. The free-flow speed is the mean speed of passenger cars measured during flows of less than 1000 pc/hr/ln (pcphpl). Field measurement is the preferred way to measure FFS. However, when field measurements are not available (such as for future facilities or for proposed changes to existing facilities), FFS can be estimated using Eq. 73.17 (*HCM* Eq. 11-1), with adjustments for lane width,  $f_{LW}$ ; right-side lateral clearance,  $f_{LC}$ ; and *total ramp density*, TRD, in ramps per mile. These factors are further described in *HCM* Chap. 11.<sup>3</sup>

$$\text{FFS} = 75.4 \frac{\text{mi}}{\text{hr}} - f_{LW} - f_{LC} - \left(3.22 \frac{\text{mi}}{\text{hr}}\right) \text{TRD}^{0.84} \quad 73.17$$

Due to the considerable variations between observed and predicted values, the *HCM* recommends rounding FFS to the nearest 5 mph. Density thresholds for each LOS remain the same for all FFS criteria, so the maximum service flow varies for each LOS.

<sup>2</sup>This study is *Driver Population Adjustment Factors for the Highway Capacity Manual Work Zone Capacity Equation*, a paper presented at the 2008 Transportation Research Board's annual meeting in Washington, D.C., by Kevin Heaslip, PhD, PE and Chuck Louisell, PhD, PE, submitted November 15, 2007.

<sup>3</sup>Previous editions of the *HCM* included equations for the *base free-flow speed* (BFFS). These equations have been replaced with the base free-flow value 75.4 mi/hr in Eq. 73.17, which represents the BFFS.

### Example 73.3

A four-lane (two lanes in each direction) freeway passes through rolling terrain in an urban area. The freeway is constructed with 11 ft lanes and abutment walls 2 ft from the outer pavement edges of both slow lanes. The one-direction peak hourly volume during the weekday commute is 1800 vph. Traffic includes 3% buses and 5% trucks. The ramp density is one ramp per mile. The peak-hour factor is 0.90. The posted speed limit is 65 mph. (a) What is the passenger car equivalent flow rate per lane? (b) What is the speed during peak-hour travel? (c) What is the density? (d) What is the weekday peak-hour level of service?

#### Solution

(a) Trucks and buses have the same vehicle equivalents, so the "truck" fraction is 8%. There are no RVs. From Table 73.6,  $E_T = 2.5$ . From Eq. 73.16,

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1)} = \frac{1}{1 + (0.08)(2.5 - 1)} = 0.893$$

Convert the volume to flow rate per lane. The commute population presumably knows the route, so  $f_p = 1.0$ . From Eq. 73.15,

$$v_p = \frac{V}{(\text{PHF})Nf_{HV}f_p} = \frac{1800 \text{ vph}}{(0.90)(2)(0.893)(1)} = 1120 \text{ pcphpl}$$

(b) The actual free-flow speed, FFS, is calculated from Eq. 73.17. Round to the nearest 5 mi/hr as specified by the *HCM*.

$$f_{LW} = 1.9 \frac{\text{mi}}{\text{hr}} \quad [\text{HCM Exh. 11-8}]$$

$$f_{LC} = 2.4 \frac{\text{mi}}{\text{hr}} \quad [\text{HCM Exh. 11-9}]$$

$$\text{TRD} = 1.0 \frac{\text{ramp}}{\text{mi}}$$

$$\begin{aligned} \text{FFS} &= 75.4 \frac{\text{mi}}{\text{hr}} - f_{LW} - f_{LC} - \left(3.22 \frac{\text{mi}}{\text{hr}}\right) \text{TRD}^{0.84} \\ &= 75.4 \frac{\text{mi}}{\text{hr}} - 1.9 \frac{\text{mi}}{\text{hr}} - 2.4 \frac{\text{mi}}{\text{hr}} - \left(3.22 \frac{\text{mi}}{\text{hr}}\right)(1.0)^{0.84} \\ &= 67.88 \text{ mi/hr} \quad [\text{say } 70 \text{ mi/hr}] \end{aligned}$$

(c) The density is

$$\begin{aligned} D &= \frac{v_p}{S} = \frac{1120 \text{ pcphpl}}{70 \frac{\text{mi}}{\text{hr}}} \\ &= 16 \text{ pc/mi-ln (pcpmpl)} \end{aligned}$$

(d) From Table 73.9, with a free-flow speed of 70 mph, the level of service (based on flow rate) is B.

**Example 73.4**

An urban freeway segment is being designed for an AADT of 60,000 weekday commuters traveling at 60 mph in 12 ft lanes. Heavy trucks constitute 5% of the total traffic. The directionality factor is 75%. The  $K$ -factor is 9.8%. The freeway segment consists of 1 mi of 4% upward grade. The lateral clearances are 10 ft on the right and 6 ft on the left. The free-flow speed, FFS, is 65 mph. The peak hour factor, PHF, is 0.92. How many lanes are needed for LOS D?

*Solution*

Use Eq. 73.2 to convert AADT to design hourly volume.

$$\text{DDHV} = DK(\text{AADT}) = (0.75)(0.098) \left( 60,000 \frac{\text{veh}}{\text{day}} \right) \\ = 4410 \text{ vph}$$

From *HCM* Exh. 11-11, for a 4% upgrade 1 mi in length with 5% trucks, the passenger car equivalent for trucks is 2.5. From Eq. 73.16,

$$f_{\text{HV}} = \frac{1}{1 + P_T(E_T - 1)} = \frac{1}{1 + (0.05)(2.5 - 1)} \\ = 0.930$$

From Table 73.8 with FFS = 65 mph and LOS D, the maximum service flow rate is 2030 pcphpl.

The adjustment factor for a driver population of weekday commuters is  $f_p = 1.0$ .

$$V_2 \text{ lanes} = v_p(\text{PHF})Nf_{\text{HV}}f_p \\ = \left( 2030 \frac{\text{pc}}{\text{hr-ln}} \right)(0.92)(2 \ln)(0.930)(1) \\ = 3474 \text{ vph} \quad [< 4410 \text{ vph}]$$

$$V_3 \text{ lanes} = v_p(\text{PHF})Nf_{\text{HV}}f_p \\ = \left( 2030 \frac{\text{pc}}{\text{hr-ln}} \right)(0.92)(3 \ln)(0.930)(1) \\ = 5211 \text{ vph} \quad [> 4410 \text{ vph}]$$

Three lanes are required.

## 14. MULTILANE HIGHWAYS

(Capacity analysis of multilane highways is covered in *HCM* Chap. 14.)

Multilane highways generally have four to six lanes and posted speed limits between 40 mph and 55 mph. The flow directions may be divided by a median, may be undivided with only a centerline separating them, or may have a two-way left-turn lane (TWLT). Multilane highways are typically located in suburban areas or between central cities along high-volume corridors. As such, they often are used by public transit, include bike lanes, and carry high traffic volumes. Access is generally

through at-grade intersections.<sup>4</sup> Signals are generally spaced close together in urban areas and several miles apart in suburban or rural areas. Segments with more frequently placed signals must be analyzed as interrupted flow urban streets.

While uninterrupted flow on multilane highways is similar to that on freeways, there are several different factors that must be accounted for. Various degrees of interacting side traffic are present (such as from uncontrollable driveways and intersections, and from opposing flows on undivided cross sections). As a result, speeds and capacities on multilane highways are lower than on basic freeways with similar cross sections.

Multilane highways are not completely access controlled. The *free-flow speed*, FFS, is the theoretical speed of a vehicle under all actual conditions except interference by other vehicles. Free-flow speed is the theoretical speed when density is zero, but is essentially unchanged for densities up to 1400 pcphpl. Free-flow speed is determined from the base free-flow speed, BFFS, with adjustments for median type,  $f_M$ ; lane width,  $f_{\text{LW}}$ ; total lateral clearance,  $f_{\text{LC}}$ ; and density of access points,  $f_A$ . The base free-flow speed is covered in *HCM* Chap. 14, but is approximately 5 mph greater than the speed limit for 50 mph and 55 mph speed limits. For speed limits less than 50 mph, it is approximately 7 mph greater. Values of the adjustments are obtained from Table 73.10 and the appropriate tables in *HCM* Chap. 14. (Though similar in concept to freeway adjustments, some highway values are different. Accordingly, different symbols are used.)

$$\text{FFS} = \text{BFFS} - f_M - f_{\text{LW}} - f_{\text{LC}} - f_A \quad 73.18$$

The *15 min passenger car equivalent flow rate*,  $v_p$ , in pcphpl is given by Eq. 73.19.  $V$  is the volume of vehicles passing a point each hour,  $f_{\text{HV}}$  is the same heavy-vehicle factor used in freeway analysis, and PHF is the peak hour factor. Where specific local data are not available, the *HCM* recommends reasonable estimates of PHF of 0.75 to 0.95. Lower values are typical of low volume rural conditions, and higher values are typical of urban and suburban peak-hour conditions. For congested conditions, a PHF of 0.95 should be used. The driver population adjustment factor,  $f_p$ , ranges from 0.85 to 1.00. The *HCM* recommends using a value of 1.00, which represents familiar (e.g., commuter) drivers, unless there is sufficient evidence to use a lower value.

$$v_p = D_m(\text{FFS}) = \frac{V}{N(\text{PHF})f_{\text{HV}}f_p} \quad 73.19$$

<sup>4</sup>Segments between signals that are placed 2 mi or more apart function similarly to freeways and can be considered as such for analysis purposes.

**Table 73.10** Level of Service Criteria for Multilane Highways\*

			LOS				
free-flow speed		criteria	A	B	C	D	E
60 mi/hr	maximum density (pcpmpl)	11	18	26	35	40	
	maximum service flow rate (pcphpl)	660	1080	1550	1980	2200	
55 mi/hr	maximum density (pcpmpl)	11	18	26	35	41	
	maximum service flow rate (pcphpl)	600	990	1430	1850	2100	
50 mi/hr	maximum density (pcpmpl)	11	18	26	35	43	
	maximum service flow rate (pcphpl)	550	900	1300	1710	2000	
45 mi/hr	maximum density (pcpmpl)	11	18	26	35	45	
	maximum service flow rate (pcphpl)	490	810	1170	1550	1900	

(Multiply mph by 1.609 to obtain km/hr.)

(Multiply pcpmpl by 0.621 to obtain pc/km/ln.)

\*Density is the primary determinant of LOS. LOS F is characterized by highly unstable and variable traffic flow. Prediction of accurate flow rate, density, and speed at LOS F is difficult.

*Highway Capacity Manual 2010.* Copyright, National Academy of Sciences, Washington, D.C., Exhibits 14-4 and 14-17. Reproduced with permission of the Transportation Research Board.**Example 73.5**

An undivided suburban multilane highway segment with four 11 ft lanes (two in each direction) is used by weekday commuters. There is no median, and the two lanes in each direction are separated by a striped centerline. The estimated free-flow speed under ideal conditions is 60 mph. The segment contains 4% upgrades and downgrades 0.8 mi long. The fraction of recreational vehicles on this segment is essentially zero. However, the fraction of trucks is 10%. The lateral clearance on the right-hand side of the slow lane is 6 ft from the pavement edge. There is a 2 ft shoulder on each outside lane. There are no points of entry to the highway segment.

- (a) What is the hourly volume in the upgrade direction for LOS C? (b) What is the maximum capacity of the downgrade section? (c) What is the LOS in the downgrade section during the morning peak if the peak-hour traffic volume is 1300 vph?

**Solution**

- (a) The base free-flow speed is given as BFFS = 60 mph.

The median type adjustment factor for undivided highways is found from *HCM* Exh. 14-10, as  $f_M = 1.6$ .

The lane width adjustment factor for 11 ft lanes is found from *HCM* Exh. 14-8, as  $f_{LW} = 1.9$ .

For undivided highways with only a striped centerline, the left side clearance is zero. However, the median factor accounts for the proximity of the two opposing lanes. The left-edge lateral clearance is taken as 6 ft per the *HCM*. The total lateral clearance is 6 ft + 2 ft = 8 ft. The adjustment factor for lateral clearance for four-lane highways is found in *HCM* Exh. 14-9, as  $f_{LC} = 0.9$ .

If there are no access points, *HCM* Exh. 14-11 gives the access-point density adjustment factor as  $f_A = 0$ .

Use Eq. 73.18.

$$\begin{aligned} \text{FFS} &= \text{BFFS} - f_M - f_{LW} - f_{LC} - f_A \\ &= 60 \frac{\text{mi}}{\text{hr}} - 1.6 \frac{\text{mi}}{\text{hr}} - 1.9 \frac{\text{mi}}{\text{hr}} - 0.9 \frac{\text{mi}}{\text{hr}} - 0 \frac{\text{mi}}{\text{hr}} \\ &= 55.6 \text{ mi/hr (mph)} \end{aligned}$$

Round to 55 mph in order to use data from Table 73.10. The maximum density at LOS C is 26 pcpmpl.

Use Eq. 73.19.

$$\begin{aligned} v_p &= D_m(\text{FFS}) = \left(26 \frac{\text{pc}}{\text{mi-lane}}\right) \left(55.6 \frac{\text{mi}}{\text{hr}}\right) \\ &= 1446 \text{ pc/hr-lane (pcphpl)} \end{aligned}$$

From Exh. 14-13 of the *HCM*, the passenger car equivalent of trucks on a 4% grade 0.8 mi long with 10% trucks is  $E_T = 2.5$ . From Eq. 73.16, the heavy-vehicle adjustment factor is

$$\begin{aligned} f_{HV} &= \frac{1}{1 + P_T(E_T - 1)} = \frac{1}{1 + (0.10)(2.5 - 1)} \\ &= 0.870 \end{aligned}$$

Assume a value of 0.95 for the peak hour factor as recommended by the *HCM*. Solve Eq. 73.19 for the volume.

$$\begin{aligned} V &= v_p N(\text{PHF}) f_{HV} f_p \\ &= \left(1446 \frac{\text{pc}}{\text{hr-lane}}\right) (2 \text{ lanes}) (0.95) (0.870) (1.0) \\ &= 2390 \text{ pc/hr (vph)} \end{aligned}$$

(b) From Exh. 14-5 of the *HCM*, at 55 mph, a maximum capacity of 2100 pcphpl will be reached at LOS E.

From Exh. 14-15 of the *HCM*, the passenger car equivalent of trucks on a 4% downgrade 0.8 mi long is  $E_T = 1.5$ . From Eq. 73.16, the heavy-vehicle adjustment factor is

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1)} = \frac{1}{1 + (0.10)(1.5 - 1)} \\ = 0.952$$

Use Eq. 73.19 to calculate the hourly volume.

$$V = v_p N(\text{PHF}) f_{HV} f_p \\ = \left( 2100 \frac{\text{pc}}{\text{hr-lane}} \right) (2 \text{ lanes})(0.95)(0.952)(1.0) \\ = 3798 \text{ pc/hr (vph)}$$

(c) Use Eq. 73.19 to calculate the service flow rate.

$$v_p = \frac{V}{N(\text{PHF}) f_{HV} f_p} = \frac{1300 \frac{\text{pc}}{\text{hr}}}{(2)(0.95)(0.952)(1.0)} \\ = 719 \text{ pc/hr-lane (pcphpl)}$$

From part (a), the free-flow speed is 55.6 mph. From Eq. 73.19, the peak density is

$$D_m = \frac{v_p}{\text{FFS}} = \frac{719 \frac{\text{pc}}{\text{hr-lane}}}{55.6 \frac{\text{mi}}{\text{hr}}} \\ = 12.9 \text{ pc/mi-lane (pcpmpl)}$$

Using Table 73.10, for 55 mi/hr,  $11 \text{ pcpmpl} < 12.9 \text{ pcpmpl} < 18 \text{ pcpmpl}$ ; therefore, the level of service is B.

## 15. TWO-LANE HIGHWAYS

(Capacity analysis of two-lane highways is covered in *HCM* Chap. 15.)

Highways are classified according to driver expectations of mobility and access. *Class I highways* are those that function as primary arterials connecting urban with suburban areas, daily commuter routes, major intercity routes, and links to other arterial highways. Drivers on Class I highways expect to travel at relatively high speeds for long periods of time (i.e., mobility is favored over access).

Highways where slower travel is expected by drivers (i.e., access is favored over mobility) are referred to as *Class II highways*. Examples of Class II highways include sightseeing routes, scenic byways, routes through rugged terrain, and highways that connect to Class I highways. Class II highways are generally used on relatively short trips, the beginning and end of longer trips, or trips for which sightseeing plays a significant role.

*Class III two-lane highways* are segments of Class I or Class II two-lane highways that pass through small towns or developed recreational areas. They serve moderately developed areas where local traffic mixes with through traffic, and where unsignalized access points occur more frequently. Class III two-lane highways may include longer segments passing through relatively spread-out recreational areas and areas with increased roadside densities.

Under base conditions, the capacity of a two-lane highway is 1700 pcph for each direction of travel. This capacity is essentially independent of the directional distribution of traffic on the highway, although for extended lengths of two-lane highway, the capacity will not exceed 3200 pcph for both directions of travel combined. For short lengths of two-lane highway—such as tunnels and bridges—a combined capacity of 3200 pcph to 3400 pcph for both directions of travel may be achieved.

The performance criteria (i.e., measures of effectiveness used to determine LOS) for highways include

- *average travel speed (ATS)*: the average time required to travel a highway segment divided by the segment length, an indicator of mobility.
- *percent time spent following (PTSF)*: the average percentage of time that vehicles must travel in platoons behind slower vehicles due to the inability to pass, reflecting the convenience of travel. PTSF is sometimes calculated as the percentage of vehicles traveling at headways of less than 3.0 sec, or as the percentage of vehicles traveling in platoons.
- *percent of free-flow speed (PFFS)*: the ability vehicles have to travel at, or near, the posted speed limit

The performance criteria of Class I, two-lane highways in non-mountainous terrain with no traffic signals include ATS and PTSF. Performance of Class II highways is determined only by PTSF. Performance of Class III highways is determined only by PFFS as these highways are generally limited in length and have lower posted speed limits. Table 73.11 lists the LOS criteria for two-lane highways.

If the actual volume of traffic,  $v_p$ , for both directions is greater than 3200 pcph, then the roadway is over capacity (i.e., saturated), and LOS is F. If  $v_p$  in a single direction is greater than 1700 pcph, LOS is also F. In these three cases, no further analysis is needed to determine how the highway is performing.

LOS for two-lane highways can be evaluated for general segments (e.g., level or rolling terrain), two-way segments with specific upgrades and downgrades, or one-way directional segments. *Specific upgrades and downgrades* are those that have grades of 3% or greater and lengths of 0.6 mi or greater. The one-way directional segment methodology treats heavy vehicles differently and can only be used in level or rolling terrain, not in conditions that qualify for specific upgrades and downgrades.

**Table 73.11** LOS Criteria for Two-Lane Highways

LOS	Class I highways		Class II highways	Class III highways
	ATS (mi/hr)	PTSF (%)	PTSF (%)	PFFS (%)
A	>55	≤35	≤40	>91.7
B	>50–55	>35–50	>40–55	>83.3–91.7
C	>45–50	>50–65	>55–70	>75.0–83.3
D	>40–45	>65–80	>70–85	>66.7–75.0
E	≤40	>80	>85	≤66.7

*Highway Capacity Manual 2010.* Copyright, National Academy of Sciences, Washington, D.C., Exhibit 15-3. Reproduced with permission of the Transportation Research Board.

Directional segment methodology is not covered in this chapter.

In addition to having different methodologies for general highway segments and specific upgrades and downgrades, the various adjustment factors for ATS and PTSF are different. Table 73.12 lists the *HCM* exhibits for each case.

**Table 73.12** HCM Exhibits for Two-Lane Highway Adjustments

	ATS	PTSF
general sections		
grade adjustment, $f_g$	15-9	15-16
truck equivalent, $E_T$	15-11	15-18
recreational vehicle, $E_R$	15-11	15-18
specific upgrades		
grade adjustment, $f_g$	15-10	15-17
truck equivalent, $E_T$	15-12	15-19
recreational vehicle, $E_R$	15-13	15-19

The free-flow speed, FFS, is the speed of traffic under low-low conditions. If ATS methodology will be used, FFS can be determined two ways: The average speed,  $S_{FM}$ , based on field measurements (observations) can be adjusted for flow rate and heavy vehicles, or FFS can be calculated from the *base free-flow speed*, BFFS. The base free-flow speed is generally specified by the agency, and usually will be somewhat higher (e.g., 10 mi/hr faster) than the posted speed limit or the design speed. In Eq. 73.20,  $v_f$  is the observed flow rate for the period corresponding to  $S_{FM}$ . In Eq. 73.21,  $f_{LS}$  is the *lane and shoulder adjustment factor* from *HCM* Exh. 15-17, and  $f_A$  is the *adjustment for access point density* (intersections and driveways) from *HCM* Exh. 15-18.

$$FFS = S_{FM} + 0.00776 \frac{v_f}{f_{HV,ATS}} \quad [\text{field measurements}] \quad 73.20$$

$$FFS = BFFS - f_{LS} - f_A \quad [\text{estimated BFFS}] \quad 73.21$$

The demand flow rate,  $v_i$  (passenger car flow rate for speed), is the adjusted hourly demand in passenger car

equivalents for the peak 15 minutes, calculated from the hourly volume,  $V_i$ . The subscript  $i$  is used to denote either the analysis direction,  $d$ , or the opposing direction,  $o$  (e.g.,  $v_d$  or  $v_o$ ). For clarity,  $v_{i,ATS}$ ,  $f_{g,ATS}$ , and  $f_{HV,ATS}$  for ATS use are distinguished from their percent time spent following counterparts  $v_{i,PTSF}$ ,  $f_{g,PTSF}$ , and  $f_{HV,PTSF}$  by the use of subscripts ATS and PTSF, but have the same meanings otherwise. Equation 73.22 is only used for Class I highways.

$$v_{i,ATS} = \frac{V_i}{(\text{PHF})f_{g,ATS}f_{HV,ATS}} \quad [\text{ATS}] \quad 73.22$$

Similarly, the demand flow rate for percent time spent following is

$$v_{i,PTSF} = \frac{V_i}{(\text{PHF})f_{g,PTSF}f_{HV,PTSF}} \quad [\text{PTSF}] \quad 73.23$$

The PHF is used to convert hourly volumes to flow rates and represents the hourly variation in traffic flow. If the demand volume is measured in 15 min increments, it is unnecessary to use the PHF to convert to flow rates. Therefore, since two-lane highway analysis is based on demand flow rates for a peak 15 min period within the analysis hour (usually the peak hour), the PHF in Eq. 73.22 and Eq. 73.23 is given a value of 1.00.

The average travel speed in the analysis direction,  $ATS_d$ , is estimated from the FFS, the demand flow rate, the opposing flow rate, and the adjustment factor for the percentage of no-passing zones in the analysis direction,  $f_{np}$ , as given in *HCM* Exh. 15-15. Equation 73.24 only applies to Class I and Class III two-lane highways.

$$ATS_d = FFS - 0.0076(v_{d,s} + v_{o,s}) - f_{np,s} \quad 73.24$$

If the PTSF methodology is used, the formula for the demand flow rate,  $v_{i,ATS}$ , is the same, although different values of  $f_g$  and  $f_{HV}$  apply. The base percent time spent following in the analysis direction, BPTSF, is given by Eq. 73.25, where  $a$  and  $b$  are constants as found from Table 73.13 (*HCM* Exh. 15-20).

$$\text{BPTSF}_d = (1 - e^{av_d^b}) \times 100\% \quad 73.25$$

The percent time spent following, PTSF, is calculated from the BPTSF, the adjustment factor for the percentage of no-passing zones in the analysis direction,  $f_{np}$  (*HCM* Exh. 15-21), and the demand flow rates in the analysis and opposing directions.

$$\text{PTSF}_d = \text{BPTSF}_d + f_{np,PTSF} \left( \frac{v_{d,PTSF}}{v_{d,PTSF} + v_{o,PTSF}} \right) \quad 73.26$$

**Table 73.13** Coefficients for Estimating BPTSF

opposing demand flow rate, $v_o$ (pc/h)	coefficient $a$	coefficient $b$
≤200	-0.0014	0.973
400	-0.0022	0.923
600	-0.0033	0.870
800	-0.0045	0.833
1000	-0.0049	0.829
1200	-0.0054	0.825
1400	-0.0058	0.821
≥1600	-0.0062	0.817

Note: Straight-line interpolation of  $a$  to the nearest 0.0001 and  $b$  to the nearest 0.001 is recommended.

Equation 73.26 is used to determine LOS for Class I and Class II highways only. Class III highways use the percent free-flow speed, PFFS, instead.

$$\text{PFFS} = \frac{\text{ATS}_d}{\text{FFS}} \quad 73.27$$

## 16. URBAN STREETS

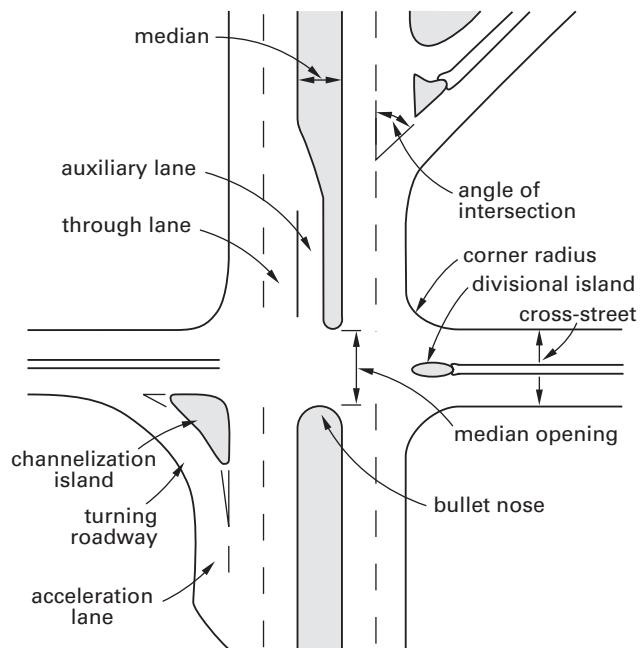

*Urban streets* are roadways that have fixed traffic interruptions at frequent intervals. These interruptions include signaled intersections spaced less than 2 mi (3.2 km) apart, roundabouts, and transit facilities. *HCM* Chap. 16 and Chap. 17 provide integrated methodologies for quantitatively evaluating the performance of urban streets, including the LOS for each transportation mode (i.e., automobile, pedestrian, bicycle, and mass transit).

## 17. SIGNALIZED INTERSECTIONS

(Capacity analysis of signalized intersections is covered in *HCM* Chap. 18.)

Signalized intersections are controlled by signals operating in two or more phases. Each phase consists of three intervals: green, amber (i.e., “yellow”), and red. For a typical intersection with two streets crossing at 90° to each other, a *two-phase signal* is one that has one phase for each axis of travel (e.g., one phase of north-south movements and one phase of east-west movements). A *three-phase signal* provides one of the roads with a left-turn phase. In a *four-phase signal*, both roads have left-turn phases. Figure 73.5 shows typical elements of an intersection.

Level of service for signalized intersections is defined in terms of control delay in the intersection. *Control delay* consists of only the portion of delay attributable to the control facility (e.g., initial deceleration delay, queue

**Figure 73.5** Elements of an Intersection

move-up time, stopped delay, and final acceleration delay), but not geometric delay or incident delay.

*Geometric delay* is caused by the need for vehicles to slow down in order to negotiate an intersection. For example, a vehicle would need to slow down in order to enter a separate left-turn lane or negotiate a roundabout, regardless of the traffic already in the intersection. *Queueing delay* is the delay caused by the need to slow down in order to avoid other vehicles already present. All or parts of queueing delay may be included in geometric delay. For example, the time a driver takes to determine if there is traffic that needs to be avoided overlaps both geometric and queueing delay. *Incident delay* occurs when there is an incident (i.e., an accident). There are nine general categories of incidents (fatal injury, personal injury, property damage, mechanical/electrical failure, other stalls, flat tires, abandoned vehicles, debris on roadway, and everything else). Incident delay includes all times for which lanes and shoulders are blocked, including response and clearance times.

Delay can be measured in the field, or it can be estimated using procedures as outlined in the *HCM*. LOS criteria are stated in terms of control delay per vehicle for a 15 min analysis period, as given in Table 73.14. Because of this criterion, an intersection may be operating below its maximum capacity but have an unacceptable delay, and, therefore, it would be classified as LOS F (failure). This is a different meaning for “LOS F,” which generally indicates that demand exceeds capacity.

The capacity of a signalized intersection is calculated for each lane group. *Capacity* is the maximum rate of flow for the subject lane group that may pass through

**Table 73.14** Level of Service Criteria for Signalized Intersections

level of service	control delay per vehicle (sec)
A	$\leq 10.0$
B	$> 10.0 \text{ and } \leq 20.0$
C	$> 20.0 \text{ and } \leq 35.0$
D	$> 35.0 \text{ and } \leq 55.0$
E	$> 55.0 \text{ and } \leq 80.0$
F	$> 80.0$

*Highway Capacity Manual 2010.* Copyright, National Academy of Sciences, Washington, D.C., Exhibit 18-4. Reproduced with permission of the Transportation Research Board.

the intersection under prevailing traffic, roadway, and signalization conditions. The rate of flow is generally measured or projected for a 15 min period. Capacity is given in terms of vph and is dependent on many factors, including the width of approach, parking conditions, traffic direction (one- or two-way traffic), environment, bus and truck traffic, and percentage of turning vehicles.

Rather than calculate the capacity of the entire intersection, a total volume-capacity ( $v/c$ ) flow ratio is computed for all the critical lane groups within the intersection as a measure of the overall intersection performance. The *critical lane groups* are those lane groups that have the maximum *flow ratio*,  $v/s$ , also known as *saturation flow ratio*, for each signal phase. The *critical movements* consume the maximum amount of time during each signal phase. For example, in a two-phase signal at a typical cross-street intersection, opposing lane groups move during the same green time (phase). Generally, one of the lane groups, or *approaches*, will have a higher flow ratio ( $v/s$ ) and will require more green time than the other approach. This would be the critical lane group,  $X_{ci}$ , for that phase.

In capacity analysis, volume-capacity ratios ( $v/c$ ) are computed for each intersection movement and for all of the critical movements together. The  $v/c$  ratios are determined by dividing the peak 15 min rate of flow on an approach or lane group by the capacity of the approach or lane group. Both the traffic flow and the geometric characteristics are taken into consideration. The objective is to provide the minimum number of lane groups to adequately characterize the intersection operation.

The capacity of an approach or lane group is given by Eq. 73.28.  $s_i$  is the *saturation flow rate* in vphg for lane group  $i$  (i.e., in vphgpl), which is the flow rate per lane at which vehicles can pass through a signalized intersection in a stable moving queue.  $N$  is the number of lanes.  $g_i/C$  is the *effective green ratio* for the lane group.

$$c_i = N s_i \left( \frac{g_i}{C} \right) \quad 73.28$$

$$s_{\text{vphgpl}} = \frac{3600 \frac{\text{sec}}{\text{hr}}}{\text{saturation headway}_{\text{sec/veh}}} \quad 73.29$$

The ratio of flow to capacity ( $v/c$ ) is known as the *degree of saturation* and *volume-capacity ratio*. For convenience and consistency with the literature, the degree of saturation for lane group or approach  $i$  is designated as  $X_i$  instead of  $(v/c)_i$ , which might be confused with level of service  $i$ . When the flow rate equals the capacity,  $X_i$  equals 1.00; when flow rate is zero,  $X_i$  is zero.

$$X_i = \left( \frac{v}{c} \right)_i = \frac{v_i}{N s_i \left( \frac{g_i}{C} \right)} = \frac{v_i C}{N s_i g_i} \quad 73.30$$

When the overall intersection is to be evaluated with respect to its geometry and the total cycle time, the concept of the critical  $v/c$  ratio,  $X_c$ , is used. The *critical v/c ratio* is usually obtained for the overall intersection considering only the critical lane groups or approaches. For a typical cross intersection with a two-, three-, or four-phase signal, once the total cycle length is selected, the time for each phase is proportioned according to the critical ratios,  $X_{ci}$ , of each phase. Other factors can affect the detail adjustment of the phase length such as lost time, pedestrian crossings, and approach conditions. In Eq. 73.31,  $C$  is the total cycle length and  $L$  is the *lost time* per cycle. Time is lost when the intersection is not used effectively, as during start-up through the intersection. Lost time includes start-up time and some of the amber signal time. In conservative studies, lost time includes all of the amber signal time.

$$X_c = \left( \frac{C}{C - L} \right) \sum_{i \in ci} y_{c,i} \quad 73.31$$

The cycle lost time,  $L$ , is found from Eq. 73.32, where  $l$  is the phase lost time.

$$L = \sum_{i \in ci} l_{t,i} \quad 73.32$$

Equation 73.31 can be used to estimate the signal timing for the intersection if a critical  $v/c$  ratio is specified for the intersection. This equation can also be used to estimate the overall sufficiency of the intersection by substituting the specified maximum permitted cycle length and determining the resultant critical  $v/c$  ratio for the intersection.

When the critical  $v/c$  ratio is less than 1.00, the cycle length provided is adequate for all critical movements to pass through the intersection if the green time is proportionately distributed to the different phases. If the total green time is not proportionately distributed to the different phases, it is possible to have a critical  $v/c$  ratio of less than 1.00, but one or more individual oversaturated movements may occur within a cycle.

*Saturation flow rate*,  $s$ , is defined as the total maximum flow rate on the approach or group of lanes that can pass through the intersection under prevailing traffic and roadway conditions when 100% of the effective

green time is available. Saturation flow rate is expressed in units of vehicles per hour of effective green time (vphg) for a given lane group.

Saturation flow rate is calculated from the ideal saturation flow rate,  $s_o$ , which is assumed to be 1900 passenger cars per hour of green per lane (abbreviated “pcphgpl”). Adjustments are made for lane width,  $f_w$ ; heavy vehicles,  $f_{HV}$ ; grade,  $f_g$ ; existence of parking lanes,  $f_p$ ; stopped bus blocking,  $f_{bb}$ ; type of area,  $f_a$ ; lane utilization,  $f_{LU}$ ; right-hand turns,  $f_{RT}$ ; left-hand turns,  $f_{LT}$ ; and pedestrians and bicycles turning left and right,  $f_{Lpb}$  and  $f_{Rpb}$ . All of the adjustments are tabulated in the *HCM*.

$$s = s_o N f_w f_{HV} f_g f_p f_{bb} f_a f_{LU} f_{RT} f_{LT} f_{Lpb} f_{Rpb} \quad 73.33$$

Other important concepts in signalized intersection analysis are arrival type and platoon ratio. The *arrival type* (AT) is a categorization of the quality of progression through the intersection. There are six categories—arrival types 1 through 6. Arrival type 1 represents a “very poor progression” where 80% or more of the lane group arrives at the start of the red signal phase. Arrival type 6 represents near-ideal “exceptional progression” with the percentage of arrivals at the start of the green signal phase approaching 100%. The *platoon ratio*,  $R_p$ , is the ratio of the fraction of all vehicles in movement arriving during the green phase and the green signal time fraction. The default value is 1.00 for arrival type 3, which corresponds to random arrivals. *HCM* Exh. 18-8 quantifies arrival type by platoon ratio.

$$R_p = \frac{P_{\text{green}}}{\frac{g}{C}} \quad 73.34$$

### Example 73.6

A signalized intersection, without pedestrian access and located in a central business district, has an approach with two 11 ft lanes on a 2% downgrade. 10% of the traffic consists of heavy trucks, but there are no buses or RVs. Both lanes are through lanes; no turns are permitted.

There are no parking lanes. Arrivals to the intersection are random. What is the saturation flow rate of the approach?

*Solution*

Refer to the *HCM* to obtain the required adjustment factors.

$$s_o = 1900 \text{ pcphgpl} \quad [\text{HCM p. 16-26}]$$

$N = 2$  lanes

$$f_w = 1.00 \quad [\text{HCM Exh. 18-13}]$$

$$E_T = 2.0 \quad [\text{HCM p. 18-36}]$$

From *HCM* Eq. 18-6,

$$f_{HV} = \frac{100}{100 + \%HV(E_T - 1)} = \frac{100}{100 + (10)(2.0 - 1)} = 0.909$$

From *HCM* Eq. 18-7,

$$f_g = 1 - \frac{\%G}{200} = 1 - \frac{-2}{200} = 1.010$$

$$f_p = 1.000 \text{ for no parking} \quad [\text{HCM p. 18-37}]$$

$$f_{bb} = 1.000 \text{ for no bus blocking} \quad [\text{HCM p. 18-37}]$$

$$f_a = 0.900 \text{ for a central business district (CBD)} \quad [\text{HCM p. 18-37}]$$

$$f_{LU} = 1.0 \quad [\text{HCM p. 18-38}]$$

There is no pedestrian access and no turns are permitted, so

$$f_{RT} = 1.000$$

$$f_{LT} = 1.000$$

$$f_{Lpb} = 1.000$$

$$f_{Rpb} = 1.000$$

From Eq. 73.33,

$$s = s_o N f_w f_{HV} f_g f_{bb} f_a f_{LU} f_{RT} f_{LT} f_{Lpb} f_{Rpb}$$

$$\begin{aligned} &= \left( 1900 \frac{\text{pc}}{\text{hr-g-lane}} \right) (2 \text{ lanes})(1.00)(0.909)(1.010) \\ &\quad \times (1.000)(1.000)(0.90)(1.0)(1.000)(1.000) \\ &\quad \times (1.000)(1.000) \\ &= 3140 \text{ pcphg} \end{aligned}$$

## 18. CYCLE LENGTH: WEBSTER'S EQUATION

For each traffic flow at an intersection, there is a cycle length, known as the *resonant cycle length*, that optimizes the two-way progression for the controlling group. The optimum cycle length is a function of the speed of the traffic between intersections and the distances between intersections. The cycle length and splits can be determined by using either Webster's equation or the Greenshields-Poisson Method.

*Webster's equation* for minimum delay determines cycle lengths,  $C$ , for an isolated, pre-timed location. Despite its shortcomings, the equation provides a starting point for determining signal timings. It was developed by F.V. Webster of England's Road Research Laboratory

in the 1960s. The equation was developed from observations and measurements of delay at a large number of intersections with different geometric designs and cycle lengths. Random arrivals and fixed-time operation are inherent assumptions in using Webster's equation, although these two conditions are rarely valid in the United States. The equation becomes unstable at high levels of saturation and should not be used at locations where demand approaches capacity.

$$C = \frac{1.5L + 5}{1 - \sum_{\text{critical phases}} Y_i} = \frac{1.5L + 5}{1 - \sum_{\text{critical phases}} \left(\frac{v}{c}\right)_i} \quad 73.35$$

In Eq. 73.35,  $L$  is the lost time per cycle, and  $\sum Y_i$  is the sum of the degree of saturation taken over all critical approaches or lanes in the phase. The lost cycle time, usually taken as the sum of all intergreen periods, is estimated as the yellow change time plus the red clearance time, and can be assumed as five seconds.

To use Webster's equation, after identifying the critical phases, estimate the lost time per cycle,  $L$ , by multiplying the number of critical phases per cycle (2, 3, or 4) by five seconds, giving  $L$  possible values of 10 sec, 15 sec, or 20 sec. Estimate the degree of saturation,  $Y$ , for each critical phase by dividing the demand by the saturation flow (normally 1900 vehicles per hour per lane).  $C$  is generally rounded to the next higher five seconds.

## 19. CYCLE LENGTH: GREENSHIELDS METHOD

The *Greenshields model* (also referred to as the *Greenshields-Poisson method*) was developed by B. D. Greenshields in 1947 based on observations. Like Webster's equation, this method provides a starting point for determining signal timing. The method assumes vehicles arrive randomly (i.e., they do not interact) and describes arrivals of vehicles at an intersection by the Poisson distribution. The statistical nature of the method implicitly accommodates more vehicles than is expected on average. Some percentage of the time (e.g., 5–15%) the demand will exceed the time allocated, and not all arrivals at the intersection will be accommodated.

The Greenshields model is best suited for low-volume intersections, as the assumption of randomness is not always valid, particularly in urban areas when the critical lane volume exceeds 400 vph, and in congested areas. When the random assumption is not valid, the method will suggest unrealistically long cycle lengths, producing high delay and long lines of vehicles. The predicted cycle lengths can be used to determine the applicability of the method. If the cycle length calculated from the 85th percentile arrivals is greater than 80 sec for operation with two critical phases, 100 sec for three critical phases, and 120 sec for four critical phases, the volume is probably too high to use this method.

The method calculates the *phase time* (the time required to pass  $n$  vehicles in the critical lane) as

$$t_{\text{phase}} = 3.8 + 2.1n \quad 73.36$$

To use this method, assume a cycle length,  $C$ . Good starting assumptions are 60 sec for two critical phases, 75 sec for three critical phases, and 100 sec for four critical phases. Calculate the number of cycles per hour as  $3600 \text{ sec}/C$ . Then, for each critical phase, determine the mean arrival rate per lane by dividing the demand volume by the number of lanes and by the number of cycles per hour. Use the Poisson distribution to convert the mean arrival rate to the maximum expected arrival rate at the initial desired percentile level, generally 95% (see Table 73.15). Calculate the phase time from the expected arrival rate using Eq. 73.36. Add the times required for all of the critical phases, including the clearance and change times required (nominally 5 sec) for each critical phase. If the sum is more than 5 sec less than the assumed cycle, repeat the steps starting with the new (shorter) cycle length. If the sum is greater than the assumed cycle length by more than 5 sec, repeat using a lower percentile (e.g., 90% or 85%).

**Table 73.15** Poisson Arrivals per Cycle by Probability of Clearance

## 20. WARRANTS FOR INTERSECTION SIGNALING

MUTCD Sec. 4C contains methodology for determining when four-way traffic signals should be considered for an intersection. Specifically, charts and tables help determine if one or more of the conditions (known as *warrants*) that might justify traffic signals is present. The

traffic signal warrants have become progressively more quantitative with each *MUTCD* edition, and it is no longer possible to perform the analysis without consulting the *MUTCD* charts and tables.

Identifying a warrant is necessary but not sufficient to require signalization. Conditions that might exclude signalization even when a warrant is satisfied include an overall decrease in safety or effectiveness of the intersection and disruption of progressive traffic flow.

An engineering study of traffic volumes and destinations (i.e., turns) is required in order to use the *MUTCD* warrants. Counts of vehicles by type (heavy trucks, passenger cars and light trucks, public-transit vehicles, and in some locations, bicycles) and of pedestrians are required. Also needed is knowledge of speed limits, accident history, local needs of the elderly and disabled, and geometric design.

In some situations, traffic control signals (as compared to stop sign control) might undesirably increase vehicular delay and change the frequency of certain types of crashes. Alternatives to traffic control signals include installing signs along the major street to warn road users of an approaching stop-sign controlled intersection, increasing the intersection sight distances by relocating stop lines and making other geometric changes, installing measures to reduce speeds on the approaches, installing flashing warning beacons, installing or increasing roadway lighting to improve nighttime performance, restricting turning movements at particular times or throughout the day, and reducing the number of vehicles per approach lane by adding lanes on the minor approach street.

Intersection delays might also be reduced by increasing the capacity of the roadway in one or more directions. Widening a minor approach road will decrease that road's required green time. Such widening can easily be achieved by eliminating parking on that road in the vicinity of the intersection. In all cases of proposed roadway widening, a comparison should be made of the increased pedestrian crossing time to the green time saved due to improved vehicular flow.

- *Warrant 1, Eight-Hour Vehicular Volume:* The *MUTCD* specifies two alternative conditions, A and B, that if satisfied will result in Warrant 1. *MUTCD* Table 4C-1 establishes minimum vehicular volume in both directions, justifying signalization based on pure volume (condition A) and based on potential for interruption of continuous traffic (condition B). Satisfaction of either condition for any eight hours during a standard day is sufficient for Warrant 1. A combination of condition A and condition B uses 80% of the base warrant volumes. When the major street speed exceeds 40 mph (70 km/h), or in isolated communities with a population of less than 10,000, volumes are 70% of the base warrant volumes for conditions A or B, or 56% of the base volume for a combination of A and B.

- *Warrant 2, Four-Hour (Average Hourly) Vehicular Volume:* *MUTCD* Fig. 4C-1 and Fig. 4C-2 are used to determine whether the traffic approaching the intersection from one direction is the principal reason for evaluating signalization. *MUTCD* Fig. 4C-1 applies generally; Fig. 4C-2 applies to intersections with 85th percentile approach speeds in excess of 40 mph (70 kph) or in isolated communities with populations of less than 10,000. Satisfaction of either condition for any four hours during an average day is sufficient for Warrant 2.

- *Warrant 3, Peak Hour:* This warrant is designed to identify intersections whose minor-street traffic experiences undue delays for a minimum of one hour per day. It is expected that this warrant will be applied in cases where high-occupancy facilities (e.g., office and industrial complexes) attract or discharge large numbers of vehicles over a short period of time. Both graphical (*MUTCD* Fig. 4C-3 and Fig. 4C-4) and comparative minimum cut-offs for vehicle volume are given. Satisfaction of either condition for any single hour during an average day is sufficient for Warrant 3.

- *Warrant 4, Pedestrian Volume:* This warrant is designed to provide relief for pedestrians crossing a high-volume main street at intersections and in the middle of the block. In order to be applicable, the nearest existing signal must be at least 300 ft (90 m) away. The pedestrian volume warrant is evaluated graphically using *MUTCD* Fig. 4C-5 and Fig. 4C-7. Warrant 4 is satisfied when either of the plotted points representing the per-hour vehicle volumes on an average day for any consecutive fourhours per day or for any four consecutive 15-minute periods falls above its respective curve.

- *Warrant 5, School Crossing:* A large number of student pedestrians crossing a major street may justify signalization. The warrant requires a minimum of 20 students during the highest crossing hour and the determination that there are fewer adequate crossing gaps in the traffic stream than there are minutes in the period when children are crossing. There cannot be another traffic control signal closer than 300 ft (90 m). All other methodologies for providing crossing opportunities should be considered before applying Warrant 5.

- *Warrant 6, Coordinated Signal System:* Signals can be justified if they will induce desirable platooning and progressive movement of vehicles. This warrant can be applied to streets on which the traffic is predominantly one-way or two-way, as long as resulting signals are at least 1000 ft (300 m) apart, and the existing signals are so far apart that vehicular platooning is not achieved.

- *Warrant 7, Crash Experience:* This warrant is based on crash frequency. Three conditions are specified, all of which must be met: (A) Alternative remediation and enforcement efforts have been unsuccessful in

reducing crash frequency. (B) Five or more crashes involving reportable personal injury or property damage and that would have been prevented by signalization have occurred within a 12-month period. (C) The intersection experiences a minimum level of traffic during each of any eight hours of an average day. (See the *MUTCD*.)

- **Warrant 8, Roadway Network:** Signalization may be considered to encourage concentration and organization of traffic flow on a roadway network. Routes that can be considered for this warrant must be part of a current or future highway system that serves as the principal roadway network for through-traffic flow or includes highways entering or serving a city. This warrant requires either an intersection volume of 1000 vehicles per hour during the peak hour of a typical weekday and is expected to meet Warrants 1, 2, and 3 during an average weekday in the future, or the intersection has or soon will have a volume of at least 1000 vehicles per hour during each of any five hours of the weekend (i.e., Saturday or Sunday).

## 21. FIXED-TIME CYCLES

*Fixed-time controllers* are the least expensive and simplest to use. They are most efficient only where traffic can be accurately predicted. Fixed-time controllers are necessary if sequential intersections or intersections spaced less than  $\frac{1}{2}$  mi (0.8 km) apart are to be coordinated.

In general, the fixed signal cycle length should be between 35 sec and 120 sec. Green cycle lengths with fixed-time controllers should be chosen to clear all waiting traffic in 95% of the cycles. Usually, the 85th percentile speed is used in preliminary studies. Since the green cycle must handle peak loads, level of service is sacrificed during the rest of the day, unless the cycle length is changed during the day with *multi-dial controllers*.

Amber time is usually 3–6 sec. Six seconds may be used for higher speed roadways. A short all-red clearance interval may be provided after the amber signal to clear the intersection. It is also necessary to check that pedestrians can cross the intersection in the available walk time. (See Sec. 73.25.) A short all-red clearance interval is suggested after the green walk signal terminates.

Determining cycle lengths of signalized intersections is covered in *HCM* Chap. 18. Queuing models and simulation can also be used to determine or check cycle lengths in complex situations.

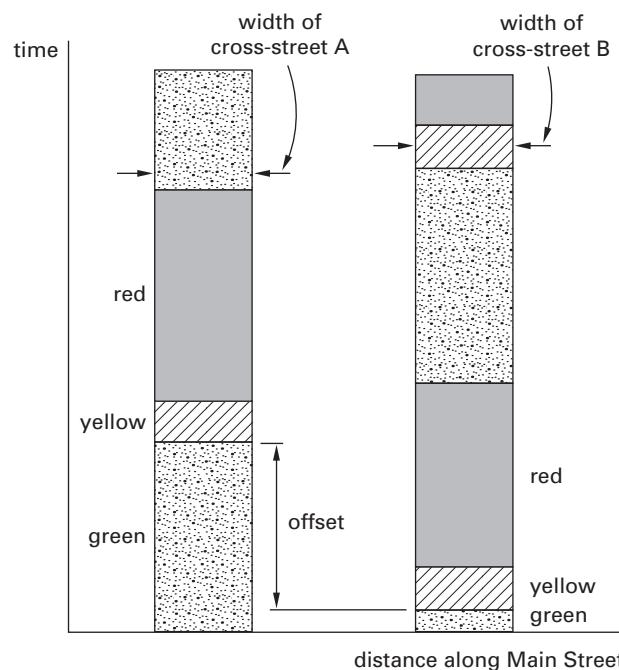

## 22. TIME-SPACE DIAGRAMS

To minimize the frustration of drivers who might otherwise have to stop at every traffic signal encountered while traveling in a corridor, it is desirable to coordinate

adjacent fixed-time signals. With *alternate mode operation*, every other signal will be green at the same time. By the time a vehicle moving at a specific speed has traveled the distance between two adjoining signals, the signal being approached will turn green. For *double-alternate mode operation*, two adjacent pairs of signals will have the same color (i.e., red or green), while the following two adjacent signals will have the opposite color. Alternate mode is preferred. Unless all of the signals are equidistant, it is unlikely that all inconvenience will be eliminated from the traffic stream.

Signal coordination is essentially achieved by setting the controller's *offset*. *Offset* is the time from the end of one controller's green cycle to the end of the next controller's green cycle. The following graphical procedure can be used to establish the offset by drawing *time-space diagrams* (*space-time diagrams*). The horizontal axis represents distance (typical scales are 1 in:100 ft or 1 in:200 ft), and the vertical axis represents time (usually in seconds). (See Fig. 73.6.)

**Figure 73.6** Time-Space Diagram Construction

**step 1:** Draw the main and intersecting streets to scale along the horizontal scale. When signals are separated by short distances, the cross-street widths should be drawn accurately.

**step 2:** Assume or obtain the actual average travel speed along the main street. (This is rarely the posted speed limit.) Starting at the lower left corner, draw a diagonal line representing the average speed.

**step 3:** Make an initial assumption for the cycle length. For a two-way street, the cycle length should be

either two times (alternate mode) or four times (double-alternate mode) the travel time at the average speed between intersections of average separation. The *effective green time* includes that portion (e.g., half) of the amber time that vehicles will continue to move through the intersection. Similarly, the *effective red time* includes the remainder of the amber time. The general timing guidelines of 35 sec minimum and 120 sec maximum apply.

*step 4:* Minimize the conflict between effective green and effective red periods at adjacent intersections. This can be done heuristically by cutting strips of paper for each intersection and marking off green and red periods according to the time scale. The strips are placed on the time-space diagram with offsets determined by the average speed and average intersection separation.

*step 5:* Check to see if the assumed cycle can accommodate the heaviest traveled intersection.

Figure 73.7 shows a time-space diagram with diagonal lines drawn between green cycle limits. (The two sets of diagonal lines represent the traffic flows in the two opposing directions.) The vertical distance between the diagonal lines indicates the green “window” of travel, known as the *bandwidth*. The *platoon length* is the horizontal distance between diagonal lines. The signal offset is the time difference (measured in the vertical direction) between the start of successive signals’ green periods.

### 23. TRAFFIC-ACTIVATED TIMING

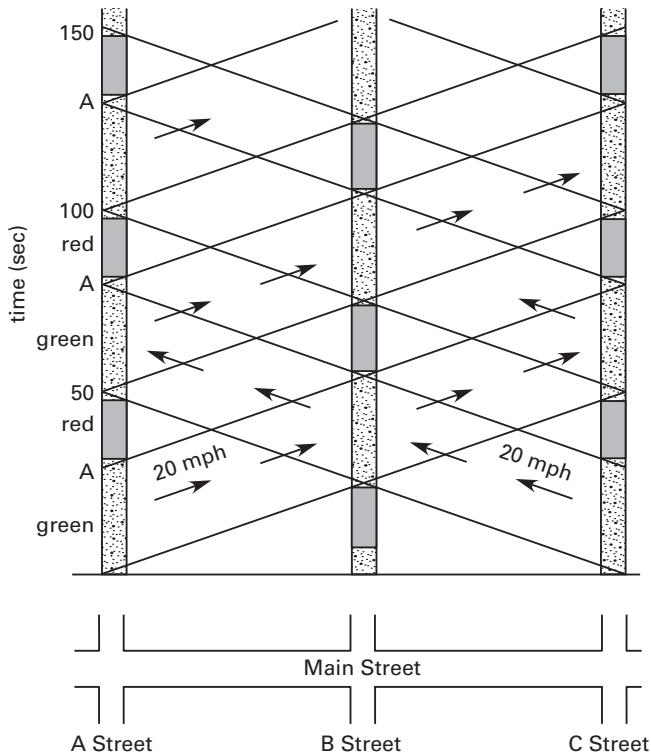

*Traffic-activated controllers* (or *activated controllers*) vary the green time periods in relation to the approach volume of traffic. Fully activated controllers manage all approaches based on traffic volume. Semi-activated controllers use a traffic-activated signal for at least one approach and a fixed-time signal for at least one of the other approaches. Both types are initially more expensive than fixed-time controllers. However, activated controllers do a better job of controlling flow, and they are better accepted by drivers.

Since cycle changes with activated controllers adjust to the arriving traffic volume, less detailed traffic counts are needed. Four parameters must be specified to completely define the timing sequence: initial period, vehicle time period, maximum time period, and clearance allowance.

- *Initial period:* The initial period must allow enough time for traffic stopped between the stop line and the detector to begin moving. The number of cars between the stop line and the detector is calculated from Eq. 73.37.

$$\text{no. of cars in initial period} = \frac{\text{distance between line and detector}}{\text{car length}} \quad 73.37$$

Figure 73.7 Time-Space Diagram Bandwidth

The first car can be assumed to cross the stop line approximately 5 sec after the green signal appears. The next car will require 3 sec more. Subsequent cars between the detector and stop line require  $2\frac{1}{4}$  sec. Studies have shown the average start-up lot time and average arrival headway to be approximately half of these values. However, these values accommodate the slowest of drivers.

- *Vehicle period:* The vehicle period must be long enough to allow a car crossing the detector (moving at the slowest reasonable speed) to get to the intersection before the amber signal appears. It is not necessary to have the vehicle get entirely through the intersection during the green, since the amber period will provide additional time. In a 30 mph (50 km/h) zone, a speed of approximately 20 mph (30 km/h) into the intersection is reasonable.
- *Maximum period:* The maximum period is the maximum delay that the opposing traffic can tolerate. For a main street, 60 sec is typical, while 30–40 sec is appropriate for a side street. There is no national regulation setting a maximum cycle length, although some agencies may have a maximum. A few authorities recommend a 150 sec or 160 sec maximum cycle length; however, the period should generally not exceed 120 sec. Theoretically, longer cycle lengths increase intersection capacity because less time is associated with starting up (i.e., lost time). However, after 120 sec, the capacity gain is small: less than a few percentage points.

- *Amber period:* The amber clearance period can be determined from the time required to perceive the light, brake, and stop the vehicle, plus the assumed average speed into the intersection. Amber periods of 3–6 sec are typical.
- *Green period:* The green period is the smaller of the sum of initial and vehicle periods and the maximum period.
- *All-red clearance period:* The all-red clearance period is a short period (i.e., 1 sec or 2 sec) that occurs after the amber period where all signals show red to allow for the full clearance of the intersection before the next green period begins.

## 24. PEDESTRIANS AND WALKWAYS

(Capacity analysis of pedestrian and bicycle movements in walkways is covered in *HCM* Chap. 16 as part of urban street analysis, in *HCM* Chap. 17 as part of intersections and roundabout analysis, and in *HCM* Chap. 23 as part of off-street facilities.)

The *HCM* recommends using an average walking speed of 4.0 ft/sec (1.22 m/s) and a 3 sec starting delay if elderly users constitute less than 20% of the walkway users. However, some people can walk as fast as 6 ft/sec (1.8 m/s), and 30–40% walk slower than 4 ft/sec (1.2 m/s). If more than 20% of walkway users are elderly, it may be appropriate to use a design speed of 3.3 ft/sec (1.0 m/s) and a 4–5 sec starting delay. Physically challenged individuals require additional consideration. An upgrade of 10% or greater reduces walking speed by 0.3 ft/sec (0.1 m/s).

The level of service (LOS) for pedestrians in walkways, sidewalks, and queuing areas is categorized in much the same way as for freeway and highway vehicles. Table 73.16 relates important parameters to the level of service. The primary criterion for determining pedestrian level of service is *space* (the inverse of density) per pedestrian. This, in turn, affects the speed at which pedestrians can walk. Mean speed and flow rate are supplementary criteria.

The *peak pedestrian flow rate*,  $v_{p,15}$ , is the number of pedestrians passing a particular point during the 15 min peak period (ped/15 min). The *effective walkway width*,  $W_E$ , is determined by subtracting any unusable width, including perceived “buffer zones” from adjacent features, from the total walkway width (ft or m). (Refer to *HCM* Exh. 17-17.) The average *pedestrian unit flow rate* (also known as *unit width flow*),  $v$ , is the number of pedestrians passing a particular point per unit width of walkway (ped/min-ft).

$$v = \frac{v_{p,15}}{15 W_E} \quad [HCM \text{ Eq. 23-3}] \quad 73.38$$

*Pedestrian speed*,  $S_p$ , is the average pedestrian walking speed (ft/sec). *Pedestrian density* is the average number of pedestrians per unit area (ped/ft<sup>2</sup> or ped/m<sup>2</sup>). The

**Table 73.16** Pedestrian Level of Service on Walkways and Sidewalks<sup>a</sup>

LOS	pedestrian space in ft <sup>2</sup> /ped	average speed in ft/sec	flow rate in ped/min-ft <sup>b</sup>	volume-capacity ratio <sup>c</sup>
A	> 60	> 4.25	≤ 5	≤ 0.21
B	> 40–60	> 4.17–4.25	> 5–7	> 0.21–0.31
C	> 24–40	> 4.00–4.17	> 7–10	> 0.31–0.44
D	> 15–24	> 3.75–4.0	> 10–15	> 0.44–0.65
E	> 8–15 <sup>d</sup>	> 2.50–3.75	> 15–23	> 0.65–1.0
F	≤ 8 <sup>d</sup>	≤ 2.50	variable	variable

(Multiply ft<sup>2</sup>/ped by 0.0929 to obtain m<sup>2</sup>/ped.)

(Multiply ft/sec by 0.3048 to obtain m/s.)

(Multiply ped/min-ft by 3.28 to obtain ped/min-m.)

<sup>a</sup>This table does not apply to walkways with steep grades (e.g., >5%).

<sup>b</sup>pedestrians per minute per foot width of walkway

<sup>c</sup>v/c ratio = flow rate/23. LOS is based on average space per pedestrian.

<sup>d</sup>In cross-flow situations, the LOS E-F threshold is 13 ft<sup>2</sup>/ped.

*Highway Capacity Manual 2010*. Copyright, National Academy of Sciences, Washington, D.C., Exhibit 23-1. Reproduced with permission of the Transportation Research Board.

reciprocal of pedestrian density is *pedestrian space*,  $A_p$  (ft<sup>2</sup>/ped or m<sup>2</sup>/ped), where  $v_p$  is the pedestrian flow per unit width (ped/min-ft or ped/min-m).

$$A_p = \frac{S_p}{v_p} \quad [HCM \text{ Eq. 23-4}] \quad 73.39$$

The maximum pedestrian *capacity* in walkways is 23 ped/min-ft, pedestrians per minute per foot of walkway width (75 ped/min-m). This occurs when the space is approximately 5–9 ft<sup>2</sup>/ped (0.47–0.84 m<sup>2</sup>/ped). Capacity drops significantly as space per pedestrian decreases, and movement effectively stops when space is reduced to 2–4 ft<sup>2</sup>/ped (0.19–0.37 m<sup>2</sup>/ped).

The *HCM* reports impeded flow starts at 530 ft<sup>2</sup>/ped (49 m<sup>2</sup>/ped), which is equivalent to 0.5 ped/min-ft (1.6 ped/min-m). These values are taken as the limits for LOS A. Also reported is that jammed flow in platoons starts at 11 ft<sup>2</sup>/ped (1 m<sup>2</sup>/ped), corresponding to 18 ped/min-ft (59 ped/min-m), which are used as the thresholds for LOS F. A *platoon* is a group of pedestrians walking together in a group.

## 25. CROSSWALKS

(Capacity analysis of pedestrians and bicycles at crosswalks is covered in *HCM* Chap. 18.)

Analysis of pedestrians in *crosswalks* is slightly different than in pure walkways. Walking is affected by signaling, turning vehicles, platooning, and interception of the platoon of pedestrians coming from the opposite side.

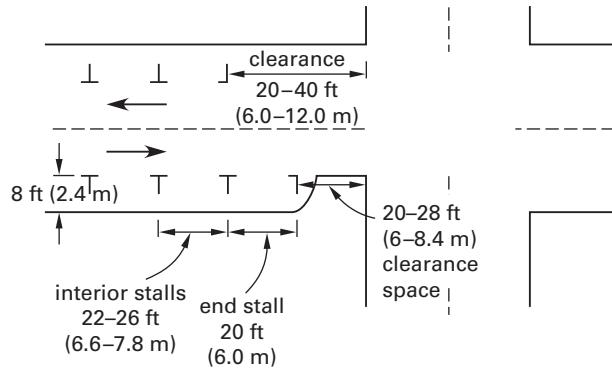

## 26. PARKING

The minimum parallel street parking *stall width* is commonly taken as 7 ft (2.1 m) in a residential area and may range from 8 ft to 11 ft (2.4 m to 3.3 m) in a

commercial or industrial area. This width accommodates the vehicle and its separation from the curb. Stalls 7 ft (2.1 m) wide are substandard and should be limited to residential areas and attendant-parked lots. Widths larger than 9 ft (2.7 m) are appropriate in shopping areas where package loading is expected. If the width is specified between 10 ft and 12 ft (3.0 m and 3.7 m), the street parking corridor can be used for delivery trucks or subsequently converted to an extra traffic lane or bicycle path. The minimum length of a parallel street parking stall is 18 ft (5.4 m). In order to accommodate most cars, longer lengths between 20 ft and 26 ft (6.0 m and 7.8 m), may be used.

Figure 73.8 illustrates parallel street parking near an intersection as recommended by the AASHTO *Green Book*. The 20–28 ft (6–8.4 m) clearance from the last stall to the intersection is required to prevent vehicles from using the parking lane for right-turn movements.

**Figure 73.8** AASHTO Green Book Parallel Parking Design

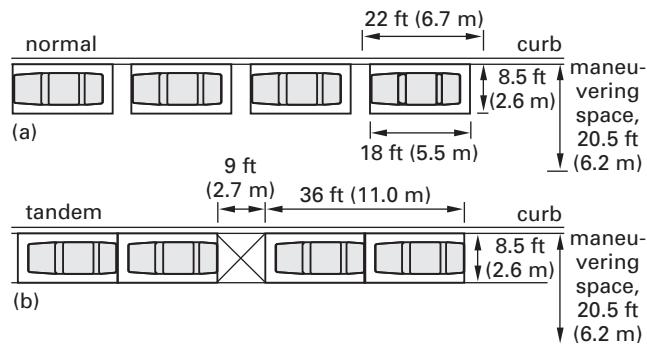

From *A Policy on Geometric Design of Highways and Streets*, 2011, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

**Tandem parking** (also known as *double-alternate parking*) provides two shortened stalls placed end to end with a single maneuver zone. With tandem parking, each vehicle will be boxed in in at least one direction. A parking vehicle pulls into the stall space and maneuver zone. The vehicle is removed from the traffic stream in about 4 sec. (With the traditional parallel parking procedure, traffic may halt for as much as 30 sec or more while a vehicle attempts to back into the parking space.) The original (1970) tandem design required 56 ft (17.1 m): two 20 ft (6.1 m) stalls and a 16 ft (4.9 m) maneuver zone. With modern smaller cars, the required space can be reduced to 45–50 ft (13.7–15.3 m): two 18 ft (5.5 m) stalls and a 9–14 ft (2.7–4.3 m) maneuver zone. Other dimensions may work. Typical tandem parking geometry is given in Fig. 73.9.

**Diagonal parking (angle parking)** can be specified with angles to the curb of 45°, 60°, 75°, and 90°. The effects of diagonal parking on lane width can be determined from trigonometry. The significant disadvantage of

**Figure 73.9** Typical Tandem Curb Parking Geometry

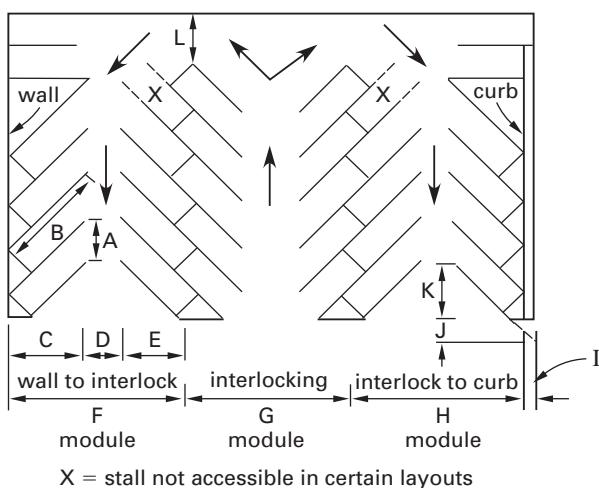

impaired vision when backing up should be considered when designing angle parking.

In designing *parking lots*, the maximum capacity of the lot can be calculated by dividing the gross lot area by the minimum area per car (e.g., 280–320 ft<sup>2</sup> (26–30 m<sup>2</sup>) depending on the types of cars in the community). Figure 73.10 and accompanying Table 73.17 show a typical module with two 90° spaces and an aisle between that can be used as a template for quick layout of spaces. Even though most textbooks show the need for a 26 ft aisle when using 9 ft wide × 18.5 ft long stalls set at 90°, a slightly smaller 60 ft module using 18 ft long stalls and a 24 ft wide two-way aisle has proven more than adequate for general traffic in much of the United States. The practical limits needed for door opening space between cars and driver or passenger access to vehicles suggest a stall width of no less than 8.5 ft (2.6 m), unless vehicles are segregated by general size. Widths in excess of 9 ft (2.7 m) and lengths in excess of 18.5 ft (5.6 m) are rarely necessary. For selected spaces with restricted access, such as the end space against a wall or the last space at the end of a blind aisle, additional width should be added. In many jurisdictions, local zoning requirements set the minimum stall size and other parameters (such as fire access lanes) that may exceed standard published references.

Space efficiency and access convenience are optimized in parking lots having a minimum of odd-shaped boundaries and that are more or less rectangular in shape. Some handbooks suggest 60° stall angles, one-way aisles, and stall overlaps to obtain space efficiency. These types of layout can show good parking densities but sometimes result in odd space configurations and many unusable spaces, leading to losses in efficiency. For instance, one-way aisles are susceptible to blockage due to careless parking or maneuvering delays. Layout and line stripe maintenance of skew angles with overlapping spaces are more difficult, especially where detail adjustments are necessary to accommodate lot perimeter irregularities. Diagonal layouts quite often have odd-shaped leftover spaces that become subject to improper parking when the lot is crowded.

More recent experience has shown that 90° stalls and two-way aisles provide high customer acceptance for

**Figure 73.10** Parking Lot Layout  
(use with Table 73.17)

	—	24.0	24.0	24.0	24.0

(Multiply ft by 0.3048 to obtain m.)

random-arrival situations. Breaking up long aisles with a cross passage every 20 spaces or so allows users to move freely among the aisles while hunting for an available space and provides additional exit paths should blockage occur. Shorter aisles placed 90° from the access lanes allow vehicles to quickly enter and leave available spaces, thereby improving the level of service of the lot. Many cars today are equipped with power steering and have more compact outlines, making them easily maneuverable into smaller spaces. This can reduce driver frustration and the potential for vehicle damage. As with any design question, several layout arrangements should be considered before the final one is selected.

Other facts that must be considered when designing a parking lot include the location of driveways, lighting,

landscaping, sidewalks, and entry/exit systems (i.e., gates, doors, ticketing, and so on). Only after these factors have been specified can the layout be designed to maximize the number of parking places.

ADA (Americans with Disabilities Act) *accessible parking spaces* (i.e., “handicapped parking”) are required in all parking lots for visitors, customers, and employees. The total number of accessible spaces is given in Table 73.18. The number of designated van-accessible spaces is obtained by dividing the total number of accessible spaces by eight and rounding up, with no less than one van-accessible space. All remaining spaces can be car accessible.

**Table 73.18** Minimum Number of Accessible Parking Spaces<sup>a</sup>

total number of parking spaces in lot	total minimum number of car- and van-accessible parking spaces <sup>b</sup>

501–1000	2% of total
> 1000	20 plus 1 for each 100 over 1000

<sup>a</sup>Subject to changes in ongoing legislation.

<sup>b</sup>One-eighth of total minimum accessible spaces must be van accessible.

Source: ADA Standards for Accessible Design 4.1.2(5)

Accessible spaces may be dispersed among multiple lots with accessible entrances. Spaces should be located closest to accessible building entrances. An accessible curb cut is required from the parking lot to the general walkway. The accessible route must be at least 3 ft (0.9 m) wide. The slope along the accessible route should not be greater than 1:12 in the direction of travel.

Car-accessible spaces should be 8 ft (2.4 m) wide, with a 5 ft (1.5 m) accessible aisle alongside. Two adjacent accessible spaces can share one aisle. Van-accessible spaces should be 8 ft (2.4 m) wide, with an 8 ft (2.4 m) access aisle. Vans with lifts generally exit on the passenger side. Van-accessible spaces also require a 98 in (2490 mm) minimum height clearance. All surfaces must be stable and slip-resistant, and have a maximum cross slope of 2%. Signage with the accessibility symbol must be provided. Special van-accessible signage is required for appropriate spaces.

## 27. HIGHWAY INTERCHANGES

*Highway interchanges* allow traffic to enter or leave a highway. Interchange locations are affected by the

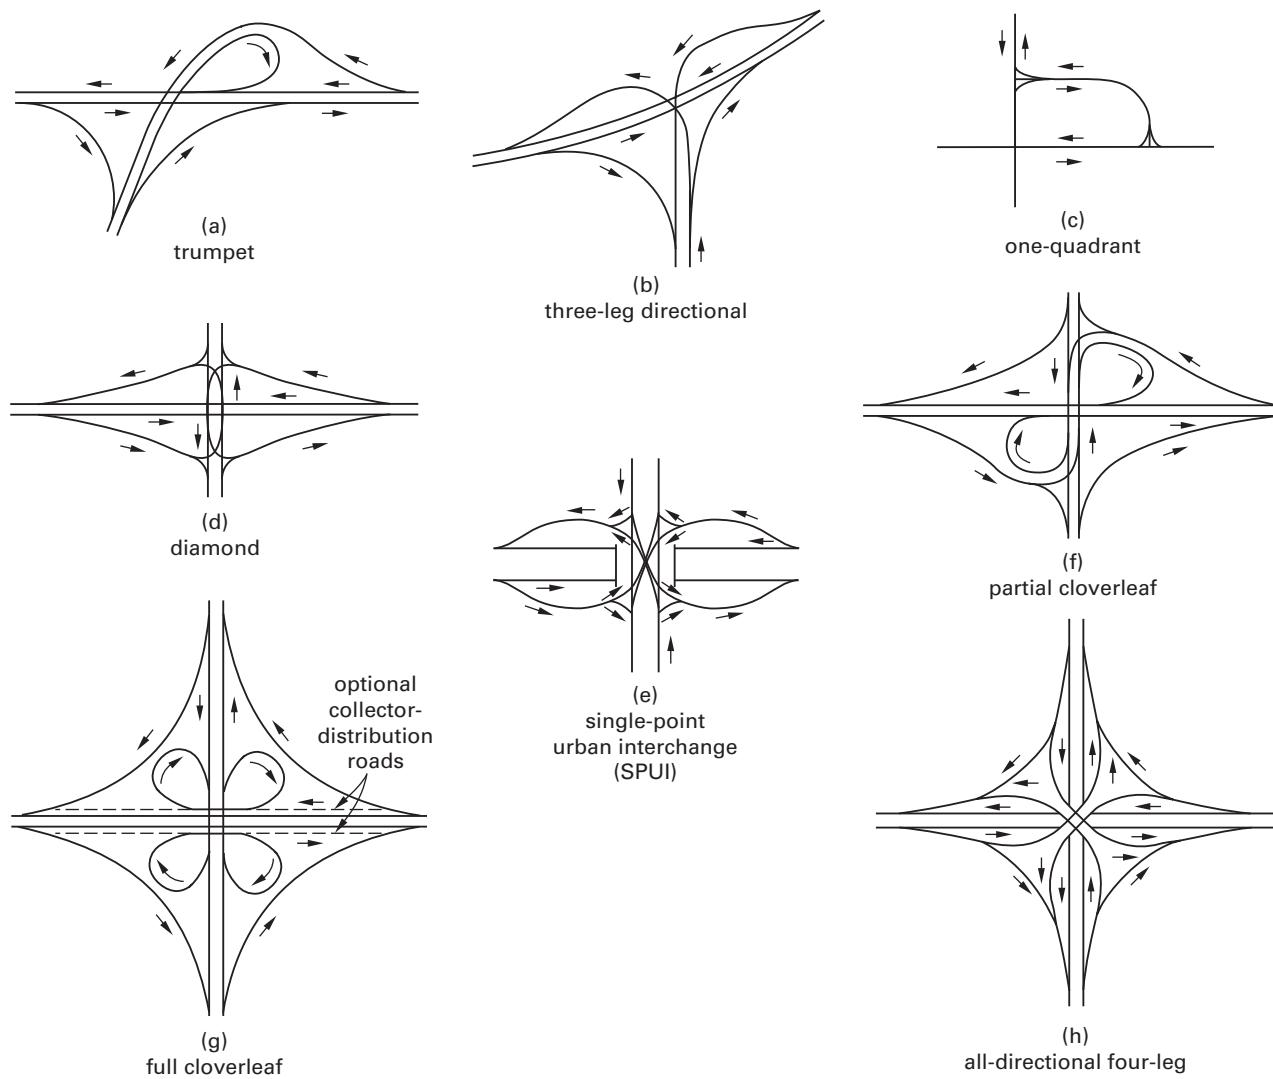

volume of traffic expected on the interchange, convenience, and required land area. The frequency of interchanges along a route should be sufficient to allow weaving between the interchanging traffic. Factors affecting the type of interchange chosen include cost, available land, total flow volume, volume of left turns, and volume of weaving movement. Except in extreme cases, several different designs may be capable of satisfying the design requirements shown in Fig. 73.11 and Fig. 73.12.

*Diamond interchanges* are suitable for major-road-minor-road intersections. Diamond interchanges can

handle fairly large volume roadways and can accommodate some left turns at grade. Left turns must be made directly on the minor highway. They lend themselves to staged construction. The frontage roads and/or ramps can be constructed, leaving the freeway lanes to be built at a later date. The right-of-way costs are low, since little additional area around the freeway is required.

Diamond interchanges force traffic using a ramp to substantially reduce its speed. Since the capacity per ramp is limited to approximately 1000 vph, diamond interchanges cannot be used for freeway-to-highway intersections.

Figure 73.11 Interchange Types

Since diamond interchanges (except for the single-point interchange) place two signalized intersections in close proximity, it is possible for *demand starvation* to occur. Demand starvation occurs when a portion of the green signal of the downstream intersection is unused due to delays or blockage at the upstream intersection. Demand starvation can be caused by suboptimal signal coordination, as well as by queues from the downstream intersection effectively blocking departures from the upstream intersection.

*Cloverleaf interchanges* incorporate loop connections and allow nonstop left turn movement. *Partial cloverleafs* (known as *parclos*) provide for nonstop left turns along selected routes only, whereas *full cloverleafs* provide nonstop turning for all four traffic directions. (A *loop* or *loop ramp* is a 270° turn in the direction opposite the final direction of travel.) Cloverleafs provide for free flow by separating the traffic in both directions. However, they require large rights-of-way. Cloverleaf intersections slow traffic from the design speed and require short weaving distances. Turning traffic follows a circuitous route. The practical limit of capacity of loop ramps is approximately 800–1200 vph. Cloverleaf interchanges should not be used to connect two freeways with large volumes of turning traffic.

Both diamond and cloverleaf intersections can be improved by various means, including by the use of a third level and collector-distributor roads to increase the speed and volume of weaving sections. *Directional interchanges (all-directional interchanges)* allow direct or semidirect connections for left turn movements. The design speeds of connections normally are near the design speed of the through lanes, and large traffic volumes can be handled without significant weaving. However, large rights-of-way are required. Directional interchanges are expensive because of the structures provided. Directional interchanges may contain three or four layers or be of *rotary bridge* design.

When there are only three approach legs, *T*-, *Y*-, or *trumpet interchanges* can be used.

The *single-point urban interchange* (SPUI), also known as the *urban interchange* and *single-point diamond interchange*, is a type of diamond interchange with a single signalized intersection controlling all left turns. All right turns are free flow, which increases the capacity above that of traditional diamond interchanges.

The main advantage of SPUIs is that they require only a narrow right-of-way, thereby reducing land acquisition

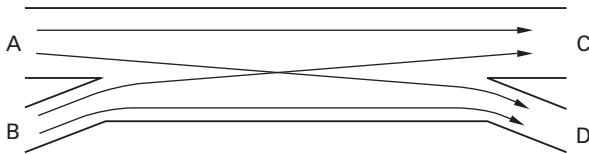

cost. The main disadvantage, as with all traffic bridges, is a high construction cost. There are additional geometric design features that require careful consideration, such as the elliptical left-hand turning path, pedestrian accommodations, and the difficulty in accommodating freeways approaching with high skew angles (e.g., more than 30°).

## 28. WEAVING AREAS

(Analysis and design procedures for weaving areas are covered in *HCM* Chap. 12.)

*Weaving* is the crossing of at least two traffic streams traveling in the same general direction along a length of highway without traffic control. In the freeway segment shown in Fig. 73.13, flows A–D and B–C cross the paths of other traveling vehicles, so these flows are the segment's *weaving movements*. Flows A–C and B–D do not cross any other vehicles' paths, so they are the segment's *nonweaving movements*.

Figure 73.13 Freeway Weaving Segment

*Highway Capacity Manual 2010.* Copyright, National Academy of Sciences, Washington, D.C., Exhibit 12-1. Reproduced with permission of the Transportation Research Board.

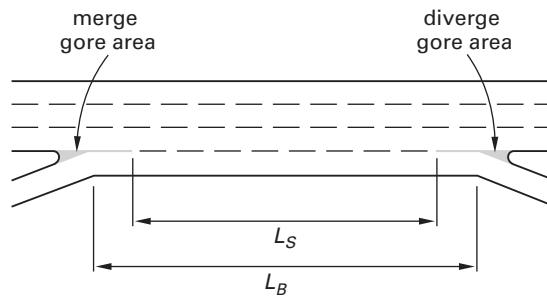

Weaving is an issue that must be considered in interchange selection, and interchanges without weaving are favored over interchanges with weaving. Weaving areas require increased lane-change maneuvers and result in increased traffic turbulence. Making a weaving segment longer allows for more time for lane changes. Under demand conditions, longer weaving segments increase capacity and decrease traffic density and turbulence.

The operating characteristics of a weaving segment are affected by the length, width, and configuration of the weaving segment. The *weaving segment length*<sup>5</sup> is the distance between the merge and diverge segments. There are two measures of length used in the *HCM*, as shown in Fig. 73.14. The *short length*,  $L_S$ , is the distance between the end points of any barrier markings (i.e., solid white lines) that discourage or prohibit lane changing. The *base length*,  $L_B$ , is the distance between *gore areas* where the left edge of the ramp lane and the right edge of the freeway lane meet. Where no solid white

lines are present, the two lengths are the same (i.e.,  $L_S = L_B$ ).

The *weaving segment width* is measured as the number of continuous lanes within the merging and diverging (i.e., entry and exit) gore areas. It is primarily controlled by the number of lanes on the entry and exit legs and the weaving segment configuration.

Figure 73.14 Lengths of a Weaving Segment

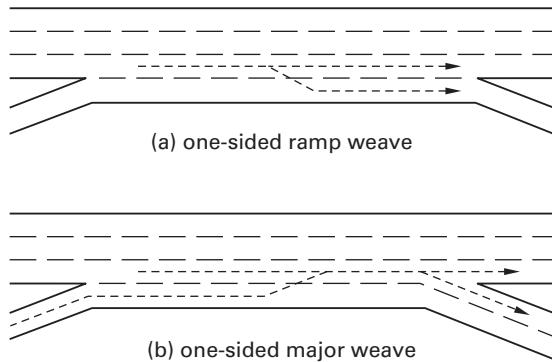

*Highway Capacity Manual 2010.* Copyright, National Academy of Sciences, Washington, D.C., Exhibit 12-2. Reproduced with permission of the Transportation Research Board.

The *weaving segment configuration* refers to the relative placement and number of entry and exit lanes for a roadway section. Configuration is based on the number of required lane changes that must be performed by the two weaving flows in the section. The *HCM* identifies two types of weaving segment configurations: one-sided and two-sided weaving segments.

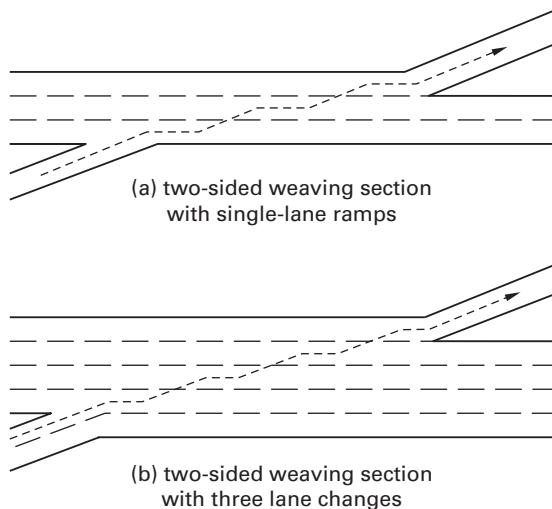

*One-sided weaving segments* have the entry and the exit from the weaving segment on the same side of the freeway. Figure 73.15 illustrates two types of one-sided weaving segments. Figure 73.15(a) illustrates a *one-sided ramp weave* where the on- and off-ramp are connected by a continuous auxiliary lane and where every weaving vehicle must make one lane change. Figure 73.15(b) illustrates a *one-sided major weave* where no continuous auxiliary lane is present and only the ramp to the freeway weaving segment requires a lane change. A *major weave segment* is a segment where three or more entry or exit legs have multiple lanes.

*Two-sided weaving segments* have an on-ramp on one side of the freeway closely followed by an off-ramp on the opposite side of the freeway. Figure 73.16(a) illustrates a *two-sided weaving section with single-lane ramps* where a one-lane, right-side on-ramp is closely followed by a one-lane, left-side off-ramp (or vice versa). It is the most common type of two-sided weave. Figure 73.16(b) illustrates a less common two-sided weave, where one of the ramps has multiple lanes. Typically, two-sided weaving segments require drivers to make three or more lane changes when entering or exiting the freeway. Though Fig. 73.16(a) only requires two lane changes, it still qualifies as a two-sided weaving segment because the entering and exiting vehicles create a weaving flow with the through-traffic movement.

<sup>5</sup>Previous editions of the *HCM* tied definitions of weaving segments to cloverleaf interchanges as most existing weaving segments were part of such interchanges. The *HCM* has replaced such definitions with a more general definition of length to reflect the fact that newer weaving segments occur in a variety of situations and designs.

## 29. TRAFFIC CALMING

Although traditional designs based on the *HCM* and the *AASHTO Green Book* have intended to maximize the flow of traffic, *traffic calming* features are introduced to slow the flow. Such features include traffic circles, narrow streets, curb extensions, and textured crosswalks. These features, which generally are contrary to traditional design guidelines in the *AASHTO Green Book*, are in response to a new urbanism that encourages consideration of historical, community, and aesthetic factors.

## 30. ECONOMIC EVALUATION

*Road user costs* include fuel, tires, oil, repairs, time, and accidents. Such costs affect design decisions where there

are delays due to congestion, stops, turning, and so on. A reduction in road-user costs can be used to economically justify (i.e., as an economic warrant) interchanges and other features. Reductions in road-user costs are generally far greater than the increased cost of travel times that interchanges cause (compared to at-grade intersections).

Generally, public projects (such as interchanges) are justified using a benefit-cost ratio of annual benefits to annual capital costs. *Annual benefits* is the difference in road-user costs between the existing and improved conditions. *Annual capital costs* is the sum of interest and the amortization of the cost of the improvement. When staged construction is anticipated, incremental costs must be used to justify the construction of future subsequent stages.

Much can be done to improve the safety of some roadway sections. Features such as breakaway poles, cushioned barriers, barriers separating two directions of traffic, and direction channeling away from abutments are common. These features must be economically justified, particularly where they are to be retrofitted to existing highways. The justification is usually the value of personal injury and property damage avoided by the installation of such features.

There are three general classifications of accidents (also called *crashes*): those with property damage only, those with injury combined with property damage, and those involving death with property damage. The cost of each element (i.e., death, injury, and property damage) can be evaluated from insurance records, court awards, state disability records, and police records. Actuaries may be able to prepare estimates of remaining potential earnings. Also, federal agencies such as the U.S. National Safety Council and OSHA are active in monitoring and maintaining similar statistics.

## 31. CONGESTION PRICING

*Congestion pricing* (CP) is the charging of higher tolls (on toll roads and bridges) during peak traffic hours. CP limits the use of roadways during peak periods by providing an economic disincentive. The disincentive can be a toll (also called a *cordon charge* or *road-access charge*) on an otherwise free road. It can also be a fuel tax, or even a car purchase and ownership taxation. On toll facilities, tolls can be raised only during peak hours. Alternatively, additional lanes can be constructed to collect tolls from single-occupancy vehicles.

Congestion pricing is a politically sensitive concept. It has not been met with significant success.

## 32. QUEUING MODELS

A *queue* is a waiting line. Time spent in a system (i.e., the *system time*) includes the *waiting time* (time spent waiting to be served) and the *service time*. *Queuing theory* can be used to predict the system time,  $W$ , the

time spent in the queue,  $W_q$ , the average queue length,  $L_q$ , and the probability that a given number of customers will be in the queue,  $p\{n\}$ .

Different queuing models accommodate different service policies and populations. For example, some multiserver processes (e.g., tellers drawing from a line of banking customers) draw from a single queue. Other processes (e.g., bridge tolltakers) have their own queues. Most models predict performance only for steady-state operation, which means that the service facility has been open and in operation for some time. Start-up performance often must be evaluated by simulation.

The following basic relationships are valid for all queuing models predicting steady-state performance.  $1/\lambda$  is the average time between arrivals, and  $1/\mu$  is the average service time per server. For a system to be stable and viable (i.e., to reach a steady-state equilibrium queue length),  $\lambda$  must be less than  $\mu s$ , where  $s$  is the number of servers. This is known as the *undersaturated condition*. The *utilization factor*,  $\rho$ , is defined as the ratio  $\lambda/\mu$ .

$$L = \lambda W \quad 73.40$$

$$L_q = \lambda W_q \quad 73.41$$

$$W = W_q + \frac{1}{\mu} \quad 73.42$$

Most queuing models are mathematically complex and fairly specialized. However, two models are important because they adequately predict the performance of simple queuing processes drawing from typical populations. These are the M/M/1 single-server model and the M/M/ $s$  multi-server model.

### 33. M/M/1 SINGLE-SERVER MODEL

In the M/M/1 single-server model, a single server ( $s = 1$ ) draws from an infinite calling population. The service times are exponentially distributed with mean  $\mu$ . The specific service time distribution is defined by Eq. 73.43.

$$f(t) = \mu e^{-\mu t} \quad 73.43$$

As a consequence of using the exponential distribution, the probability of a customer's remaining service time exceeding  $h$  (after already spending time with the server) is given by Eq. 73.44. The probability is not affected by the time a customer has already spent with the server.

$$P\{t > h\} = e^{-\mu h} \quad 73.44$$

Arrival rates are described by a Poisson distribution with mean  $\lambda$ . The probability of  $x$  customers arriving in any period is

$$p\{x\} = \frac{e^{-\lambda} \lambda^x}{x!} \quad 73.45$$

The following relationships describe an M/M/1 model.  $p\{n\}$  is the probability that  $n$  customers will be in the system, either being served or waiting for service.

$$p\{0\} = 1 - \rho \quad 73.46$$

$$p\{n\} = p\{0\}\rho^n \quad 73.47$$

$$W = \frac{1}{\mu - \lambda} = W_q + \frac{1}{\mu} = \frac{L}{\lambda} \quad 73.48$$

$$W_q = \frac{\rho}{\mu - \lambda} = \frac{L_q}{\lambda} \quad 73.49$$

$$L = \frac{\lambda}{\mu - \lambda} = L_q + \rho \quad 73.50$$

$$L_q = \frac{\rho\lambda}{\mu - \lambda} \quad 73.51$$

#### Example 73.7

A state's truck weigh station has the ability to handle an average of 20 trucks per hour. Trucks arrive at the average rate of 12 per hour. Performance is described by an M/M/1 model. Find the steady-state values of (a) the time spent waiting to be weighed, (b) the time spent in the queue, (c) the number of trucks in the station, (d) the number of trucks in the queue, and (e) the probability that there will be five trucks in the system being weighed or waiting to be weighed at any time.

*Solution*

The utilization factor is

$$\rho = \frac{\lambda}{\mu} = \frac{12 \frac{\text{trucks}}{\text{hr}}}{20 \frac{\text{trucks}}{\text{hr}}} = 0.6$$

(a) Using Eq. 73.48, the average time spent waiting in the queue and being weighed is

$$W = \frac{1}{\mu - \lambda} = \frac{1}{20 \frac{\text{trucks}}{\text{hr}} - 12 \frac{\text{trucks}}{\text{hr}}} = 0.125 \text{ hr/truck}$$

(b) Using Eq. 73.49, the average time spent waiting in the queue is

$$W_q = \frac{\rho}{\mu - \lambda} = \frac{0.6}{20 \frac{\text{trucks}}{\text{hr}} - 12 \frac{\text{trucks}}{\text{hr}}} = 0.075 \text{ hr/truck}$$

(c) Using Eq. 73.50, the average number of trucks in the station is

$$L = \frac{\lambda}{\mu - \lambda} = \frac{12 \frac{\text{trucks}}{\text{hr}}}{20 \frac{\text{trucks}}{\text{hr}} - 12 \frac{\text{trucks}}{\text{hr}}} = 1.5$$

(d) Using Eq. 73.51, the average number of trucks waiting in the queue is

$$L_q = \frac{\rho\lambda}{\mu - \lambda} = \frac{(0.6)\left(12 \frac{\text{trucks}}{\text{hr}}\right)}{20 \frac{\text{trucks}}{\text{hr}} - 12 \frac{\text{trucks}}{\text{hr}}} = 0.9$$

(e) Using Eq. 73.46 and Eq. 73.47, the probability of five trucks is

$$p\{0\} = 1 - \rho = 1 - 0.6 = 0.4$$

$$p\{5\} = p\{0\}\rho^5 = (0.4)(0.6)^5 = 0.031$$

### 34. M/M/s MULTI-SERVER MODEL

Similar assumptions are made for the M/M/s model as for the M/M/1 model, except that there are  $s$  servers instead of 1. Each server has an average service rate of  $\mu$  and draws from a single common calling line. Therefore, the first person in line goes to the first server that is available. Each server does not have its own line. (This model can be used to predict the performance of a multiple-server system where each server has its own line if customers are allowed to change lines so that they go to any available server.) The following equations describe the steady-state performance of an M/M/s system with  $\rho = \lambda/\mu s$ .

$$W = W_q + \frac{1}{\mu} \quad 73.52$$

$$W_q = \frac{L_q}{\lambda} \quad 73.53$$

$$L_q = \frac{p\{0\}\rho\left(\frac{\lambda}{\mu}\right)^s}{s!(1-\rho)^2} \quad 73.54$$

$$L = L_q + \frac{\lambda}{\mu} \quad 73.55$$

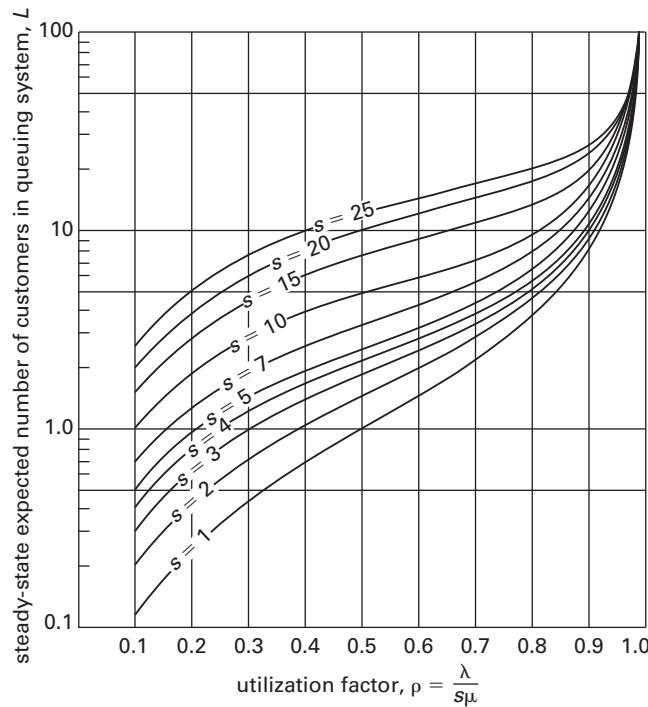

$$p\{0\} = \frac{1}{\frac{\left(\frac{\lambda}{\mu}\right)^s}{s!\left(1 - \frac{\lambda}{s\mu}\right)} + \sum_{j=0}^{s-1} \frac{\left(\frac{\lambda}{\mu}\right)^j}{j!}} \quad 73.56$$

$$p\{n\} = \frac{p\{0\}\left(\frac{\lambda}{\mu}\right)^n}{n!} \quad [n \leq s] \quad 73.57$$

$$p\{n\} = \frac{p\{0\}\left(\frac{\lambda}{\mu}\right)^n}{s!s^{n-s}} \quad [n > s] \quad 73.58$$

Figure 73.17 is a graphical solution to the M/M/s multiple-server model.

**Figure 73.17** Mean Number in System ( $L$ ) for M/M/s System

### Example 73.8

A company has several identical machines operating in parallel. The average breakdown rate is 0.7 machines per week. Assume the number of breakdowns per week is a Poisson distribution. There is one repair station for the entire company. It takes a maintenance worker one entire week to repair a machine, although the time is reduced in proportion to the number of maintenance workers assigned to the repair. Each maintenance worker is paid \$400 per week. Machine downtime is valued at \$800 per week. Other costs (additional tools, etc.) are to be disregarded. What is the optimum number of maintenance workers at the repair station?

*Solution*

Using two or more maintenance workers only decreases the repair time, so this is a single-server model, even with multiple maintenance workers.

The average number of machines breaking down each week is the mean arrival rate,  $\lambda = 0.7$  per week. With one worker, the repair rate,  $\mu$ , is 1.0 per week.

The average time a machine is out of service (waiting for its turn to be repaired and during the repair) is  $W$ , the “time in the system.” Using Eq. 73.48,

$$W = \frac{1}{\mu - \lambda} = \frac{1}{1 - 0.7} = 3.33 \text{ wk}$$

With one maintenance worker, the average downtime cost in a week is

$$\begin{aligned} & \left( \frac{\text{downtime cost}}{\text{machine-wk}} \right) (\text{no. of machines})(\text{no. of wk}) \\ &= (\text{downtime cost}) \lambda W \\ &= \left( 800 \frac{\$}{\text{machine-wk}} \right) (0.7 \text{ machines})(3.33 \text{ wk}) \\ &= \$1864 \end{aligned}$$

However, the product of  $\lambda$  and  $W$  is the same as the average number of machines in the system,  $L$ . The average number of machines in the system,  $L$  (i.e., being repaired or waiting for repair), is found using Eq. 73.50.

$$L_1 = \frac{\lambda}{\mu - \lambda} = \frac{0.7}{1 - 0.7} = 2.33$$

The total average weekly cost with one worker is the sum of the costs of the worker and the downtime.

$$C_{t,1} = (1 \text{ worker}) \left( 400 \frac{\$}{\text{wk}} \right) + (2.33)(\$800) = \$2264$$

With two workers, the values are

$$\mu = (2 \text{ workers}) \left( \frac{1}{\text{worker-wk}} \right) = 2/\text{wk}$$

$$L_2 = \frac{0.7}{2 - 0.7} = 0.538$$

$$C_{t,2} = (2) \left( 400 \frac{\$}{\text{wk}} \right) + (0.538)(\$800) = \$1230$$

With three workers, the values are

$$\mu = (3 \text{ workers}) \left( \frac{1}{\text{worker-wk}} \right) = 3/\text{wk}$$

$$L_3 = \frac{0.7}{3 - 0.7} = 0.304$$

$$C_{t,3} = (3) \left( 400 \frac{\$}{\text{wk}} \right) + (0.304)(\$800) = \$1443$$

Adding workers will increase the costs above  $C_3$ . Two maintenance workers should staff the maintenance station.

### Example 73.9

Twenty identical machines are in operation. The hourly reliability for any one machine is 90%. (That is, the probability of a machine breaking down in any given hour is 10%.) The cost of downtime is \$5 per hour. Each broken machine requires one technician for repair, and the average repair time is one hour. If all technicians are busy, broken machines wait idle. Each technician costs \$2.5 per hour. How many separate technicians should be used?

### Solution

This is a multiple-server model. It is assumed that the M/M/ $s$  assumptions are satisfied. The mean arrival rate,  $\lambda$ , is  $(0.10)(20) = 2$  per hour. The repair rate,  $\mu$ , is 1 per hour. Clearly, one technician cannot handle the workload, nor can two technicians. The average number of machines in the system,  $L$  (i.e., being repaired or waiting for repair), is calculated for two, three, four, and five servers. The total cost per hour is calculated as

$$C = 2.5s + 5L$$

$s$	$p_0$	$L_q$	$L$	cost per hour
2	—	—	—	infinite
3	0.11	0.89	2.89	22.0
4	0.13	0.17	2.17	20.9
5	0.13	0.04	2.04	22.7

The minimum hourly cost is achieved with four technicians.

## 35. AIRPORT RUNWAYS AND TAXIWAYS

Analysis of airport capacity is based on traffic counts and determination of a “design aircraft.” The Federal Aviation Administration (FAA) has prepared Federal Advisory Circulars outlining the requirements for each airplane design group and airport or runway designation.

Runways are usually oriented into the prevailing wind. They are usually designated based on the *magnetic azimuth* of the runway centerline. A designation will consist of a number and, in the case of parallel runways, a letter. (Single-digit runway designation numbers are not preceded by zeros.) On single runways, dual parallel runways, and triple parallel runways, the designation number will be the whole number nearest one-tenth of the magnetic azimuth when viewed from the direction of the approach. For example, if the magnetic azimuth was 192°, the runway designation marking would be 19. For a magnetic azimuth of 57°, the runway designation would be 6. For a magnetic azimuth ending with the number 5, such as 135°, the runway designation can be either 13 or 14. In the case of parallel runways, each runway designation number is supplemented by a letter (i.e., L for left and R for right) to indicate their relative positions as viewed from an approaching airplane (e.g., 18L or 18R).

Taxiways are surfaces used by aircraft to move around on the ground. (They may also be used by wheeled helicopters for taking off and landing.) In order to differentiate taxiways from runways, taxiways are designated by letters, normally starting with “A.” Unlike runways, the designation is not dependent on the direction of travel. Large airports with many taxiways may designate taxiways with letters followed by numbers (e.g., “A-2”). Taxiways with numbers tend to be in the same general location on the field, associated with a particular runway, and/or grouped together. Taxiways are normally parallel to and perpendicular to runways.

A short perpendicular taxiway typically connects a runway to a parallel taxiway.

Since taxiing at slow speeds on a long runway prevents subsequent aircraft from landing on that runway, *high-speed exits (high-speed taxiways)* may be used at a high-volume airport. This allows aircraft to turn off the runway centerline without decelerating to a normal taxi speed. High speed taxiways make shallow angles, typically around 30°, to the runway centerline.

## 36. DETOURS

A *detour* is a temporary rerouting of road users onto an existing highway in order to avoid a temporary traffic control zone. A *diversion* is a temporary rerouting of road users onto a temporary roadway around the work zone. If they are used, warning and taper lengths are generally not included in detour lengths.

## 37. TEMPORARY TRAFFIC CONTROL ZONES

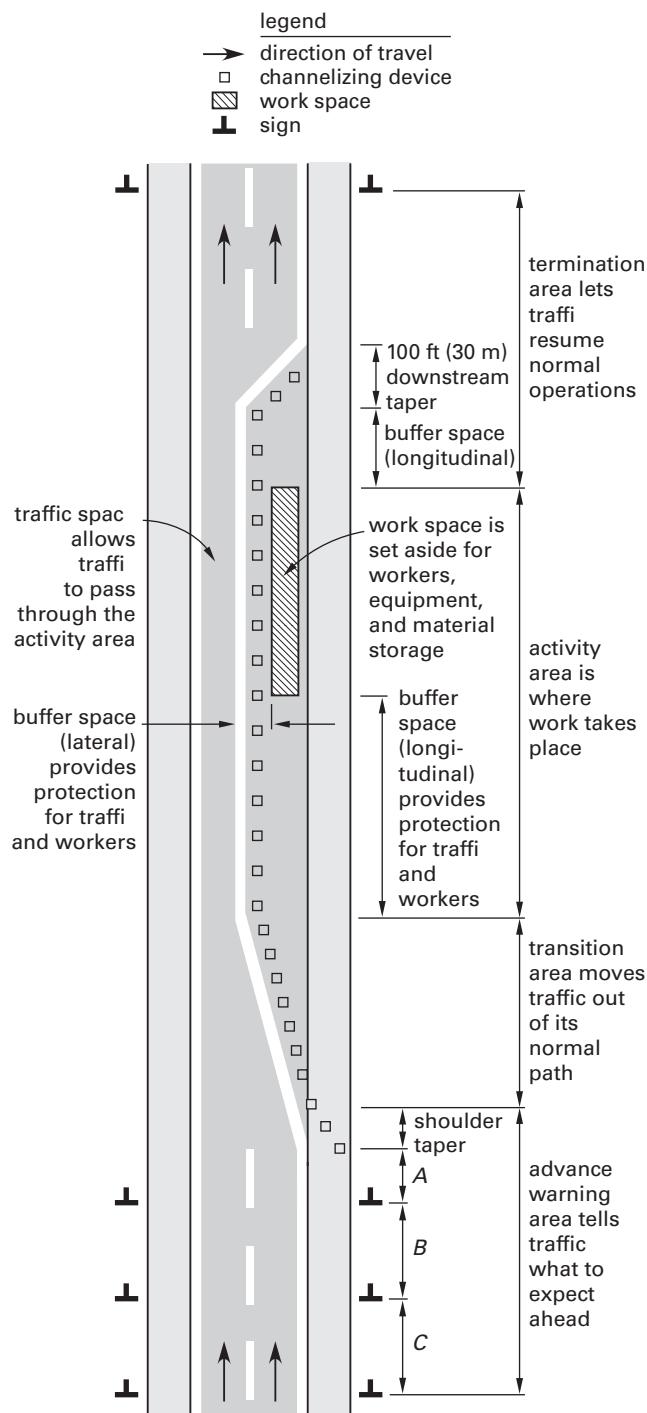

*Temporary traffic control zones* are areas of a roadway where the normal conditions (width, speed, direction, route, etc.) are changed by police or other authorized officials, signs, or *temporary traffic control (channelization) devices* (e.g., cones, tubular markers, drums, and barricades). Temporary traffic control zones may be used in areas of construction and maintenance, or in response to an incident (accident, natural disaster, or other emergency). The control zone extends from the first notification point to the last temporary traffic control device.

Properly implemented temporary traffic control zones are composed of four sections (*areas*): (1) advance warning area, (2) transition area, (3) activity area, and (4) termination area. These areas are illustrated in Fig. 73.18.

Except in areas where the advance warning area may be eliminated because the activity area does not interfere with normal traffic, road users will learn of the traffic control zone in the *advance warning area*. The warning can be accomplished by signage, flashing light trailers, or by rotating lights and strobes on parked vehicles. Three consecutive points of warning are required, as illustrated in Fig. 73.18. Table 73.19 summarizes the *MUTCD*'s suggested distances *A*, *B*, and *C*, between the three consecutive warning signs.

In the transition area, vehicles are redirected out of their normal paths by the use of *tapers*. A taper is created by using channelization devices and/or other pavement markings. Channelization design is specified by the distance between devices and the overall length of the transition area. The *MUTCD* specifies that, except for downstream and one-lane, two-way tapers, the maximum distance between channelization devices is 1 ft for every mph of speed (0.2 m for every kph). For downstream and one-lane, two-way tapers, the maximum distance between channelization devices is approximately 20 ft (6.1 m).

Figure 73.18 Sections of a Temporary Traffic Control Zone

Reprinted with permission from Fig. 6C-1 of the *Manual on Uniform Traffic Control Devices*, 2009 ed., U.S. Department of Transportation, Federal Highway Administration, 2009.

**Table 73.19** Suggested Advance Warning Sign Spacing

road type	distance between signs (see Fig. 73.18) <sup>a</sup>		
	A (distance between the first sign and the beginning of the transition)	B (distance between the first sign and the second sign)	C (distance between the second sign and the third sign)
urban (low speed) <sup>b</sup>	100 ft (30 m)	100 ft (30 m)	100 ft (30 m)
urban (high speed) <sup>b</sup>	350 ft (100 m)	350 ft (100 m)	350 ft (100 m)
rural	500 ft (150 m)	500 ft (150 m)	500 ft (150 m)
expressway/freeway	1000 ft (300 m)	1500 ft (450 m)	2640 ft (800 m)

(Multiply ft by 0.3048 to obtain m.)

<sup>a</sup>The columns A, B, and C provide the dimensions shown in MUTCD Fig. 6H-1 through Fig. 6H-46. The “first sign” is the sign in a three-sign series that is closest to the temporary traffic control (TTC) zone. The “third sign” is the sign that is furthest upstream from the TTC zone.<sup>b</sup>The speed category is to be determined by the highway agency.Source: Table 6C-1 of the *Manual on Uniform Traffic Control Devices*, 2009 ed., U.S. Department of Transportation, Federal Highway Administration, 2009.

The minimum taper length depends on the type of transition. Table 73.20 summarizes the MUTCD’s suggested *taper lengths*,  $L$ . In Eq. 73.59 and Eq. 73.60,  $S$  is the posted speed limit, the off-peak 85th percentile speed prior to work starting, or the anticipated operating speed.

$$L_m = \frac{W_m S_{\text{km/h}}^2}{155} \quad [S \leq 60 \text{ km/h}] \quad [\text{SI}] \quad 73.59(a)$$

$$L_{\text{ft}} = \frac{W_{\text{ft}} S_{\text{mph}}^2}{60} \quad [S \leq 40 \text{ mph}] \quad [\text{U.S.}] \quad 73.59(b)$$

$$L_m = \frac{W_m S_{\text{km/h}}}{1.6} \quad [S > 70 \text{ km/h}] \quad [\text{SI}] \quad 73.60(a)$$

$$L_{\text{ft}} = W_{\text{ft}} S_{\text{mph}} \quad [S > 45 \text{ mph}] \quad [\text{U.S.}] \quad 73.60(b)$$

*Merging tapers* (where two lanes merge) are longer than *nonmerging tapers* and require the full taper length since vehicles are required to merge into a common road space. When more than one lane must be closed, merged traffic should be permitted to travel approximately  $2L$  before the second lane is merged. *Shifting tapers* (where traffic moves to an entirely different travel path) require a minimum length of  $L/2$  but can benefit from longer lengths. *Shoulder tapers* preceding shoulder construction on an untraveled improved shoulder with a minimum width of 8 ft (2.4 m) that might be mistaken as a driving lane require a minimum length of  $L/3$ . When two-directional traffic on a two-way road is slowed, stopped, and alternately channeled into a single lane by a *flagger*, *two-way traffic tapers* with a maximum length of 100 ft (30 m) are used, one at each end. *Downstream tapers* are useful in providing a visual cue to drivers but are optional. When used, they have lengths of 100 ft per lane.

**Table 73.20** Taper Length Criteria for Temporary Traffic Control Zones

type of taper	taper length, $L$ (as calculated from Eq. 73.59 and Eq. 73.60)
merging taper	$L$ minimum
shifting taper	0.5 $L$ minimum
shoulder taper	0.33 $L$ minimum
one-lane, two-way traffic	50 ft (15 m) minimum, 100 ft (30 m) maximum
downstream taper	50 ft (15 m) minimum, 100 ft (30 m) maximum per lane

(Multiply ft by 0.3048 to obtain m.)

Source: Table 6C-3 of the *Manual on Uniform Traffic Control Devices*, 2009 ed., U.S. Department of Transportation, Federal Highway Administration, 2009.

As shown in Fig. 73.18, the *activity area* consists of the actual work space, traffic space, and buffer space. The *work space* is the part of the highway that is closed to road users and is set aside for workers, equipment, and materials. It also includes a *shadow vehicle* if one is used upstream. Work spaces are separated from passing vehicles by channelization devices or temporary barriers.

The *traffic space* is the part of the highway in which road users are routed through the activity area. The *buffer space* is a lateral and/or longitudinal (with respect to the work space) area that separates road user flow from the work space or an unsafe area. It might provide some recovery space for an errant vehicle. The buffer space should not be used for storage of equipment, vehicles, or supplies. If a shadow vehicle is used, the buffer space ends at the bumper first encountered. If a lateral buffer area is provided, its width is chosen using engineering judgment.

## 1. INTRODUCTION

Bridges are routinely rated by all U.S. states to document their condition, capacity, and safety.<sup>2,3</sup> Based on information reported by each state, the U.S. Department of Transportation's Federal Highway Administration (FHWA) maintains a database of information on bridges that includes various qualitative ratings, including ratings for decks, superstructures, and substructures; channel and channel protection; culverts; and comparison to modern criteria. These ratings are used

<sup>1</sup>Capacities and loads may be expressed in units of vertical load or flexural moment.

<sup>2</sup>Railroad and pedestrian bridges are not usually given rating factors.

<sup>3</sup>Bridge rating is required by the U.S. Federal Highway Administration's National Bridge Inspection Standards (NBIS).

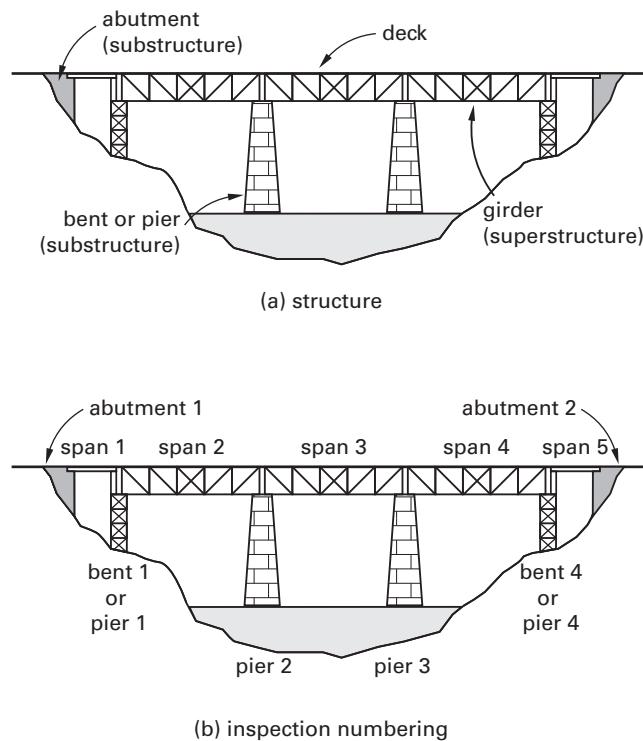

to help determine federal bridge replacement and rehabilitation funding to the states. Table 74.1 lists typical qualitative ratings based on inspections describing the structural components. Figure 74.1 illustrates the division and numbering of a bridge's structural components used in the rating process.

**Table 74.1** U.S. DOT (FHWA) Bridge Ratings for Decks, Superstructures, and Substructures

- |   |   |
|---|---|
| 9 | <i>excellent condition</i>  |
| 8 | <i>very good condition:</i> No problems are noted.  |
| 7 | <i>good condition:</i> Some minor problems are noted.   |
| 6 | <i>satisfactory condition:</i> Some structural elements show minor deterioration.   |
| 5 | <i>fair condition:</i> All primary structural elements are sound, but there is minor loss of cross section, cracking, spalling, and/or scour.   |
| 4 | <i>poor condition:</i> Advanced section loss, deterioration, spalling, and/or scour are noted.  |
| 3 | <i>serious condition:</i> Loss of section, deterioration, spalling, and/or scour have seriously affected primary structural components. Local failures may have occurred. Fatigue cracks in steel or shear cracks in concrete may be present.   |
| 2 | <i>critical condition:</i> Advanced deterioration of primary structural elements is noted. Fatigue cracks in steel or shear cracks in concrete may be present and/or scour may have removed substructure support. Unless closely monitored, it may be necessary to close the bridge until corrective action is taken. |
| 1 | <i>imminent failure condition:</i> Major deterioration or section loss is present in critical structural components and/or obvious vertical or horizontal movement affecting structure stability is observed. The bridge is closed to traffic, but it may be put back into light service following corrective action. |
| 0 | <i>failed condition:</i> The bridge is beyond corrective action and is out of service.  |

Source: *Recording and Coding Guide for the Structure Inventory and Appraisal of the Nation's Bridges*, Report No. FHWA-PD-96-001, U.S. Department of Transportation, Federal Highway Administration, Bridge Division, Bridge Management Branch, Washington, DC, 1995.

Various qualitative terms are used to describe bridges. *Fracture critical* means any failure of any key structural component could precipitate a collapse. A fracture-critical bridge is one that does not (or never did) contain

**Figure 74.1** Elements and Components of a Bridge

redundant supporting elements. Being fracture critical does not mean the bridge is inherently unsafe, only that there is a lack of redundancy in the design.

*Structurally deficient* means that a particular component of a bridge requires repair or replacement. It does not mean that the bridge is in danger of collapse or is unsafe to use. This description may be used when the bridge deck, support structure, or entire bridge have cracked or spalled concrete. If the condition is such that the bridge is unable to carry expected traffic loads, the bridge may be weight restricted.

*Functionally obsolete* means that the bridge does not meet current design or loading standards. A functionally obsolete bridge may have substandard lane widths, narrow shoulders, or low vertical clearance.

The FHWA *sufficiency rating* is a pseudo-quantitative index of the bridge's sufficiency to remain in service. It may be used to prioritize bridges in need of repair or replacement. The sufficiency rating formula is described in App. B of the FHWA's *Recording and Coding Guide for the Structure Inventory and Appraisal of the Nation's Bridges* (Report No. FHWA-PD-96-001, 1995). As set by the FHWA, the sufficiency formula agglomerates more than 20 factors, such as traffic volume, roadway width, structure type, roadway alignment, and the condition of the road deck and structure. A sufficiency rating of 100% indicates an entirely sufficient bridge, while 0% represents an entirely insufficient or deficient bridge. The sufficiency rating doesn't necessarily indicate a bridge's ability to carry traffic loads or its potential for collapse.

To be a candidate for replacement, a bridge must have a sufficiency rating of less than 50% and be either functionally obsolete or structurally deficient. To be a candidate for repair, a bridge must have a sufficiency rating of less than 80%. If the bridge is repaired, the jurisdiction is prevented from using additional federal aid on further repairs to the same bridge for 10 years.

In contrast to the qualitative and agglomerated ratings, a bridge *load rating* is a quantitative rating that represents the live load that the bridge can carry safely. The load rating can be expressed as a maximum permissible weight (i.e., "tonnage") or as a rating factor, RF, determined for a standard live load model. A bridge often has multiple rating factors, since states typically have several standard live design loads and loading models.

Although a bridge has many components (e.g., decks, parapets, railings, and substructures), only the primary superstructure components are load rated. The overall rating of the bridge is controlled by the structural member with the lowest rating. A member's rating factor can be multiplied by the weight of the standard loading (i.e., the weight of a standard design truck, such as the 20-ton HS20) to determine the rating. As demonstrated by Ex. 74.1, the rating factor may also be used to determine the theoretical design truck that corresponds with a given rating.

$$\text{bridge rating} = (\text{RF})(\text{standard loading}) \quad 74.1$$

A rating factor greater than or equal to 1.0 indicates that the bridge is safe for the intended loading. A bridge with a rating factor less than 1.0 will require either load posting, repair, or closure. *Load posting* is the placement of additional signage stating a bridge's safe loading limit. (See Fig. 74.2.) The load-limit signage is posted far enough ahead of a bridge to allow vehicles to choose alternative routes or to turn around. Load-limit signs should be posted in accordance with the *Manual on Uniform Traffic Control Devices* (MUTCD).

**Figure 74.2** Posted Weight Limit Sign

Although load ratings have been used since the early 1970s, modern load rating methodology is based on the AASHTO *Manual for Bridge Evaluation*. Excluding older allowable stress rating (ASR) methods, there are two methods available for load rating bridges: load

factor rating (LFR) and load and resistance factor rating (LRFR).<sup>4</sup> Specialized bridge software is often used to calculate the rating factors from designs and loadings. However, portions of the rating process can be performed manually in simplified cases.

## 2. STANDARD LIVE LOAD MODELS

States often use several standard live load models to specify maximum live loads for different purposes. These live load models are also the basis for determining rating factors. The *inventory rating level* is the most common and is roughly equivalent to the loads used when a bridge is designed. The inventory rating level also accounts for the subsequent natural deterioration of a bridge. Therefore, with an inventory rating model, the inventory loads are the loads a bridge can carry for an indefinite period without causing damage to the structure.

The *operating rating level* is the maximum live load the bridge can occasionally support without damaging the structure. Operating loads can potentially shorten the bridge life if routinely applied.

The *legal rating level* is a state-specific uniform legal load that is applied to all bridges, regardless of age, design, or other specifications. Since many bridges currently in use were designed using various design loads and standards, the inventory rating level does not correspond to current vehicle loadings. Therefore, the operating loads for older bridges are often less than the legal loads. In such cases, load-posting signs must be used to limit the bridge loading to the operating rating level, or repair or closure must be considered. A posted weight limit is known as the *posted load*.

Legal loads can be established by a state using its own guidelines or those provided by the AASHTO *Manual for Bridge Evaluation*. AASHTO's legal loads account for a bridge's varying span lengths: short (Type 3 truck), medium (Type 3-S2 truck), and long (Type 3-3 truck).

The *permit rating level* applies to overloaded vehicles with loads in excess of the legal and/or posted loads, but which are still permissible for infrequent passage. A state may issue a permit at its discretion to authorize an overloaded vehicle to use a bridge for an additional fee. *Permit loads* are typically based on a single lane loading rather than the two-lane distribution used for normal load calculations, since permit loads are infrequent and are often the only load on a bridge at one time.

Similar to the permit rating level, the *superload rating level* relates to vehicles that exceed a state's maximum height, width, and/or weight (typically 100 tons). Due to the size of the loads, pavement and structural analyses

are commonly performed before a permit is issued for a superloaded vehicle.

All states require private *escort vehicles (pilot vehicles)* for oversize and superloaded vehicles. In extreme cases of security, or when traffic control is required, public service (i.e., police, fire, and/or emergency) vehicles may be included. Escort vehicles have roles of guidance, traffic control, measurement, warning and signage, and remote steerage, although multiple roles are not assigned to a single vehicle.

### Example 74.1

Inventory rating factors were calculated for the primary structural members of a bridge using an HS20-44 standard truck, as shown. (a) What is the inventory rating of the bridge? (b) To what standard truck does the bridge's inventory rating correspond?

member	rating factor, RF	critical location
G1	1.65	midspan
G2	1.38	anchorage
G3	1.47	midspan

#### Solution

(a) The limiting member is G2, since it has the lowest rating factor. An HS20-44 standard truck has a weight of 36 tons. From Eq. 74.1, the inventory rating of the bridge is

$$\begin{aligned}\text{bridge rating} &= (\text{RF})(\text{standard loading}) \\ &= (1.38)(36 \text{ tons}) \\ &= 49.7 \text{ tons}\end{aligned}$$

(b) Based on an HS20 standard truck weighing 20 tons,  
 $(1.38)(20 \text{ tons}) = 27.6 \text{ tons}$

This corresponds to an HS27.6 standard truck.

## 3. LOAD FACTOR RATING (LFR) METHOD

The *load factor rating (LFR) method* is used for bridges that were not designed with the LRFD method. The LFR method rates bridges at the inventory and operating levels. The rating factors are determined for the primary superstructure members, with the lowest factor controlling the bridge's rating factor.

The AASHTO *Manual for Bridge Evaluation* equation for calculating the rating factor for a member is

$$\text{RF} = \frac{C - A_1 D}{A_2(L + I)} \quad 74.2$$

The rating factor is calculated from the member's capacity and dead and live loads. The structural capacity,  $C$ , is calculated from the AASHTO *Standard Specifications for Highway Bridges* and is dependent on the bridge's

<sup>4</sup>Bridges designed using *load and resistance factor design (LRFD)* that are rated after October 1, 2010, must use the LRFR method.

structural layout, materials, and current condition.<sup>5</sup> Dead loads,  $D$ , include the self-weight of the bridge and permanent loads that do not change over time (e.g., barriers, overlays, and utilities). Live loads,  $L$ , are transient and include vehicular and impact loads. Live loads and their distributions to individual bridge members are based on an H20/HS20 design truck with standard lane loading according to the AASHTO *Standard Specifications for Highway Bridges*.

The *dead-load factor*,  $A_1$ , equals 1.3 for all rating levels, while the *live-load factor*,  $A_2$ , is 2.17 for inventory level and 1.3 for operating level. The *impact factor*,  $I$ , is added to the live loads to account for impact loads caused by the movement of traffic. The impact factor varies based on the span length,  $L$ .

$$I = \frac{50}{L + 125} \leq 0.3 \quad 74.3$$

When the LFR method is used, bridge capacity can be calculated and reported by the rating factor, the U.S. tonnage (based on a standard HS20 loading of 20 tons), or metric tonnage (based on a standard MS18 loading equal to 32.4 metric tons).

#### 4. LOAD AND RESISTANCE FACTOR RATING (LRFR) METHOD

The *load and resistance factor rating (LRFR) method* is appropriate for bridges that were designed using the LRFD method. The LRFR method can determine load ratings for both operating and inventory levels, as well as for strength, service, and fatigue limit states.<sup>6</sup> Strength is typically the controlling limit state and, therefore, is the main determinant for bridge posting, closing, and repair. Service and fatigue evaluations can be used where required.

The basic LRFR equation for determining the rating factor applies a number of adjustment factors to the dead and live loads.

$$RF = \frac{C - \gamma_{DC}DC - \gamma_{DW}DW \pm \gamma_PP}{\gamma_{LL}(LL + IM)} \quad 74.4$$

The dead loads acting on a member are divided into those caused by structural components and attachments, DC, and by wearing surfaces and utilities, DW. LRFD load factors are applied to both dead load types:  $\gamma_{DC}$  for structural components and attachments and  $\gamma_{DW}$  for wearing surfaces and utilities.  $P$  represents any permanent loads other than dead loads and has an LRFD load

<sup>5</sup>Any cracking or deterioration of the bridge must be considered in the capacity calculation.

<sup>6</sup>The LRFR method uses *limit states* for strength, service, and fatigue to ensure safety and serviceability in the load rating. These limit states are introduced in the AASHTO *LRFD Bridge Design Specifications* (AASHTO *LRFD*). The *strength limit state* adjusts the structure's capacity due to the effects of permanent and live loading. The *service limit state* accounts for cracking and other deformations caused by stress. The *fatigue limit state* considers ranges of cyclical stresses to prevent cracking due to fatigue.

factor of  $\gamma_P$ . An *evaluation live-load factor*,  $\gamma_{LL}$ , is applied to the live loads, LL. The *dynamic load allowance*, IM, is added to the static live loads to approximate the dynamic live loads.

The member capacity,  $C$ , is calculated from Eq. 74.5. As shown in Eq. 74.5, the product of  $\phi_c$  and  $\phi_s$  represents the lower limit for strength limit states.

$$C = \phi\phi_c\phi_sR_n \quad 74.5$$

$$\phi_c\phi_s \geq 0.85 \quad 74.6$$

The *nominal resistance*,  $R_n$ , is the bridge's capacity to withstand loads. Resistance depends on the bridge's structural layout and materials and the condition of the bridge members. The nominal resistance is determined by inspection. The capacity is calculated by applying three safety factors to the nominal resistance.

The *resistance factor*,  $\phi$ , is the same factor used in LRFD bridge design and depends on the construction materials. (See AASHTO *LRFD Bridge Design Specifications*.)

The *condition factor*,  $\phi_c$ , accounts for the deterioration of bridge members over time and varies based on members' current condition. The condition factor is 0.85 for members in poor condition, 0.95 for members in fair condition, and 1.0 for members in good condition.

The *system factor*,  $\phi_s$ , adjusts for redundancy in the structure. A bridge with low redundancy will have a low system factor. The system factor is 1.0 when rating shear. System factors for flexure and axial forces are based on the superstructure type and can be found in the AASHTO *Manual for Bridge Evaluation*.

To analyze a bridge using the LRFR method, the bridge is checked using a standard HL-93 design load.<sup>7</sup> If the inventory rating factor is greater than or equal to 1.0, nonpermit loads are satisfied, and no further analysis is required. If the HL-93 design load produces a rating factor less than 1.0, additional legal load ratings are performed. Permit load ratings are required if the resultant legal load rating is less than 1.0.

<sup>7</sup>In the LRFD method, the HL-93 load is equivalent to the 36-ton H20/HS20 design truck in simultaneous combination with the HS20 uniform lane loading. The HL-93 load gets its name from "Highway Load" and the year (1993) in which the loading was proposed.

## 1. HIGHWAY SAFETY

*Highway safety* is an all-encompassing term that covers much more than highways. The term *transportation network* is used to account for the complex interactions of various types of roads, features, facilities, vehicles, and drivers. Highway safety concepts are applicable to more than just existing transportation networks. Such concepts are useful during planning and design.

Roadway safety can be perceived in two ways: objective safety and subjective safety. *Objective safety* is the use of quantitative techniques, independent of the observer, to measure safety. *Subjective safety* is the perception of how safe a person feels. Subjective safety depends on the observer.

## 2. HIGHWAY SAFETY STANDARDS

For many years, the subjects of highway and roadside safety, accident mitigation, and crash analysis were covered in such standards and publications as the American Association of State Highway and Transportation Officials' (AASHTO's) *A Policy on Geometric Design of Highways and Streets* (AASHTO *Green Book*), the Transportation Research Board and the National Research Council's *Highway Capacity Manual* (HCM), the U.S. Department of Transportation and the Federal Highway Administration's *Manual on Uniform Control Devices* (MUTCD), and various Occupational Safety and Health Act (OSHA) provisions. These standards are referenced throughout this book. This chapter draws heavily on AASHTO's *Highway Safety Manual* (HSM). Since safety decisions are made throughout projects, the HSM is useful during planning, design, construction, operations, and maintenance activities.<sup>1</sup>

According to the HSM, safety analysis has been traditionally a *descriptive analysis*, which is characterized as including historical information such as crash frequency, crash rate, and property damage to describe safety performance. The HSM goes beyond descriptions and discusses methods associated with *quantitative predictive analysis*. The HSM uses its methods to estimate the expected number and severity of crashes at sites with similar geometric and operational characteristics under

<sup>1</sup>In many cases, HSM methods are not significantly more sophisticated than the methods that have been used by competent practitioners in the past. In some regards, the HSM improves common practice only by standardizing terms, defining sequences, and giving substance to basic concepts. By turning common sense into procedure, the HSM may overly complicate simple concepts.

existing conditions, future conditions, and roadway design alternatives.

According to the HSM, the traditional descriptive crash analysis approach has been reactive, summarizing and quantifying crashes that have already happened. The HSM approach is proactive; it is used to predict the expected number and severity of crashes at sites with similar characteristics. The HSM describes highway safety quantifiably and specifies methods for numerically ranking and evaluating proposed roadway safety features.

The HSM consists of 17 chapters grouped into four parts (Part A through Part D) that are presented in three volumes. Volume 1 is made up of Part A and Part B, and it includes Chap. 1 through Chap. 9. Within Vol. 1, Part A "Introduction, Human Factors, and Fundamentals" is presented in Chap. 1 and Chap. 2. Also within Vol. 1, Part B "Roadway Safety Management Process" is presented in Chap. 4 through Chap. 9.

## 3. VEHICLE DYNAMICS

A moving surface vehicle (e.g., car, truck, or bus) is decelerated by five major forms of resistance: inertia, grade, rolling, curve, and air resistance. The *inertia resistance* (*inertial resisting force*),  $F_i$ , is calculated from the vehicle mass,  $m$ , and acceleration,  $a$ .

$$F_i = ma \quad [\text{SI}] \quad 75.1(a)$$

$$F_i = \frac{ma}{g_c} = \frac{wa}{g} \quad [\text{U.S.}] \quad 75.1(b)$$

For a vehicle ascending a constant incline  $\theta$ , the *grade resistance* is the component of the vehicle weight,  $w$ , acting parallel and down a frictionless inclined surface. The *grade* or *gradient*,  $G$ , is the slope in the direction of roadway. Grade is usually specified in percent. For example, a roadway with a 6% grade would increase in elevation 6 ft for every 100 ft of travel. For grades commonly encountered in road and highway design, there is essentially no difference in the road length and the horizontal measurement.

$$\begin{aligned} F_g &= w \sin \theta \\ &\approx w \tan \theta = \frac{wG\%}{100} \end{aligned} \quad 75.2$$

The *rolling resistance* can be calculated theoretically as presented in Chap. 72. For analysis of vehicle dynamics, the coefficient of rolling friction,  $f_r$ , used in Eq. 75.3 is generally considered to be constant.<sup>2</sup> For modern vehicles, it is reported as approximately 0.010–0.015 and is approximately constant at 13.5 lbf per 1000 lbm of mass (130 N per kg) for all speeds up to 60 mph

<sup>2</sup>An approximate relationship between speed and coefficient of rolling resistance for vehicles operating on typical paved roads was reported as follows (Taborek, J.J. May–Dec. 1957. Mechanics of Vehicles. *Machine Design*).

$$f_r = 0.01 \left( 1 + \frac{v_{\text{ft/sec}}}{147} \right)$$

(97 kph). For higher speeds, it should be increased 10% for every 10% increase in speed above 60 mph (97 kph). Rolling resistance is even higher for gravel roads and roads in poor condition.

$$F_r = f_r w \cos \phi \approx f_r w \quad 75.3$$

*Curve resistance* is the force exerted on the vehicle by its front wheels when the direction of travel is changing. Components of the curve resistance also impede the vehicle's forward motion, decreasing the *fuel economy*. As with centrifugal force, it is a function of the curve radius and vehicle speed. Curve resistance is generally obtained experimentally or from a table of typical values. When the vehicle is traveling in a straight direction, the curve resistance is zero.

*Air resistance* is the drag force given by Eq. 75.4, where *A* is the frontal cross-sectional area.

$$F_D = \frac{C_D A \rho v^2}{2} \quad [\text{SI}] \quad 75.4(a)$$

$$F_D = \frac{C_D A \rho v^2}{2 g_c} \quad [\text{U.S.}] \quad 75.4(b)$$

In the absence of any information about the drag coefficient and/or air density, the average air resistance for modern cars can be approximated from Eq. 75.5, where all of the constants have been accumulated into an *air resistance coefficient*.

$$F_D = K A v^2 \approx 0.0011 A_{\text{m}^2} v_{\text{km/h}}^2 \quad [\text{SI}] \quad 75.5(a)$$

$$F_D = K A v^2 \approx 0.0006 A_{\text{ft}^2} v_{\text{mi/hr}}^2 \quad [\text{U.S.}] \quad 75.5(b)$$

The *propulsion power*, *P*, (excluding the power used by power steering, air conditioner, and other accessories) is given by Eq. 75.6, where the sum of all resistances may be referred to as the *tractive force* or *tractive effort*. (Appropriate conversions can be made to horsepower and kilowatts.) For a typical vehicle, only about 50% of the nominal engine horsepower (brake power) rating is available at the flywheel for propulsion (i.e., after accessories). If the power is known, Eq. 75.6 can be solved for the maximum acceleration or velocity. Since the velocity also appears in the expression for drag force, a trial and error solution may be needed.

$$P = (F_i + F_g + F_r + F_c + F_D)v \quad 75.6$$

Regardless of how much power a vehicle's engine may be capable of developing, there is a point beyond which the use of additional power will merely result in spinning the driving tires. (The maximum tractive force is  $f_s w$ .) Beyond that point, no additional tractive effort can be generated to overcome resistance. The maximum tractive force as limited by wheel spinning is found by summing moments about some point on the vehicle, typically the tire-roadway contact point for the nondriven wheels.

The moment from the unknown tractive force balances the moments from all of the resistance forces.<sup>3</sup>

Analysis of performance under acceleration and deceleration is the same as for any body under uniform acceleration. A vehicle's instantaneous forward velocity and tangential velocity of the tires at the roadway are the same.

$$v_{\text{vehicle}} = v_{t,\text{tire}} = 2\pi r_{\text{tire}} n_{\text{tire}} \quad 75.7$$

The engine-wheel speed ratio depends on the transmission and *differential gear ratios*. The *transmission gear ratio* is the ratio of the engine speed to the driveshaft speed. Unless there is an *overdrive gear*, the typical transmission gear ratio used for highest speeds is approximately 1:1. The differential gear ratio (typically between 2.5:1 and 4:1) is the ratio of driveshaft to tire speeds.

$$n_{\text{wheel}} = \frac{n_{\text{engine}}}{R_{\text{transmission}} R_{\text{differential}}} \quad 75.8$$

$$R_{\text{transmission}} = \frac{n_{\text{engine}}}{n_{\text{driveshaft}}} \quad 75.9$$

$$R_{\text{differential}} = \frac{n_{\text{driveshaft}}}{n_{\text{wheel}}} \quad 75.10$$

The relationship between brake engine power and engine-generated torque, *T*, is

$$P_{\text{kW}} = \frac{T_{\text{N-m}} n_{\text{rpm}}}{9549} \quad [\text{SI}] \quad 75.11(a)$$

$$P_{\text{hp}} = \frac{T_{\text{in-lbf}} n_{\text{rpm}}}{63,025} \quad [\text{U.S.}] \quad 75.11(b)$$

Only 75–90% of the engine propulsion power or torque reaches the rear wheels. This represents the mechanical efficiency,  $\eta_m$ . The remainder is lost in the transmission, differential, and other gear-reduction devices. The engine-generated tractive effort reaching the driving wheels is

$$F_{\text{tractive}} = \frac{\eta_m T R_{\text{transmission}} R_{\text{differential}}}{r_{\text{tire}}} \quad 75.12$$

Equation 75.13 gives the relationship between vehicle speed and engine speed. The loss fraction, *i*, is typically between 0.02 and 0.05 and primarily accounts for slippage in the clutch and automatic transmission.

$$v = \frac{2\pi r_{\text{tire}} n_{\text{rev/sec}} (1 - i)}{R_{\text{transmission}} R_{\text{differential}}} \quad 75.13$$

The *loaded tire radius*, *r*, varies based on tire pressure, tread wear, tire design, applied load, and speed. It is typically 84% to 96% of the tire radius, with lower *r* values associated with large tires and higher *r* values associated with small tires.

<sup>3</sup>Unless specific information is known about the location of the vehicle's center of gravity and other properties, assumptions may need to be made about the point of application of the resistance forces.

The mass and volumetric rates of *fuel consumption* can be found from the horsepower and brake specific fuel consumption.

$$\dot{m}_{\text{fuel}, \text{kg}/\text{h}} = P_{\text{brake}, \text{kW}} (\text{BSFC}_{\text{kg}/\text{kW}\cdot\text{h}}) \quad [\text{SI}] \quad 75.14(a)$$

$$\dot{m}_{\text{fuel}, \text{lbm}/\text{hr}} = P_{\text{brake}, \text{hp}} (\text{BSFC}_{\text{lbm}/\text{hp}\cdot\text{hr}}) \quad [\text{U.S.}] \quad 75.14(b)$$

$$\dot{Q}_{\text{fuel}, \text{L}/\text{h}} = \frac{\dot{m}_{\text{fuel}, \text{kg}/\text{h}} (1000 \frac{\text{L}}{\text{m}^3})}{\rho_{\text{kg}/\text{m}^3}} \quad [\text{SI}] \quad 75.15(a)$$

$$\dot{Q}_{\text{fuel}, \text{gal}/\text{hr}} = \frac{\dot{m}_{\text{fuel}, \text{lbm}/\text{hr}} (7.48 \frac{\text{gal}}{\text{ft}^3})}{\rho_{\text{lbm}/\text{ft}^3}} \quad [\text{U.S.}] \quad 75.15(b)$$

The distance traveled per volume of fuel (also known as *fuel economy*),  $s'$ , is

$$s'_{\text{fuel}, \text{km/L}} = \frac{v_{\text{km/h}}}{\dot{Q}_{\text{fuel}, \text{L}/\text{h}}} \quad [\text{SI}] \quad 75.16(a)$$

$$s'_{\text{fuel}, \text{mi/gal}} = \frac{v_{\text{mi/hr}}}{\dot{Q}_{\text{fuel}, \text{gal}/\text{hr}}} \quad [\text{U.S.}] \quad 75.16(b)$$

### Example 75.1

A 2500 lbm (1100 kg) off-road utility vehicle has a frontal area of  $22 \text{ ft}^2$  ( $2.0 \text{ m}^2$ ). At 30 mph (50 km/h), the vehicle has a maximum tractive force of 320 lbf (1400 N). While traveling off-road over gravel in still air, the rolling resistance is 50 lbf per ton of vehicle weight ( $0.25 \text{ N/kg}$ ). The air resistance coefficient,  $K$ , is  $0.002 \text{ lbf}\cdot\text{hr}^2/\text{ft}^2\cdot\text{mi}^2$  ( $0.04 \text{ N}\cdot\text{h}^2/\text{m}^2\cdot\text{km}^2$ ). What straight gravel grade can the vehicle climb while maintaining a constant forward velocity of 30 mph (50 km/h)?

#### SI Solution

Since the grade is straight, there is no curve resistance. Since the speed is constant, there is no inertial resistance. Since the air resistance coefficient has units, it is not a coefficient of drag. The air resistance is

$$F_D = KAv^2 = \left(0.04 \frac{\text{N}\cdot\text{h}^2}{\text{m}^2\cdot\text{km}^2}\right)(2.0 \text{ m}^2)\left(50 \frac{\text{km}}{\text{h}}\right)^2 \\ = 200 \text{ N}$$

The rolling resistance is

$$F_r = f_r m = \left(0.25 \frac{\text{N}}{\text{kg}}\right)(1100 \text{ kg}) \\ = 275 \text{ N}$$

The grade resistance is

$$F_g = F_{\text{tractive}} - F_D - F_r = 1400 \text{ N} - 200 \text{ N} - 275 \text{ N} \\ = 925 \text{ N}$$

The maximum grade is given by Eq. 75.2.

$$G = \frac{F_g}{w} = \frac{F_g}{mg} = \frac{925 \text{ N}}{(1100 \text{ kg})(9.81 \frac{\text{m}}{\text{s}^2})} \\ = 0.0857 \quad (8.6\%)$$

#### Customary U.S. Solution

Since the grade is straight, there is no curve resistance. Since the speed is constant, there is no inertial resistance. Since the air resistance coefficient has units, it is not a coefficient of drag. The air resistance is

$$F_D = KAv^2 = \left(0.002 \frac{\text{lbf}\cdot\text{hr}^2}{\text{ft}^2\cdot\text{mi}^2}\right)(22 \text{ ft}^2)\left(30 \frac{\text{mi}}{\text{hr}}\right)^2 \\ = 39.6 \text{ lbf}$$

A vehicle with a mass of 2500 lbm has a weight of 2500 lbf in standard gravity. The rolling resistance is

$$F_r = f_r w = \frac{\left(50 \frac{\text{lbf}}{\text{ton}}\right)(2500 \text{ lbf})}{2000 \frac{\text{lbf}}{\text{ton}}} \\ = 62.5 \text{ lbf}$$

The grade resistance is

$$F_g = F_{\text{tractive}} - F_D - F_r = 320 \text{ lbf} - 39.6 \text{ lbf} - 62.5 \text{ lbf} \\ = 217.9 \text{ lbf}$$

The maximum grade is given by Eq. 75.2.

$$G = \frac{F_g}{w} = \frac{217.9 \text{ lbf}}{2500 \text{ lbf}} \\ = 0.08716 \quad (8.7\%)$$

## 4. DYNAMICS OF STEEL-WHEELED RAILROAD ROLLING STOCK

The kinematic analysis of rail rolling stock is similar to that of vehicles, though different variables and terminology are used. The *drawbar pull*, DBP, is the net tractive force (behind the locomotive) and is the force available for hauling cars. Drawbar pull is calculated from the *car resistance*, CR; *accelerating force*, AF; *tractive force at the driving axles*, TFDA; and *locomotive resistance*, LR. The *tonnage rating* is the DBP divided by the total resistance per ton for an average car. The *ruling gradient* is the maximum grade that occurs along the route and that requires the full DBP

for an extended period of time. Ruling grades limit the weight (length) of a train that can be accommodated with a single locomotive.

$$\begin{aligned} \text{DBP} &= \text{TFDA} - \text{LR} \\ &= \text{CR} + \text{AF} \end{aligned} \quad 75.17$$

The approximate tractive effort at the driving axles of a *diesel-electric locomotive unit* is given by Eq. 75.18. Typical efficiencies,  $\eta_{\text{drive}}$ , of diesel-electric drive systems vary from 0.82 to 0.93, with 0.82 being typically used. The efficiency of diesel-electric locomotives is essentially constant throughout the speed range.

$$F_{\text{tractive},N} = \frac{175 P_{\text{kW,rated}} \eta_{\text{drive}}}{v_{\text{km/h}}} \quad [\text{SI}] \quad 75.18(a)$$

$$F_{\text{tractive,lbf}} = \frac{375 P_{\text{hp,rated}} \eta_{\text{drive}}}{v_{\text{mph}}} \quad [\text{U.S.}] \quad 75.18(b)$$

Bearing and rolling resistance are affected by weight, while aerodynamic resistance is affected by streamlining and car loading. All of the journal, bearing, track, and rolling resistance, flange contact, and aerodynamic forces (except for incidental resistances) resisting the tractive effort were accumulated in the 1926 *Davis equation*. The original equation was appropriate for typical steam-powered freight trains of the era and for speeds around 40 mi/hr. The equation is applied to each car separately, with the individual resistances summed for the entire train.

Since its origination, the Davis formula has been modified many times for use with flat cars, tank cars, passenger cars, and other rolling stock. The original Davis equation is good for ballpark estimates. Under adverse conditions, such as rough track and extremely cold conditions, generous allowances of up to 100% are needed. Two forms of the equation are used, one based on the number of axles,  $n$ , in the car and the average axle loading,  $w$ , and the other based on the total car weight,  $W$ .

$$R_{\text{lbf/ton}} = 1.3 + \frac{29}{w_{\text{tons/axle}}} + 0.045v + \frac{0.0005 A_{\text{ft}^2} v_{\text{mph}}^2}{w_{\text{tons/axle}} n} \quad 75.19(a)$$

$$\begin{aligned} R_{\text{lbf/car}} &= 1.3W_{\text{tons/car}} + 29n + 0.45W_{\text{tons/car}}v \\ &\quad + 0.0005 A_{\text{ft}^2} v_{\text{mph}}^2 \end{aligned} \quad 75.19(b)$$

The 1910 *modified Davis equation*, applicable to modern, large, streamlined rolling stock moving at fast speeds, gives the *level tangent resistance*,  $R$ .  $w$  is the average loading per axle, and  $wn$  is the total weight

calculated as the average axle load times the number of axles.

$$R_{\text{lbf/ton}} = 0.6 + \frac{20}{w_{\text{tons}}} + 0.01v_{\text{mph}} + \frac{K v_{\text{mph}}^2}{w_{\text{tons}} n} \quad [\text{U.S. only}] \quad 75.20$$

The approximate frontal area of a locomotive or passenger rail car is 100–120 ft<sup>2</sup> (9.0–11 m<sup>2</sup>). Freight cars have 85–90 ft<sup>2</sup> (7.7–8.1 m<sup>2</sup>) of frontal area, though this value varies greatly with the nature of the load. Incorporating the frontal area term, the air resistance coefficient,  $K$ , has representative values of 0.0935 lbf·hr<sup>2</sup>·ton/mi<sup>2</sup> for containers on flat cars, 0.16 lbf·hr<sup>2</sup>·ton/mi<sup>2</sup> for trucks and trailers on flat cars, and 0.07 lbf·hr<sup>2</sup>·ton/mi<sup>2</sup> for all other standard rail units.

The *incidental resistances* include effects due to grade, curvature, and wind. The *grade resistance* is 20 lbf per ton for each percentage grade (i.e., essentially the weight times the grade). The *curve resistance* is approximately 0.8 lbf/ton (0.004 N/kg) per degree of curvature. Railroad curve resistance is considered equivalent to a grade resistance of 0.04% per degree of curvature. When the grade is “compensated,” the compensated grade resistance includes the curve resistance, and curve resistance can be disregarded when calculating power requirements.

## 5. COEFFICIENT OF FRICTION

In most cases, a vehicle's braking system is able to provide more braking force than can be transmitted to the pavement. The maximum deceleration is limited by the coefficient of friction between the tires and pavement.

The *coefficient of friction*,  $f$ , between a vehicle and the supporting roadway is the frictional force,  $F_f$ , divided by the normal force,  $N$ . The *normal force* is essentially the total weight of the vehicle,  $w$ , on all but the most extreme grades. The coefficient of friction is dependent on the condition of the vehicle's tires, the type and condition of the pavement, and the weather conditions. (See Table 75.1.)

$$f = \frac{F_f}{N} \quad 75.21$$

There are two coefficients of friction: static and dynamic (kinetic). (The coefficients of friction may also be referred to as *coefficients of road adhesion*.) The *coefficient of static friction* is larger than the coefficient of dynamic (kinetic) friction. While a vehicle's tires are rotating, the relative velocity between a point of contact on the tire and roadway is zero, and the coefficient of static friction controls.

Once a vehicle enters a skid, however, the *coefficient of dynamic friction* controls. Therefore, a vehicle held to its maximum braking deceleration without entering a skid (i.e., the skid is impending) will take less distance to come to a complete stop than if the vehicle locks up its tires and skids to a stop.

The coefficient of friction is not constant throughout the braking maneuver, but varies inversely with speed. This level of sophistication is not normally considered, and an average value that is representative of the speed and conditions is used.

**Table 75.1** Typical Coefficients of Skidding Friction

speed in mph (km/h)	type of pavement <sup>a</sup>				
	AC	SA	RA	PCC	wet <sup>b</sup>
<i>vehicles with new tires</i>					
11 (18)	0.74	0.75	0.78	0.76	—

50 (80)					0.31
60 (100)					0.30
70 (115)					0.29

(Multiply mph by 1.609 to obtain km/h.)

<sup>a</sup>AC—asphalt concrete, dry; SA—sand asphalt, dry; RA—rock asphalt, dry; PCC—portland cement concrete, dry; wet—all wet pavements.

<sup>b</sup>Most design problems are based on wet pavement.

Table compiled from a variety of sources; values vary widely.

since the tires of a skidding vehicle will dig through the upper layers of loose gravel or snow to find a solid layer with a greater coefficient of friction.

While ABS is active, a loud grating sound is heard and the brake pedal pulsates rapidly. This alarms some drivers and causes them to pump their brakes or remove pressure entirely from the brake pedal, eliminating the benefits of the ABS system. Also, some drivers tend to jerk the steering wheel during an ABS-assisted stop, causing the vehicle to go off course, often into an opposing lane. Because of these problems, many car insurance companies no longer offer discounts for ABS-equipped vehicles.

## 7. STOPPING DISTANCE

*Stopping distance* includes the distance traveled before the brakes are applied, as well as the distance during the braking maneuver. The *braking perception-reaction time*,  $t_p$ , is also referred to as the *PRT time* and *PIEV time*, using an acronym for perception, identification, emotion, and volition. PRT is not a fixed value. It depends on various factors, primarily driver vision acuity, lighting, the amount of information needed to be processed, the complexity of the response, and the efforts required to carry out the avoidance maneuver. PIEV time varies widely from person to person. Though the median value is approximately 0.90 sec for unexpected (unanticipated) events in complex roadway situations, individuals with slow reaction times may require up to 3.5 sec. AASHTO *Green Book* Chap. 3 lists 2.5 sec as the value used to determine the minimum *stopping sight distances*,  $s$ , and is appropriate for approximately 90% of the population.

$$s_{\text{stopping}} = vt_p + s_b$$

75.22

## 6. ANTI-LOCK BRAKES

When a vehicle begins to skid, the driver becomes unable to steer. An *anti-lock (anti-skid) braking system* (ABS), also known as a *brake assist system* (BAS), detects an impending skid and alternately removes and applies hydraulic pressure from the hydraulic brake system. This is equivalent to the driver rapidly “pumping” the brakes, a common anti-skid strategy. The application of the hydraulic pressure pulses is approximately 18 times per second. The effect is to allow the tires to rotate slightly, preventing the skid and allowing the driver to steer. There are no skid marks with anti-lock brakes.

On wet pavement and ice, ABS will generally bring the vehicle to a stop in a shorter distance than if the vehicle were to go into a skid. Since the static coefficient of friction in a “skid-impending” braking maneuver is greater than the dynamic coefficient, the ABS *braking distance* on dry pavement should also be less. However, inasmuch as the average driver is unable to apply “just the right amount” of braking to achieve the maximum deceleration, the braking distance is essentially unchanged, and the primary benefit is being able to steer. On gravel and snow-covered roads, ABS braking distances can be greater than distances without ABS,

## 8. BRAKING AND DECELERATION RATE

The maximum deceleration that can be developed in dry weather by a vehicle with tires and brakes in good condition is about  $25 \text{ ft/sec}^2$  ( $7.5 \text{ m/s}^2$ ). In wet conditions, the maximum deceleration provided by modern vehicles, tires, and roads easily exceeds  $11.2 \text{ ft/sec}^2$  ( $3.4 \text{ m/s}^2$ ). (Acceleration and deceleration are sometimes specified in miles per hour per second, mphps, or kilometers per hour per second, kphps. Multiply mphps by 1.467 to obtain  $\text{ft/sec}^2$ , and multiply kphps by 0.278 to obtain  $\text{m/s}^2$ .) However, decelerations of  $14 \text{ ft/sec}^2$  ( $4.2 \text{ m/s}^2$ ) are experienced by occupants as uncomfortable and alarming panic stops.  $11.2 \text{ ft/sec}^2$  ( $3.4 \text{ m/s}^2$ ), corresponding to the 90th percentile of commonly experienced deceleration rates, is the approximate upper limit of desirable decelerations, and  $9 \text{ ft/sec}^2$  ( $2.7 \text{ m/s}^2$ ) is the approximate maximum comfortable deceleration from high-speed travel.

If a vehicle locks its brakes and begins to skid on level ground, the deceleration rate will be  $f_{\text{dynamic}}g$ .

$$a = fg = f \left( 9.81 \frac{\text{m}}{\text{s}^2} \right) \quad [\text{SI}] \quad 75.23(a)$$

$$a = fg = f \left( 32.2 \frac{\text{ft}}{\text{sec}^2} \right) \quad [\text{U.S.}] \quad 75.23(b)$$

## 9. BRAKING AND SKIDDING DISTANCE

The braking/skidding distance required to decrease travel velocity from  $v_1$  to  $v_2$  depends on friction and grade and can be calculated from Eq. 75.24. This distance is exclusive of the time traveled during PIEV time.

$$s_b = \frac{v_1^2 - v_2^2}{2g(f \cos \theta + \sin \theta)} \quad 75.24$$

The incline angle,  $\theta$ , is small, so  $\cos \theta \approx 1.0$ , and  $\sin \theta \approx \tan \theta = G$ . The decimal grade,  $G$ , is positive when the skid is uphill and negative when the skid is downhill. Under the appropriate conditions, the friction factor,  $f$ , can be calculated from Eq. 75.23.

$$s_b = \frac{v_1^2 - v_2^2}{2g(f + G)} \quad [\text{SI}] \quad 75.25(a)$$

$$\approx \frac{v_{1,\text{km/h}}^2 - v_{2,\text{km/h}}^2}{254(f + G)}$$

$$s_b = \frac{v_1^2 - v_2^2}{2g(f + G)} \quad [\text{U.S.}] \quad 75.25(b)$$

$$\approx \frac{v_{1,\text{mph}}^2 - v_{2,\text{mph}}^2}{30(f + G)}$$

Equation 75.24 and Eq. 75.25 do not apply directly to situations where the vehicle is brought to an abrupt stop by a collision or when the driver stops braking during the skid and continues on at a slower speed. In such cases, the actual skid length can be calculated as the difference in *skidding distance* to come to a complete stop from the initial speed and the skidding distance to come to a complete stop from the final speed (i.e., the impact speed in the case of collisions).

### Example 75.2

A 4000 lbm (1800 kg) car that is traveling at 80 mph (130 km/h) locks up its wheels, decelerates at a constant rate, and slides 580 ft (175 m) along a level road before stopping. (a) Disregarding perception-reaction time, how much time does it take to stop? (b) What is the acceleration? (c) What is the decelerating force? (d) What is the coefficient of friction between the tires and the road?

### SI Solution

(a) This is a case of uniform acceleration. The initial velocity is

$$v_o = \frac{(130 \frac{\text{km}}{\text{h}})(1000 \frac{\text{m}}{\text{km}})}{3600 \frac{\text{s}}{\text{h}}} = 36.1 \text{ m/s}$$

The stopping distance,  $s$ , is 175 m. The final velocity,  $v$ , is zero.

$$t = \frac{2s}{v_o + v} = \frac{(2)(175 \text{ m})}{36.1 \frac{\text{m}}{\text{s}} + 0 \frac{\text{m}}{\text{s}}} = 9.69 \text{ s}$$

(b) Use the uniform acceleration formulas.

$$a = \frac{v - v_o}{t} = \frac{0 \frac{\text{m}}{\text{s}} - 36.1 \frac{\text{m}}{\text{s}}}{9.69 \text{ s}} = -3.73 \text{ m/s}^2$$

(c) Use Eq. 75.1.

$$F_f = ma = (1800 \text{ kg}) \left( 3.73 \frac{\text{m}}{\text{s}^2} \right) = 6714 \text{ N}$$

(d) Use Eq. 75.21.

$$f = \frac{F_f}{N} = \frac{F_f}{mg} = \frac{6714 \text{ N}}{(1800 \text{ kg})(9.81 \frac{\text{m}}{\text{s}^2})} = 0.38$$

### Customary U.S. Solution

(a) This is a case of uniform acceleration. The initial velocity is

$$v_o = \frac{(80 \frac{\text{mi}}{\text{hr}})(5280 \frac{\text{ft}}{\text{mi}})}{3600 \frac{\text{sec}}{\text{hr}}} = 117.3 \text{ ft/sec}$$

The stopping distance,  $s$ , is 580 ft. The final velocity,  $v$ , is zero.

$$t = \frac{2s}{v_o + v} = \frac{(2)(580 \text{ ft})}{117.3 \frac{\text{ft}}{\text{sec}} + 0 \frac{\text{ft}}{\text{sec}}} = 9.89 \text{ sec}$$

(b) Use the uniform acceleration formulas.

$$a = \frac{v - v_o}{t} = \frac{0 \frac{\text{ft}}{\text{sec}} - 117.3 \frac{\text{ft}}{\text{sec}}}{9.89 \text{ sec}} = -11.9 \text{ ft/sec}^2$$

(c) Use Eq. 75.1.

$$\begin{aligned} F_f &= \frac{ma}{g_c} \\ &= \frac{(4000 \text{ lbm}) \left( 11.9 \frac{\text{ft}}{\text{sec}^2} \right)}{32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}} \\ &= 1478 \text{ lbf} \end{aligned}$$

(d) Use Eq. 75.21.

$$f = \frac{F_f}{N} = \frac{1478 \text{ lbf}}{4000 \text{ lbf}} = 0.37$$

### Example 75.3

A car traveling at 80 mph (130 km/h) locks up its wheels and skids up a 3% incline before crashing into a massive stationary concrete pedestal and coming to a complete stop. The skid marks leading up to the pedestal are 300 ft (90 m) long. The coefficient of friction between the tires and road is 0.35. (a) How far would the car have skidded if it had not hit the pedestal? (b) What was the speed of the car at impact?

#### SI Solution

(a) Use Eq. 75.25. The grade is positive since the car skids uphill.

$$\begin{aligned} s_b &= \frac{v_{\text{km/h}}^2}{254(f+G)} = \frac{\left(130 \frac{\text{km}}{\text{h}}\right)^2}{(254)(0.35+0.03)} \\ &= 175.1 \text{ m} \end{aligned}$$

(b) Since the skid marks were only 90 m long, the vehicle would have skidded  $175.1 \text{ m} - 90 \text{ m} = 85.1 \text{ m}$  further. Solve Eq. 75.25 for the speed.

$$\begin{aligned} 85.1 \text{ m} &= \frac{v_{\text{km/h}}^2}{254(f+G)} = \frac{v^2}{(254)(0.35+0.03)} \\ v &= 90.6 \text{ km/h} \end{aligned}$$

#### Customary U.S. Solution

(a) Use Eq. 75.25. The grade is positive since the car skids uphill.

$$\begin{aligned} s_b &= \frac{v_{\text{mph}}^2}{30(f+G)} = \frac{\left(80 \frac{\text{mi}}{\text{hr}}\right)^2}{(30)(0.35+0.03)} \\ &= 561.4 \text{ ft} \end{aligned}$$

(b) Since the skid marks were only 300 ft long, the vehicle would have skidded  $561.4 \text{ ft} - 300 \text{ ft} = 261.4 \text{ ft}$  further. Solve Eq. 75.25 for the speed.

$$\begin{aligned} 261.4 \text{ ft} &= \frac{v_{\text{mph}}^2}{30(f+G)} = \frac{v^2}{(30)(0.35+0.03)} \\ v &= 54.6 \text{ mph} \end{aligned}$$

## 10. SPEED DEGRADATION ON UPHILL GRADES

Most modern passenger cars traveling on highways are capable of negotiating uphill grades of 4–5% without speed decreases below their initial level-highway speeds. (Older cars with high mass-to-power ratios and some smaller-sized “economy” vehicles may experience speed decreases.)

Heavy trucks experience greater speed degradations than passenger cars. The primary variables that affect actual speed decreases include the grade steepness, the grade length, and the truck’s mass-to-power ratio. *Mass-to-power ratios* are commonly stated in pounds per horsepower (lbm/hp) and kilograms per kilowatt (kg/kW). (Multiply lbm/hp by 0.6083 to obtain kg/kW.) AASHTO *Green Book* Chap. 3 contains simple graphs of speed decreases for “heavy trucks” with mass-to-power ratios of 200 lbm/hp (120 kg/kW) and recreational vehicles entering ascending grades at 55 mph (88.5 km/h).

## 11. FACTORS CONTRIBUTING TO CRASHES

Three types of factors contribute to crashes: human (i.e., physiological and emotional), environmental (including the roadway), and vehicle. *Human factors* include age, judgment, skill, attention, cell phone usage, speed, fatigue, experience, and sobriety. *Roadway/environmental factors* include horizontal geometry, traffic control devices, signs, surface friction (including dry/wet conditions), grade (i.e., steepness), weather, and medical response time. *Vehicle factors* include vehicle design (e.g., anti-lock braking systems and bumper height), vehicle condition (including brakes and tires), and maintenance.

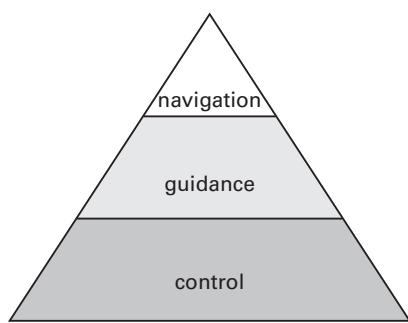

According to a study reported in the HSM, human factors contribute to a crash 93% of the time, followed by roadway factors at 34% and vehicle factors at 13%. As the percentages indicate, the three types of factors interact and overlap in complex ways.

The HSM divides the *driving task* into three hierachal sub-tasks: control, guidance, and navigation. (See Fig. 75.1.) The *control sub-task* includes maintaining the appropriate speed and staying within the driving lane. The *guidance sub-task* includes safely interacting with other vehicles and following traffic control devices. The *navigation sub-task* includes traveling a path from origin to destination by reading guide signs. Although

the navigation sub-task is the most complex, the control sub-task forms the basis of the other sub-tasks.

*Driver error* is a contributing factor in most crashes. Driver error includes errors of judgment, distractions, inattentiveness, weariness, overload of information, and deliberate violation of traffic laws. These errors are categorized into physical, perceptual, and cognitive limitations. In addition to physiological factors such as perception-reaction time, primary factors that affect driving safety and contribute to crashes are drivers' attention and information processing, vision, and speed choice.

**Figure 75.1** Driving Task Hierarchy

From *Highway Safety Manual*, 2010, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

## Attention and Information Processing

*Driver overload* occurs when a driver's attention and ability to process information is limited. Overloading makes it difficult for a driver to divide his or her attention between the control, guidance, and navigation sub-tasks. Table 75.2 presents common causes of driver overload. The HSM suggests *positive guidance techniques* that transportation designers can use to compensate for the attention and information processing limitations of drivers. (See Sec. 75.15.)

**Table 75.2** Common Causes of Driver Overload

scenario	example
high demands from more than one information source	merging into a high-volume, high-speed freeway traffic stream from a high-speed interchange ramp
the need to make a complex decision quickly	stop or go on a yellow signal close to the stop line
the need to take large quantities of information at one time	an overhead sign with multiple panels, while driving in an unfamiliar place

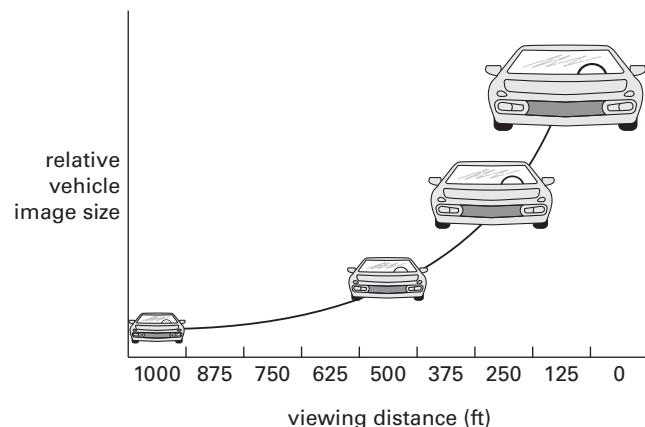

From *Highway Safety Manual*, 2010, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

## Vision

90% of all information used by drivers is received visually. The following factors collectively constitute *vision* and affect a driver's ability to visually process information.

- *visual acuity*: the ability to see details at a distance (see Fig. 75.2)
- *contrast sensitivity*: the ability to detect differences in brightness between objects and their backgrounds
- *peripheral vision*: the ability to detect objects and collect information outside of the most accurate visual range (see Fig. 75.3)
- *movement in depth*: the ability to estimate the speed of another vehicle
- *visual search*: the ability to search and collect information from the road scene

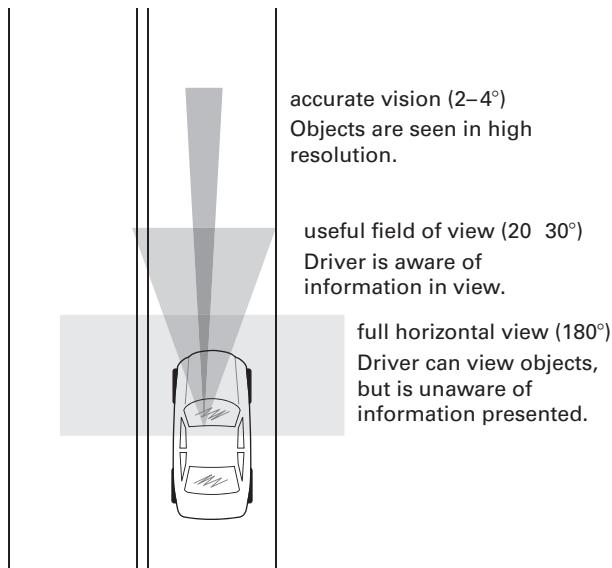

**Figure 75.2** Relative Vehicle Image Size at Distance

From *Highway Safety Manual*, 2010, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

## Driving Speed

*Driving speed* is a major factor affecting highway safety and survivability. Driving speed is influenced by posted speed limits; however, actual speed is influenced by road message and perceptual cues. *Road message cues* include alignment and geometry, terrain, and other roadway elements. For example, drivers typically drive faster on straight, wide-open roads than on narrow bridges. *Perceptual cues* include objects in a driver's peripheral view, the noise level inside the vehicle, and the speed the driver had previously been driving. A driver tends to drive faster when there are no objects in his or her peripheral views, when the vehicle cabin is quiet, and after driving fast for a long period of time. Drivers tend to drive faster on freeway exits and arterial streets immediately after having driven fast on a freeway. This is called *speed adaptation*.

**Figure 75.3** Relative Peripheral Visibility

From *Highway Safety Manual*, 2010, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

## 12. ROADWAY SEGMENT CRASH FACTORS

The importance of some factors depends on the type of element or facility involved and the category of crash. Factors that contribute to crashes along roadway segments are listed in Table 75.3.

## 13. INTERSECTION CRASH FACTORS

Factors that contribute to most crashes at signalized and unsignalized intersections are listed in Table 75.4.

## 14. BICYCLIST AND PEDESTRIAN CRASH FACTORS

Factors that contribute to crashes involving bicyclists and pedestrians are listed in Table 75.5.

## 15. SAFETY MANAGEMENT TECHNIQUES

The frequency and severity of crashes can be reduced through *safety management techniques*. In light of unavoidable human limitations, “positive guidance” techniques should be used in designing highways. *Positive guidance* means designing with human limitations in mind, reducing crashes by reducing the likelihood of driver errors. According to HSM definitions, positive guidance techniques include primacy, spreading, coding, and redundancy. *Primacy* involves limiting signs only to those that are necessary and important. *Spreading* avoids driver information overload by sequencing signs along the roadway, not concentrating them in one location. *Coding* involves differentiating and grouping signed information by using colors and shapes. For

**Table 75.3** Factors Contributing to Crashes Along Roadway Segments

type of crash	contributing factors
vehicle rollover	roadside design (drops or steep slopes), narrow shoulder width, excessive speed, pavement condition
fixed object	obstruction in or near roadway, poor lighting, missing pavement markings, inadequate signs, missing guardrail, slippery pavement, insufficient roadside clearance, excessive speed
nighttime	poor lighting, poor sign visibility, excessive speed, inadequate sight distance
wet pavement	pavement design (poor drainage, impervious pavement), missing pavement markings, poor road conditions, excessive speed
opposite-direction sideswipe or head-on	inadequate roadway geometry, narrow shoulders, excessive speed, missing pavement markings, missing signage
run-off-the-road	narrow lane width, slippery pavement, inadequate median width, inadequate maintenance, narrow shoulders, poor delineation, poor visibility, excessive speed
bridge	alignment, narrow roadway, visibility, vertical clearance, slippery pavement, surface condition, missing barrier system

example, orange signs convey construction information; rectangular signs using black text on a white background convey speed and other route information. *Redundancy* involves repeating and conveying the same information in different ways. For example, installing a “no passing” sign in addition to painting a double yellow center strip provides redundant guidance about not passing on a roadway segment.

Other characteristics described in the HSM include consistency, traditionality, sequentiality, and helpfulness. *Consistency* and *traditionality* involve presenting information in a consistent and expected manner. For example, freeway on- and off-ramps should always be right exits. *Sequentiality* involves presenting information in the order needed. *Utility* involves providing important information, suggestions, guidance, and tips (e.g., warning signs) and clues in advance in order to reduce the need for drivers to make quick, complex decisions and maneuvers.

## 16. ANALYSIS OF ACCIDENT DATA

Accident data, also known as *crash data*, are compiled and evaluated to identify hazardous features and locations, set priorities for safety improvements, support economic analyses, and identify patterns, causes (i.e., driver, highway, or vehicle), and possible countermeasures.

**Table 75.4** Factors Contributing to Vehicular Crashes at Intersections

intersection type	type of crash	contributing factors
signalized	right-angle	poor visibility of signals, inadequate signal timing, excessive speed, slippery pavement, insufficient sight distance, red light violations
	rear-end or sideswipe	inappropriate approach speeds, poor visibility of signals, unexpected lane changes, narrow lanes, unexpected stops, slippery pavement, excessive speeds
	left- or right-turn movement	misjudgment of oncoming traffic speed, pedestrian or bicycle conflicts, inadequate signal timing, deficient sight distance, conflict with right-on-red vehicles
	nighttime	poor lighting, poor sign visibility, inadequate delineation, inadequate maintenance, excessive speed, inadequate sight distance
	wet pavement	slippery pavement, missing pavement markings, inadequate maintenance, excessive speed
unsignalized	angle	restricted sight distance, high traffic volume, high approach speed, unexpected cross traffic, stop sign violations, slippery pavement
	rear-end	pedestrian crossings, driver inattention, slippery pavement, turning vehicles, unexpected lane changes, narrow lanes, restricted sight distance, inadequate traffic gaps, excessive speed
	collision at driveway	left-turning vehicles, driveway location, right-turning vehicles, large volume of through or driveway traffic, restricted sight distance, excessive speed
	head-on or sideswipe	inadequate pavement markings, narrow lanes
	left- or right-turn	inadequate traffic gaps, restricted sight distance
	nighttime	poor lighting, poor sign visibility, inadequate delineation, excessive speed, inadequate sight distance
	wet pavement	slippery pavement, missing pavement markings, inadequate maintenance, excessive speed

**Table 75.5** Factors Contributing to Crashes Involving Bicyclists and Pedestrians

type of crash	contributing factors
bicyclist	limited sight distance, inadequate signs, inadequate pavement markings, inadequate lighting, excessive speed, limited separation, narrow bike lanes
pedestrian	limited sight distance, inadequate barrier, inadequate signals or signs, inadequate signal phasing, inadequate paving markings, inadequate lighting, excessive speed, few marked pedestrian crossings, nearby land use (e.g., schools, parks)

Accidents are classified into three *severity categories*, depending on whether there is (a) property damage only (referred to as *PDO accidents*), (b) personal injury, or (c) fatalities. The *severity ratio* is defined as the ratio of the number of injury and fatal accidents divided by the total number of all accidents (including PDO accidents).

It is common to prioritize intersections according to the *accident rate*,  $R$ . The accident rate may be determined for PDO, personal injury, and fatal accidents, or the total thereof. The accident ratio is the ratio of the number of accidents per year to the average daily traffic, ADT. The rate is reported as an RMEV (i.e., rate per

million entering vehicles) taking into consideration vehicles entering an intersection from all directions.

$$R_{\text{RMEV}} = \frac{(\text{no. of accidents})(10^6)}{(\text{ADT})(\text{no. of years}) \left( 365 \frac{\text{days}}{\text{yr}} \right)} \quad 75.26$$

Routes (segments or links) between points are prioritized according to the accident rate per mile (per kilometer), calculated as the ratio of the number of accidents per year to the ADT per mile (kilometer) of length, counting traffic from all directions in the intersection. For convenience, the rate may be calculated per 100 million vehicle miles (HMVM).

$$R_{\text{HMVM}} = \frac{(\text{no. of accidents})(10^8)}{(\text{ADT})(\text{no. of years}) \left( 365 \frac{\text{days}}{\text{yr}} \right) L_{\text{mi}}} \quad 75.27$$

To identify the most dangerous features, it is necessary to determine what the accidents at an intersection or along a route had in common. This can be done in a number of ways, one of which is by drawing a collision diagram. A *collision diagram* is essentially a true-scale cumulative drawing of the intersection showing details of all of the accidents in the study. Dates, times, weather conditions, types of maneuvers, directions, severity, types of

accidents, and approximate locations are recorded on the diagram. (See Fig. 75.5.)

Common *accident-type* categories include: rear-end, right-angle, left-turn, fixed-object, sideswipe, parked-vehicle, run off road, head-on, bicycle-related, and pedestrian-related.

*Hypothesis testing* can be used to determine if installed countermeasures are being effective. The *null hypothesis* is that the highway improvements have brought no significant decrease in accident rates. The counter-hypothesis is that the highway improvements have brought significant decreases. A *chi-squared test* with a 5% confidence level is used to evaluate the two hypotheses.

#### Example 75.4

In a Minnesota study of the benefit of driving with headlights turned on, over a seven-year period, cars without lights experienced 521 fatal accidents out of a total of 1,763,134 accidents. With headlights turned on, cars experienced 158 fatal accidents out of 788,840 total accidents. (a) What are the 95% confidence limits for the accident rate per 10,000 cars driving with headlights? (b) What is the ratio of without-lights-to-with-lights accident rates? (c) Use a chi-squared test with 5% significance level,  $\alpha$ , to evaluate the hypothesis that the fatality rate is not affected by driving with headlights.

#### Solution

(a) The crash rate per 10,000 vehicles with lights is

$$R_{\text{with lights}} = \frac{(158 \text{ fatalities})(10,000)}{788,840 \text{ accidents}} = 2.003 \text{ fatalities/10,000 accidents}$$

The true fraction of fatal accidents with lights is

$$p_{\text{with lights}} = \frac{158 \text{ fatalities}}{788,840 \text{ accidents}} = 0.0002003 \text{ fatalities/accident}$$

There were 788,840 samples taken, of which 158 had a particular characteristic. The standard error, SE, of the fraction is

$$\begin{aligned} \text{SE} &= \sqrt{\frac{p(1-p)}{n}} \\ &= \sqrt{\frac{(0.0002003)(1 - 0.0002003)}{788,840}} \\ &= 1.593 \times 10^{-5} \end{aligned}$$

For a two-tail 95% confidence limit, the standard normal variate,  $z$ , is 1.96. The 95% confidence limits are

$$\begin{aligned} p \pm z(\text{SE}) &= R_{\text{with lights}} \pm (1.96)(1.593 \times 10^{-5})(10,000) \\ &= 2.003 \pm 0.310 \\ &= 2.313 \end{aligned}$$

and 1.693 fatalities/10,000 accidents

(b) The crash rate per 10,000 vehicles without lights is

$$\begin{aligned} R_{\text{without lights}} &= \frac{(521 \text{ fatalities})(10,000)}{1,763,134 \text{ accidents}} \\ &= 2.955 \text{ fatalities/10,000 accidents} \end{aligned}$$

The ratio of accident rates is

$$\frac{R_{\text{without lights}}}{R_{\text{with lights}}} = \frac{2.955}{2.033} = 1.475$$

(c) The null hypothesis,  $H_0$ , is: Driving with lights does not affect the fatality rate.

For the case of driving without headlights, there were 521 fatalities and  $1,763,134 - 521 = 1,762,613$  nonfatalities. For the case of driving with headlights, there were 158 fatalities and  $788,840 - 158 = 788,682$  nonfatalities.

The contingencies table is

	nonfatalities	fatalities	totals
without lights	1,762,613	521	1,763,134
with lights	788,682	158	788,840
totals	2,551,295	679	2,551,974

The critical chi-squared value is

$$\chi^2 = \frac{((1,762,613)(158) - (788,682)(521))^2 (2,551,974)}{(1,763,134)(788,840)(2,551,295)(679)} = 18.57$$

When a comparison is made between one sample and another, the degrees of freedom, DF, equals the number of columns minus one times the number of rows minus one, excluding the row and column for totals. In this case,  $DF = (2 - 1)(2 - 1) = 1$ .

From App. 11.B, for  $DF = 1$  and  $\alpha = 0.05$ ,  $\chi^2 = 3.841$ . Since  $18.57 > 3.841$ , the null hypothesis is disproved. It can be said with 95% or greater confidence that driving with headlights decreases the fatality rate.

#### 17. ROAD SAFETY FEATURES

Road safety features are installed to protect public life and property and to reduce traffic-related lawsuits against highway and transportation departments. The

most common actions include the installation of illumination, guardrails, and impact attenuators, as well as relocating dangerous facilities and providing clear zones.

*Guardrails* are used on roadways where there is a severe slope or vertical dropoff to the side of the road, ditches, permanent bodies of water, embankments, and roadside obstacles (e.g., boulders, retaining walls, and sign and signal supports). Guardrails with turned-down ends are now prohibited in new installations and should be upgraded. Such guardrails, rather than protecting motorists from a fixed impact or spearing, often cause *vaulting* (also known as *launching* or *ramping*) and subsequent rollover.

*Impact attenuators* are used to provide crash protection at bridge pillars, center piers, gore areas, butterfly signs, light posts, and ends of concrete median barriers. These are mainly of the *crash cushion* variety (sand barrel, water barrel, and water-tube arrays), sandwich-type units, and crushable cartridges.

*Clear zones* are unobstructed areas beyond the edge of the through traveled way and include shoulders, bike lanes, and auxiliary lanes. Obstacles are removed from these areas to provide a safe, traversable area for errant vehicles to recover. When obstacles must be placed near the traveled way (such as with highway signs and utility poles), safety features should be used. For example, slip and breakaway (frangible coupling) bases are used on poles of roadside luminaires and signs to prevent vehicles from “wrapping around” the poles. *Hinged* and weakened bases for high-voltage power poles, however, may violate other codes (e.g., the National Fire Protection Association’s *National Electrical Code*) designed to prevent high-voltage wires from dropping on the public below. Other solutions, such as placing utility lines underground, increasing lateral offset or longitudinal spacing, or dividing the load over multiple poles, should be considered.

## 18. ROADSIDE SAFETY RAILINGS

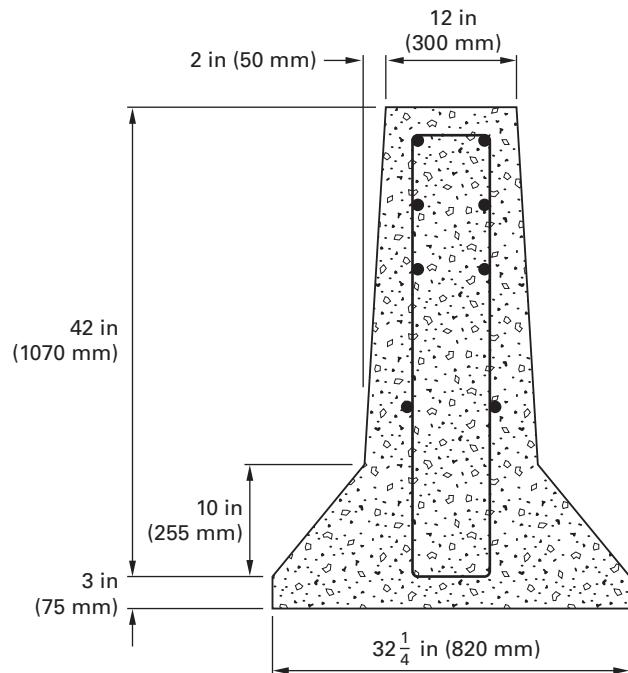

Properly designed and placed highway safety barriers and guardrails reduce the number of injuries and deaths associated with vehicles leaving the traveled surface. The most common type of highway guardrail used in the United States is the solid guardrail, made of hot dipped galvanized steel and aluminum. This steel variety is found in areas that present a higher level of danger, such as the edges of ravines and bodies of water. The *W-beam rail* is the most widely used safety system. W-beams are available with strong-post, weak-post, and wood-block cushions.

In locations where snow drifts may accumulate, *tension cable guardrails* can be used. Unlike solid guard railing, the cable allows snow to pass through, reducing accumulations. Tension cable railing also “gives” elastically to impacts received from vehicles.

*Concrete barriers* are often used as permanent median barriers as well as temporary construction barriers on

both sides of a lane. They have initial costs that are three times that of the galvanized guardrail, but they are cost-effective because they last longer and are more easily installed and replaced. The earliest concrete barrier was the *GM barrier* (*General Motors barrier*). It is similar in appearance to modern designs, but it is clearly fatter. The barrier was larger than modern design, primarily because vehicles were larger. The GM barrier is obsolete, and there are four main types of modern concrete barriers. The *Jersey barrier* (also known as a *K-rail*) is 32 in tall. It rises from a 55° angle to an 85° tapered top. The *Ontario barrier* is the same as the Jersey barrier, except it is 42 in tall. The *constant slope barrier* is also 42 in tall and has a slope of 79°. The *F-shape barrier* resembles the Jersey barrier except for the slope. A reinforced version of the 42 in Jersey barrier is used as a median divider and is known as a *heavy vehicle median barrier*. (See Fig. 75.4.)

**Figure 75.4** Ontario/Heavy Vehicle Median Barrier

## 19. MODELING VEHICLE ACCIDENTS

Traffic accident analysis, modeling, and simulation draw on many concepts. What can be done by hand (i.e., with a pencil and calculator) for a single body at a time differs dramatically with what can be done in computer analyses that use simulation techniques and draw upon finite element analysis and multi-body system models.

Modeling the vehicle dynamics (kinematics) of a body is the first step in modeling an accident. For manual calculations, common assumptions include rigid bodies (lumped masses); one or two dimensional movement;

one or two degrees of freedom; constant masses; constant friction coefficients; constant (including zero), linear, and instantaneous forces; linear stiffness; linear damping; absence of atmospheric (wind, rain, and weather) and other secondary effects; and either constant speeds, constant accelerations, or decelerations. Sophisticated computer simulations relax or eliminate all of these assumptions, and they are able to “step” through the time domain in small discrete time increments. As an added bonus, comparisons of the actual vehicle motions (obtained from the scene of the accident) with the simulation results can be used to adjust input parameters.

As a comparison, a simple model intended for manual calculations might use uniform acceleration formulas to determine acceleration, speed, and position of a rigid body in a single direction at one or two times or locations. It might use basic concepts such as conservation of momentum and work-energy principles. A simulation model, on the other hand, would determine acceleration, speed, position, and orientation for each moving body, in each of three dimensions, and for each degree of freedom (e.g., straight ahead movement, flat spinning, lateral rolling, and tumbling end for end) at each discrete time period. For body  $i$  in period  $j$ , for a particular direction (not designated),

$$a_{i,j} = \frac{F_{\text{net}}}{m_{i,j}} \quad 75.28$$

$$v_{i,j+1} = v_{i,j} + a_{i,j}\Delta t \quad 75.29$$

$$x_{i,j+1} = x_{i,j} + v_{i,j}\Delta t \quad 75.30$$

For manual analyses, the net force in Eq. 75.28 includes the effects of the vehicle engine, braking, impact from other vehicles and objects, weather, and tire-to-ground contact. For manual analyses, a constant frictional coefficient (independent of vehicle speed, mass, and location along the accident track) based on published average values would be used, and it is likely that the only force considered would be the frictional force,  $F_f = fN$ . For complex simulations, the actual tire performance (frictional forces and moments) is evaluated with a tire testing machine, after which, two different tire modeling methods are used. The first generates values needed during simulation by interpolating within the tabulated tire test measurements. The second method calculates the needed values from mathematical functions obtained by curve fitting the tire test measurements.

During an accident involving damage, the work-energy principle ( $\Delta E_k = W$ ) is always applicable. Kinetic energy is generally not conserved, and linear work ( $W = ks$ ) is applicable only in cases involving elastic deflection. Kinetic energy is transformed into deformation work according to Eq. 75.31. However, predicting deformation damage requires modeling the contact between two surfaces, which may be elastically deformable, plastically deformable, or non-deformable. In a simulation, the deformation surface is divided into

triangular or quadrilateral thin-plate finite elements, each with three or four nodes and its own mass. Equation 75.28, Eq. 75.29, and Eq. 75.30 are applied to each element. The simulation *step time*,  $\Delta t$ , is limited by the propagation speed of the deformation wave and the smallest distance between nodes in the model. The net force includes the constraining forces from adjacent elements that bend and deform. Except for the most gross, macroscopic effects, modeling vehicular damage resulting from the impact is essentially beyond the reach of manual methods.

$$\frac{mv^2}{2} = \bar{F}s \quad [\text{SI}] \quad 75.31(a)$$

$$\frac{mv^2}{2g_c} = \bar{F}s \quad [\text{U.S.}] \quad 75.31(b)$$

### Example 75.5

A 3200 lbm automobile carrying a 160 lbm driver and traveling at 30 mi/hr directly impacts a stationary, immobile wall without braking. The automobile's front end crumples backwards 1 ft before the car stops moving. The deceleration is uniform. Disregard the effects of airbag deployment. (a) Use the work-energy principle to determine the average decelerating force on the automobile. (b) Use the impulse-momentum principle to determine the maximum decelerating force on the automobile. (c) What average force will the driver experience when firmly held in an inelastic seat belt? (d) If the driver is not wearing a seat belt and is brought to rest by contacting a steering wheel/column that collapses 0.2 ft, what average force will the driver experience?

#### Solution

(a) Use the work-energy principle, Eq. 75.31, to determine the average force on the automobile.

$$\frac{\frac{mv^2}{2g_c}}{\left( \begin{array}{l} 3200 \text{ lbm} \\ + 160 \text{ lbm} \end{array} \right) \left( \frac{\left( 30 \frac{\text{mi}}{\text{hr}} \right) \left( 5280 \frac{\text{ft}}{\text{hr}} \right)}{\left( 60 \frac{\text{min}}{\text{hr}} \right) \left( 60 \frac{\text{sec}}{\text{min}} \right)} \right)^2} = F_{\text{ave}}(1 \text{ ft})$$

$$(2) \left( 32.2 \frac{\text{lbf-ft}}{\text{lbf-sec}^2} \right) = F_{\text{ave}}(1 \text{ ft})$$

$$F_{\text{ave}} = 101,000 \text{ lbf}$$

(b) The change in the automobile's momentum is

$$\Delta p = \frac{m\Delta v}{g_c}$$

$$= \frac{\left( \begin{array}{l} 3200 \text{ lbm} \\ + 160 \text{ lbm} \end{array} \right) \left( 30 \frac{\text{mi}}{\text{hr}} - 0 \frac{\text{mi}}{\text{hr}} \right) \left( 5280 \frac{\text{ft}}{\text{mi}} \right)}{\left( 32.2 \frac{\text{lbf-ft}}{\text{lbf-sec}^2} \right) \left( 60 \frac{\text{min}}{\text{hr}} \right) \left( 60 \frac{\text{sec}}{\text{min}} \right)}$$

$$= 4591 \text{ ft-lbf/sec}$$

The average speed during impact is

$$\begin{aligned}\frac{1}{2}(v_i + v_f) &= \frac{1}{2}(30 \frac{\text{mi}}{\text{hr}} + 0 \frac{\text{mi}}{\text{hr}}) \\ &= 15 \text{ mi/hr}\end{aligned}$$

The duration of the impact is

$$\Delta t = \frac{s}{v} = \frac{1 \text{ ft}}{\left(15 \frac{\text{mi}}{\text{hr}}\right)\left(5280 \frac{\text{ft}}{\text{mi}}\right)} = 0.04545 \text{ sec}$$

$$\frac{}{\left(60 \frac{\text{min}}{\text{hr}}\right)\left(60 \frac{\text{sec}}{\text{min}}\right)}$$

From the impulse-momentum principle, the impulse is equal to the change in momentum.

$$\begin{aligned}F_{\text{ave}}\Delta t &= \Delta p \\ F_{\text{ave}}(0.04545 \text{ sec}) &= 4591 \frac{\text{ft-lbf}}{\text{sec}} \\ F_{\text{ave}} &= 101,000 \text{ lbf}\end{aligned}$$

Since the force increases from zero to a maximum during the collision, the maximum force is twice the average force.

$$\begin{aligned}F_{\text{max}} &= 2F_{\text{ave}} = (2)(101,000 \text{ lbf}) \\ &= 202,000 \text{ lbf}\end{aligned}$$

(c) The driver also travels 1 ft before coming to rest. The driver's deceleration is found from uniform acceleration equations.

$$a = \frac{v^2}{2s} = \frac{\left(\frac{(30 \frac{\text{mi}}{\text{hr}})(5280 \frac{\text{ft}}{\text{mi}})}{(60 \frac{\text{min}}{\text{hr}})(60 \frac{\text{sec}}{\text{min}})}\right)^2}{(2)(1 \text{ ft})} = 968 \text{ ft/sec}^2$$

The force experienced by the driver is

$$F = \frac{ma}{g_c} = \frac{(160 \text{ lbm})\left(968 \frac{\text{ft}}{\text{sec}^2}\right)}{32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}} = 4810 \text{ lbf}$$

(d) Without a seat belt, the driver continues forward at the original speed of the automobile until impacting the steering column, and then the driver travels only 0.2 ft before coming to rest. The driver's deceleration is found from uniform acceleration equations.

$$\begin{aligned}a &= \frac{v^2}{2s} = \frac{\left(\frac{(30 \frac{\text{mi}}{\text{hr}})(5280 \frac{\text{ft}}{\text{mi}})}{(60 \frac{\text{min}}{\text{hr}})(60 \frac{\text{sec}}{\text{min}})}\right)^2}{(2)(0.2)} \\ &= 4840 \text{ ft/sec}^2\end{aligned}$$

Without a seat belt, the force experienced by the driver is

$$F = \frac{ma}{g_c} = \frac{(160 \text{ lbm})\left(4840 \frac{\text{ft}}{\text{sec}^2}\right)}{32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}} = 24,050 \text{ lbf}$$

## 20. MODELING PEDESTRIAN IMPACTS

Because a pedestrian is much lighter than a motor vehicle, a *pedestrian impact* has little effect on the vehicle speed. The pedestrian's speed increases from zero to the speed of the vehicle in approximately the time needed for the car to travel a distance equal to the pedestrian's thickness—a foot or less. The impact duration,  $t = s/v$ , is the same as the time to accelerate the pedestrian, and it can be calculated from the vehicle speed and pedestrian thickness. The average acceleration is  $a = \Delta v/t$ . The average impact force is  $F = ma$ .

## 21. HSM TERMINOLOGY

In the HSM, a transportation *project* is a series of steps taken to evaluate and improve safety. The term *crash* is preferred over *accident* and *collision*, although common usage remains inconsistent. Crashes include nonimpact incidents.<sup>4</sup>

The *crash type* refers to the nature of crash (e.g., rear-end, sideswipe). The term *network* (e.g., *transportation network*) refers to all of the roadways and elements within the project. The terms *highway* and *roadway* are used interchangeably to refer to any road, arterial, or connector. The term *element* (e.g., *roadway network element*) describes such features as intersections, roadway segments, facilities, ramps, ramp terminal intersections, and at-grade rail crossings. The term *segment* refers to a defined stretch of roadway or ramp. A *node* is an intersection in a network. A *facility* is a combination of segments and elements. A *site* is a specific crash or element location. *Site conditions (field conditions)* refer to characteristics that can be observed. (See Sec. 75.26.) A *treatment* is a change made to an element. A *countermeasure* is a treatment specifically intended to improve safety. *Base condition* represents the condition before a treatment is applied.

## 22. HSM INCIDENT DESCRIPTORS

A specific incident (i.e., crash) will usually be described by its crash data, facility description, and traffic volume. *Crash data (accident data)* includes the location; time and date; severity; collision type; and a description of the roadway, vehicles, and people involved. *Facility data* describes the crash site by specifying the roadway classification, number of lanes, length, presence of

<sup>4</sup>In this chapter, “crash” can be substituted for “accident” in most cases without any significant loss in meaning.

medians, and shoulder width. The *traffic volume data* usually specifies annual average daily traffic (AADT) volume at a crash site.

For the purpose of uniformly defining terms among jurisdictions, the HSM standardizes *crash severity* using the *KABCO severity scale* keyed to the level of injury and/or property damage: K=fatal injury (FI); A=incapacitating injury; B=noncapacitating injury; C=possible injury; O=no injury, or property damage only (PDO).

### 23. HSM CRASH ESTIMATION METHODS

*Crash estimation* is the calculation of a past or future crash frequency for a new or existing roadway under existing or alternate conditions. Historically, both the crash frequency and crash rate have been used as primary indicators of roadway safety.<sup>5</sup> *Crash frequency* is calculated from Eq. 75.32.

$$N = \frac{\text{no. of crashes}}{\text{period in years}} \quad [\text{HSM Eq. 3-1}] \quad 75.32$$

The *crash rate* (such as is calculated from Eq. 75.26 and Eq. 75.27) is calculated from Eq. 75.33. The most common highway safety *exposure* is the highway segment length in miles (kilometers).
